Precipitation of Calcite and Aragonite

BY JOHN L. WRAY AND FARRINGTON DANIELS

RECEIVED OCTOBER 22, 1956

The two common polymorphs of calcium carbonate, calcite and aragonite, have been precipitated by mixing soluble carbonate solutions with solutions of calcium ions under conditions of controlled temperature, concentration and aging. Results from these experiments have provided new information regarding the factors affecting the formation of these two crystalline varieties.

Introduction

Although the preparation of calcium carbonate has been described many times in the chemical and geological literature, the products usually have not been well defined and they have varied considerably with the experimental conditions. Among the important early workers who have attempted to determine the factors controlling the formation of the various crystalline varieties of calcium carbonate are Credner,[1] and Johnson, Merwin and Williamson.[2] A comprehensive summary of much of the early work was compiled by Mellor.[3] More recently, studies of artificial calcium carbonate have been made by deKeyser and Dugueldre.[4] Calcium carbonate can be precipitated in the laboratory in different crystalline forms as calcite, aragonite or vaterite, although calcite is the only thermodynamically stable form of pure $CaCO_3$ at room temperature and atmospheric pressure. The factors which are involved in the formation of the polymorphs of $CaCO_3$ apply then to the kinetics of metastable forms, rather than to equilibrium conditions.

The purpose of this investigation was to determine the conditions necessary to precipitate pure calcite, pure aragonite, or specific mixtures of the two. There is practical significance also for such a study. Calcium carbonate is finding extensive use in chromatography and the efficiency in such work depends not only on the size of the particles, but also on the calcite–aragonite ratio. Again, calcite and aragonite are found in nature and their origin is important in the interpretation of geologic phenomena.

Experimental

Calcium carbonate was precipitated in 500-ml. round-bottom flasks by mixing soluble carbonate solutions with solutions of calcium ions with rapid mixing by a motor-driven stirrer. Reagent grade calcium nitrate manufactured by Merck and Co. was used. Spectrographic analysis of selected impurities in this material given in parts per million are as follows: MgO, 80; Fe_2O_3, 20; MnO, 3; SrO, 30; Pb <3; and BaO <3. Sodium carbonate manufactured by the Baker Chemical Co. gave MgO <10, Fe_2O_3 <10, MnO <3, SrO <3, Pb <5, and BaO <3. The experiments were carried out at temperatures from 30 to 70 ±1° and the precipitates were aged for periods from 6 minutes to 18 hours. The solutions were mixed to give precipitates of calcium carbonate as shown in Table I.

TABLE I

CONCENTRATIONS OF SOLUTIONS USED IN PRECIPITATING $CaCO_3$

Expt. series	Soln. added	Addn. rate, ml./min.	Soln. in flask
1	20 ml. 1.0 *M* $Ca(NO_3)_2$	5	200 ml. 0.1 *M* Na_2CO_3
2	20 ml. 1.0 *M* Na_2CO_3	5	200 ml. 0.1 *M* $Ca(NO_3)_2$

Additional experiments were performed in which 1.0 *M* $Ca(NO_3)_2$ and 1.0 *M* Na_2CO_3 were mixed. At selected temperatures and aging periods, calcium chloride was substituted for calcium nitrate in experiment series 1 and 2.

The *p*H of each solution was determined with a glass electrode. At the end of each aging period the precipitate was filtered immediately through a Büchner filter, thoroughly washed with distilled water, and dried at room temperature.

The per cent. of calcite, aragonite and vaterite in the precipitates was determined by X-ray diffraction measurements and by examination with a petrographic microscope, in which the relative areas of rhombs of calcite, needles of aragonite, and spherulitic growths of vaterite were estimated with the aid of a linear scale. The limits of error in these determinations, both by X-ray diffractometer and petrographic microscope, may be as great as ±15%.

Results

Table II gives the results of experiment series 1.

The *p*H of the initial sodium carbonate solution was 10.9 at 30° and after complete precipitation with calcium nitrate it was 9.1. The sizes of the $CaCO_3$ particles ranged from about 10 to 15 μ.

The aragonite–calcite components of this series after various periods of aging, which are given in Table II between 40 and 50°, are shown graphically in Fig. 1.

Table III gives the results of experiment series 2.

The *p*H of the 0.1 *M* $Ca(NO_3)_2$ was 6.3 at 30° and increased to 9.1 with the addition of the 1 *M* Na_2CO_3. The grain size varied from about 10 to 20 μ.

The effect of increasing the concentrations of the reagents, using 1 *M* solutions of both $Ca(NO_3)_2$ and Na_2CO_3, was to give a finer grained precipitate (5–10 μ) and products that contain a much greater proportion of calcite and vaterite than aragonite when precipitated at high temperatures and allowed to age only for brief periods. For example, a precipitate containing 70% calcite, 20% vaterite and 10% aragonite was obtained at 70° after 6 minutes aging when 100 ml. of 1 *M* Na_2CO_3 was added to 100 ml. of 1 *M* $Ca(NO_3)_2$.

Essentially the same results, as shown in Tables II and III, were obtained when calcium chloride was substituted for calcium nitrate. This reagent grade material was manufactured by Mallinckrodt Chemical Works and analyzed (in p.p.m.): MgO, 25; Fe_2O_3, 25; MnO < 3; SrO, 60; Pb < 3; BaO < 3.

Many of the precipitations in experiment series 1 and 2 were repeated with reagent grade calcium nitrate manufactured by the General Chemical Company. This material analyzed (in p.p.m.): MgO, 25; Fe_2O_3, 35; MnO, 3; SrO, 40; Pb < 3; BaO < 3. These results were within ± 15% of the products obtained with the Merck calcium nitrate shown in Tables II and III.

Discussion

It is evident from the results of this investigation that it is easy to control temperature, *p*H and time so as to get either calcite or aragonite. It is surprising to find, as shown in Fig. 1, that the temperature range is so small and so critical. At 40° the precipitate is nearly pure calcite. At 45° it is 30% calcite and 70% aragonite, but changes during two hours digestion to more than 90% calcite. At 50° the precipitate is mostly aragonite. At temperatures between 45 and 50°, with suitable periods of digestion, one can obtain practically any ratio of calcite to aragonite. Although the precipitate suspended in solution may go rather rapidly to the more stable calcite, this change is stopped by filtering and drying the material. The rate of change in the dry state is indefinitely slow in the laboratory.

The temperature at which dry aragonite changes spontaneously into calcite at atmospheric pressure is quite high (usually above 400°). At very high pressures, aragonite is thermodynamically stable

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

at lower temperatures, even at room temperature. The phase equilibrium diagram for the different crystalline varieties of calcium carbonate has been fully worked out.[5]

There is much geological and laboratory evidence to show that the aragonite crystal structure is favored by the inclusion in its lattice of cations as impurities which are larger than the calcium ion, such as strontium, barium, and lead.[6,7]

The ionic radii of the cations of the calcite and aragonite groups are given in Table IV.

TABLE IV

IONIC RADII OF CATIONS, ÅNGSTRÖM UNITS[8]

	Mg	Fe	Zn	Mn	Cd	Ca	Sr	Pb	Ba
Calcite type	0.78	0.83	0.83	0.91	1.03	1.06	..	..	..
Aragonite type	..	..	..	..	..	1.06	1.27	1.32	1.43

In this Laboratory, it was found[9] that aragonite generally has a higher content of strontium than calcite, and that the formation of aragonite is induced by adding strontium, barium or lead under conditions, namely, high *p*H, such that they will be co-precipitated with the calcium carbonate. Only in case these ions are incorporated into the lattice would they be expected to produce the aragonite. It was pointed out that the presence of these larger ions under the proper conditions tends to produce the aragonite, rather than that the aragonite is produced from other causes and takes up the strontium, barium, or lead which happen to be in solution.

In studying the aging process, it is important to distinguish three different stages[10] in the mechanics of crystallization: (a) an aggregation velocity in which the ions are brought together and precipitated; (b) an orientation velocity in which the ions in colloidal or amorphous material of the precipitated particles form crystals; and (c) a rate of recrystallization.

In the present work the aggregation velocity is considered to be infinitely rapid, the orientation is probably complete in a few seconds or minutes, and the recrystallization takes place in minutes, hours or days, and longer depending on conditions.

With the facts and generalizations discussed here, it is possible to explain the experimental results and to point out the factors which affect the production of calcite or aragonite.

The formation of the unstable aragonite having a larger crystal structure than calcite is favored by the incorporation of larger-sized cations, Sr^{++}, Ba^{++} or Pb^{++}, into the $CaCO_3$ lattice. The concentration of these ions may be very low, because once a seed crystal of aragonite or calcite is formed, the rest of the crystal growth tends to follow the same crystal pattern.

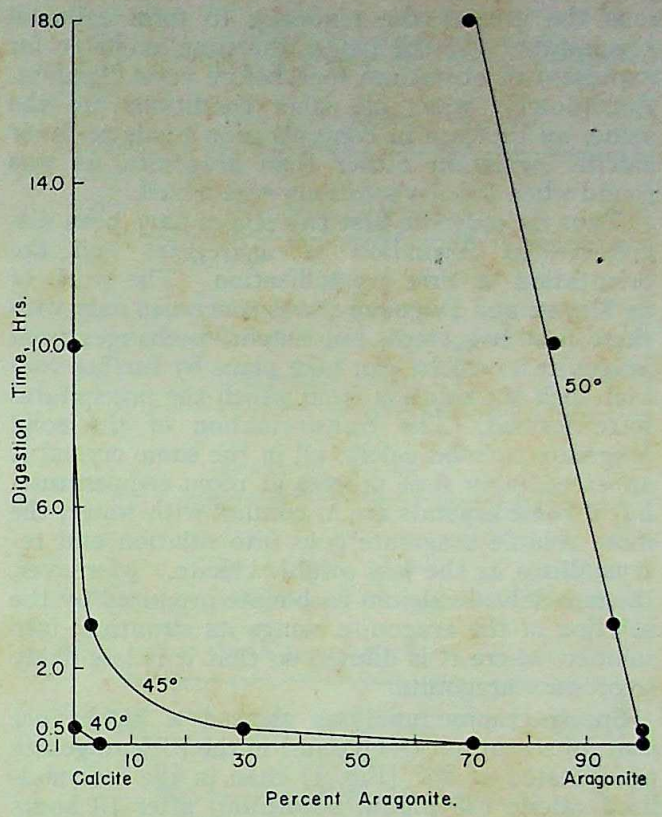

Fig. 1.—Influence of temperature and aging on the crystal form of precipitated calcium carbonate.

At low *p*H values, strontium, barium and lead carbonates do not precipitate, and the first colloidal particles of calcium carbonate to form do not contain these larger ions. Calcite is precipitated under these conditions. At higher *p*H values, however, these larger ions are co-precipitated with the calcium carbonate and there is a tendency to form aragonite.

At the instant of precipitation, the strontium ions as well as the calcium ions are brought from a large volume of solution into the small volume of the first colloid particles to form, thus giving in these aggregates a high concentration. In a matter of seconds or minutes, the colloid aggregate undergoes orientation leading to crystal formation. If there is sufficient time between precipitation and crystallization, the strontium (and barium and lead) ions can diffuse out of the colloidal particles into the strontium-depleted solution which surrounds them. Factors which tend to shorten this time for escape of strontium ions tend to produce aragonite, and those which lengthen the time before crystallization give more opportunity for the escape of strontium ions and thus tend to produce calcite.

At the higher temperatures, the rate of crystallization is accelerated rapidly and the strontium ions do not have time to escape and thus they are incorporated into the $CaCO_3$ lattice giving the larger structure—aragonite. In series 1, calcite is formed at temperatures below 40° and aragonite is formed at temperatures above 50°. At temperatures between these limits, the incorporation of strontium in the lattice is intermediate and a mixture of aragonite and calcite is formed.

The greater the concentration of precipitating

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

ions the greater the tendency to form colloidal precipitates and the longer the time available for expulsion of strontium ions before crystallization. Accordingly, when all other conditions are the same, an increase in concentration tends to favor calcite formation rather than aragonite, as was found when 1 molar solutions were mixed.

Thus far only the first two stages have been discussed—the formation of aggregates and the orientation or first crystallization. The work of de Keyser and Dugueldre[4] was concerned only with these first two steps, but extensive changes from aragonite to calcite can take place by further contact with the solution from which the precipitates were formed. The transformation of the solid aragonite to solid calcite all in the same crystal is an exceedingly slow process at room temperature, but if these crystals are in contact with water, the more soluble aragonite goes into solution and recrystallizes as the less soluble calcite. Moreover, the redissolved calcium carbonate produced by the solution of the aragonite brings its strontium into solution where it is diluted so that it is less likely to produce aragonite.

Spectrographic analyses showed a higher per cent. of strontium (80 p.p.m.) in the 70% aragonite precipitated at 45° (Fig. 1) than in the recrystallized calcite (25 p.p.m. strontium) after 10 hours of standing in the solution.

The removal of strontium ions from aragonite which is undergoing recrystallization is believed responsible for the formation of calcite. This hypothesis was confirmed with additional experiments. Pure aragonite precipitated at 50° and its surrounding solution was divided equally and placed in two separate flasks and maintained at 50°. To one of these was added 100 ml. of 0.1 *M* $Sr(NO_3)_2$. In this flask there was no trace of calcite formation after 20 hours, whereas in the flask to which strontium nitrate had not been added, about 50% of the aragonite had changed to calcite in the same period of time.

The fact that similar results were obtained with calcium nitrate of two different manufacturers probably indicates that after a certain minimum concentration of strontium and other critical impurities are reached, higher concentrations have but little further effect.

At first sight, it would be expected that the recrystallization from aragonite to calcite would go faster at high temperatures, but an examination of Fig. 1 shows that at 40° the 95% calcite changes to 100% calcite in half an hour, at 45° it changes from 30 to 100% in about 10 hours, and at 50° it changes only from zero to about 35% in 18 hours. The number of calcite crystals to act as nuclei for further growth is much less in the precipitates formed at the higher temperatures. The slowness to go from aragonite to calcite at the higher temperatures is thus explained as due to the relative absence of calcite seed crystals. This hypothesis was checked by taking out a precipitate of 50% aragonite and 50% calcite slowly changing at 45°. When this precipitate in its solution was heated to 70° the change to calcite was complete in two hours, whereas at 45° it required ten hours. If sufficient seed crystals are present, the higher temperature does give a faster rate of transformation to the stable calcite, as would be expected.

Equilibrium Ultracentrifugations of Acidic Hg(I), Hg(II), In(III), and Au(III) Solutions[1]

BY JAMES S. JOHNSON AND KURT A. KRAUS

RECEIVED DECEMBER 1, 1956

Equilibrium ultracentrifugations confirm that In(III) in HBr and Au(III) in HCl exist as mononuclear complexes. The results contradict recent suggestions based on solvent extraction data that dimers of In(III) and Au(III) exist in the aqueous phase. The method was checked by comparing apparent molecular weights of Hg(I) and Hg(II) in nitrate solutions.

In recent years the extractability of several metal ions from aqueous into organic phases has been reported to increase with decreasing concentration of the metal. For example, from 3.7 *M* HCl, the extraction coefficient of Ga(III) into bis-2-chloroethyl ether increases manyfold as the aqueous Ga(III) concentration is decreased from 10^{-2} *M* to 10^{-3} *M*.[2] Similar changes in extractability have been observed for Au(III) in HCl, In(III) in HBr and Tl(III) in HCl.[3] It has been suggested[2] that such results could be explained by the formation of unextractable dimers of the metal ion species in the aqueous phase at the higher metal concentrations, but alternate explanations have also been advanced.[4-6] Recently Irving and Rossotti have attributed this change in extractability for In(III) from HBr solutions to dimerization.[7]

We have attempted to decide between alternate explanations by molecular weight measurements with the equilibrium ultracentrifuge.

Experimental

Centrifugation techniques have been described earlier.[8,9] All centrifugations were carried out in an excess of supporting electrolyte to diminish the effect of charge. Equilibrium temperatures were 30 ± 2° in all cases. Density measurements were made with a pycnometer. Bromide analysis of $InBr_3$, kindly supplied us by Dr. J. W. Irvine, Jr., indicated 67.2% Br (theoretical 67.6%). Merck reagent grade $AuCl_3 \cdot HCl \cdot 3H_2O$ was used; chloride and gold analysis indicated an empirical formula $HAuCl_4 \cdot 3.3H_2O$. Reagent grades of Hg(I) and Hg(II) nitrates were employed, and the compositions established by mercury and nitrate analyses. All other chemicals were also reagent grade.

Results and Discussion

The optical system of the centrifuge measures the refractive index gradients (dn/dx) as a function of the radius, x. The gradients displace the shadow of an inclined bar, and the results are in terms of a displacement, Z^* (corrected for background) assumed proportional to the concentration gradient dc/dx for the solute of interest.[9] For all experiments, the values of $\ln (Z^*/x)$ at equilibrium were plotted against x^2, and the slopes, S_e, of the curves at the average radius of the cell obtained. These values of S_e and the experimental conditions are summarized in Table I.

(340.0)					

[a] Bar angle: A, 35°; B, 40°; C, 45°; D, 50°; E, 55°; F, 60°; G, 65°. Approximate speed of rotation (r.p.m.): (1) 24,600; (2) 27,670.

For an ideal solution of an uncharged, monodisperse solute, a straight line should be obtained, *i.e.*, S_e constant. Further, $S_e = d \ln (Z^*/x)/d(x^2)$ would also equal $d \ln c_2/d(x^2)$, where c_2 is the concentration of the solute of interest. For all experiments reported here, S_e was essentially constant. (See Fig. 1, a deviation plot of $\log (Z^*/x) - (S_e/2.303)\, x^2$ *vs.* x^2.) From the values of S_e, apparent molecular weights, M_e, defined by the equation

$$M_e = \frac{2RT}{(1 - \bar{v}_2\rho)\omega^2} S_e \qquad (1)$$

were computed (Table I). In this expression, R is the gas constant; T, the absolute temperature; $\bar{v}_2$, the partial specific volume of the solute of interest; ρ, the solution density; and ω, the angular velocity. The term "apparent molecular weight" is used because zero charge (*i.e.*, the solute is not dissociated into ions) is assumed in the derivation of equation 1. Ignoring charge leads to values of M_e which are lower limits of the actual molecular weights.[10] In principle, it is possible to estimate the charge or, conversely, the average degree of complexing by anions, from the decrease of S_e with concentration in one or more equilibrium centrifugations. We do not feel that the present data are accurate enough for such a detailed analysis, even if other necessary assumptions could be made. For the experiments reported here, however, estimates of the charge indicate that in no cases is it large enough to lead to confusion between monomeric and dimeric species.

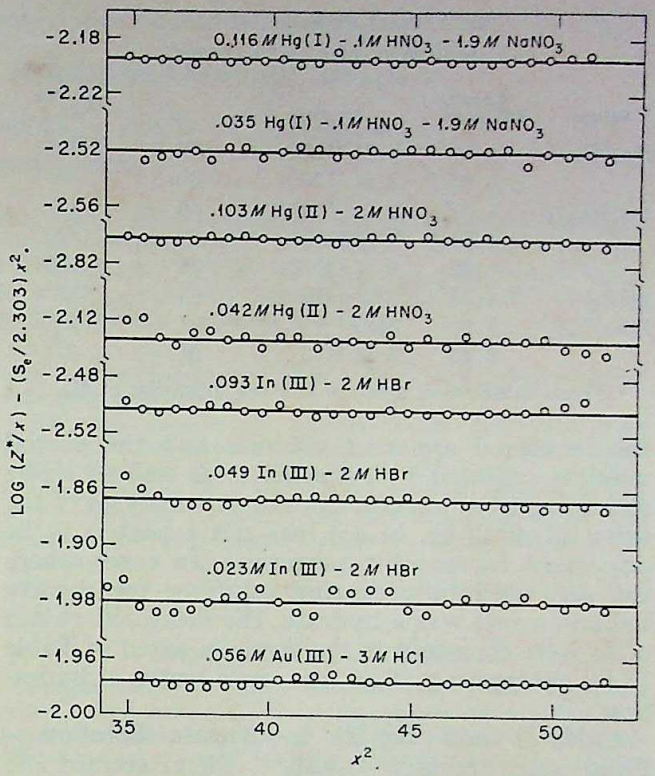

Fig. 1.—Test of constancy of S_e.

Equation 1 requires the partial specific volume of the solute in question. Density values for solutions of all these compounds are in the literature.[11] Extreme accuracy is not required for present purposes, since the quantity $(1 - \bar{v}_2\rho)$ does not differ greatly from unity. However, the literature values are rather old, and, in the case of the mercury compounds, the density measurements indicate the rather surprising result that the molar volume of $HgNO_3$ is greater than that of $Hg(NO_3)_2$. We have, therefore, made a few measurements of apparent molal volumes, ϕ_v, of these salts (Table II). Our results agree fairly well with those computed from literature values of solution densities for $InBr_3$ (*ca.* 60 cc./mole in water[11c]), and $HgNO_3$ (*ca.* 39 cc./mole[11b]), but disagree rather strongly with those for $HAuCl_4$ (*ca.* 126 cc./mole[11a]), and $Hg(NO_3)_2$ (*ca.* 35 cc./mole[11b]).

In the computation of molecular weights we have used for $\bar{v}_2$ the apparent specific volumes measured under conditions closest to those of the centrifugations (Table II). Differences between

the measured apparent volumes and the partial volumes required by equation 1, as well as errors stemming from uncertainties in the analyses of the salts (about 3 cc. in ϕ_v), are not expected to be important for present purposes. In cases where the salt used in preparing solutions for density measurements was a hydrate, the measured values of ϕ_v were corrected to the formula listed in Table II by subtracting 18 cc. per mole water of hydration.

1. Hg(I) and Hg(II) in Nitrate Solution.—From our previous results[8,9] there seemed no reason to doubt that a clear distinction could be made between monomeric and dimeric species of the ions in question by equilibrium ultracentrifugation. Nevertheless, it appeared advisable to test this on a known system of a similar type. Nitrate solutions of Hg(I) and Hg(II) were selected. Hg(I) is known to form dimers in solution, and Hg(II) is generally considered to be monomeric. The experiments were carried out in 2 M nitrate, and acidities selected to preclude interference from hydrolysis.[12] For 0.116 M Hg(I) in 0.1 M HNO_3–1.9 M $NaNO_3$ the apparent molecular weight computed by equation 1 is 495; for an initial concentration of 0.035 M Hg(I) in the same supporting electrolyte, 505 is obtained. These may be compared with 525, the formula weight for $(HgNO_3)_2$. The experimental values are not much different from each other, nor much lower than the theoretical value for the dimer; *i.e.*, there is little interference from a charge effect.

For 0.103 M Hg(II) in 2 M HNO_3 we find M_e = 295; for 0.042 M Hg(II) the value is 315. The formula weight of $Hg(NO_3)_2$ is 325. The method thus definitely distinguishes between a monomeric Hg(II) and a dimeric Hg(I) species of mercury.

2. In(III) in HBr.—The solvent extraction measurements of Irving and Rossotti,[7] which indicated dimerization of In(III) in aqueous bromide solutions, were carried out with 1M HBr solutions. For the centrifugations, 2M HBr solutions were used. With the stability constants reported for In(III) bromide complexes[13] and with constants for dimerization given by Irving and Rossotti,[7] one concludes that most of the In(III) should be dimerized even at the lowest In(III) concentrations encountered in the centrifugations.

Centrifugations were carried out at initial In(III) concentrations 0.023, 0.049 and 0.093 M. The values of M_e obtained were 300, 260 and 245, respectively. Comparison with the formula weight of $InBr_3$, 355, indicates that no appreciable fraction of the indium is dimeric under these conditions. The substantial decrease of M_e with increasing In(III) concentration, and the lowness of all values with relation to the formula weight suggest that the average number of bromide ions complexed by In(III) is not as great as estimated by Irving and Rossotti.[13b] More accurate results are required, however, before the charge of such complexes can be determined with confidence.

3. Au(III) in HCl.—A single centrifugation of Au(III) in 3M HCl was carried out at an initial gold concentration of 0.056M. The observed value of M_e was 330; the formula weight of $HAuCl_4$ is 340, *i.e.*, Au(III) is not dimerized in these solutions.

4. General Discussion.—The results of the equilibrium ultracentrifugations leave little doubt that both the In(III) bromide and Au(III) chloride complexes are monomeric (mononuclear) under conditions where anomalies in solvent extraction data have been interpreted in terms of formation of dimeric complexes in the aqueous phase. The explanation for the non-constancy of the extraction coefficients (increase with decreasing metal concentration) for these and similar complex salts must, therefore, be sought in the properties of the organic phase, *i.e.*, in a decrease of the stoichiometric activity coefficients γ_0 of the distributing components (*e.g.*, $HAuCl_4$ or $HInBr_4$) in the organic phase. This could result from various dissociation reactions as, for example, proposed by Saldick.[5]

The low concentration extraction anomaly which gave rise to this study limits the region where solvent extraction substantially follows Nernst's law (concentration independence of extraction coefficients) in much the same way that a similar anomaly limits it, at least for some systems, at high metal concentrations.[14] In these cases, extractability increases with metal concentration. There is apparently now general agreement that the deviations from Nernst's law at high concentrations also stem from a decrease of the stoichiometric activity coefficients γ_0 in the organic phase[15] (polymerization in the organic phase), though for a short time variations of the activity coefficients in the aqueous phase had been held responsible.[16]

Dimorphic Modifications of Beryllium Diiodide, BeI_2[1]

BY ROWLAND E. JOHNSON, E. STARITZKY AND R. M. DOUGLASS

RECEIVED AUGUST 9, 1956

Two polymorphic modifications of beryllium diiodide have been found. Form I apparently corresponds to the previously described phase, and form II is a heretofore undescribed high-temperature phase stable above 350°. Form I is tetragonal. Powder X-ray diffraction data indicate cell dimensions $a_0 = 6.12 \pm 0.01$ Å., $c_0 = 10.63 \pm 0.02$ Å., $Z = 4$. Form II is orthorhombic with cell dimensions $a_0 = 16.48 \pm 0.02$ Å., $b_0 = 16.702 \pm <0.01$ Å., $c_0 = 11.629 \pm <0.01$ Å., $Z = 32$. Volume per formular unit and Lorentz–Lorenz refraction, respectively, of the two forms are nearly identical.

Introduction

In view of recent work on the subhalides of other elements, particularly aluminum iodide,[2] attempts were made to prepare sub- and superiodides of beryllium. The attempts were unsuccessful, but in the course of this work two polymorphic modifications of beryllium diiodide were found, hereafter designated form I and form II. It seems likely that the previously reported beryllium diiodide[3] corresponds to form I, and that form II is a previously unrecognized high-temperature modification. Because beryllium diiodide is extremely hygroscopic all operations were carried out in sealed glass tubes or in an inert-atmosphere box.

Beryllium Diiodide Form I

Preparation.—Beryllium diiodide form I was prepared by heating beryllium metal chips or diberyllium carbide in a stream of hydrogen and iodine, after the method of Messerknecht and Biltz.[3] Slight modifications permitted use of high-vacuum techniques. Reaction was carried out in silica-glass tubes at various temperatures between 750 and 1100°, and in this range temperature did not appear to affect yield. The products were sealed off in evacuated bulbs fitted with small side arms. On heating the bulbs to about 85° small amounts of silicon tetraiodide impurity (identified by melting point and spectral analysis) sublimed into the side arms which were then sealed off and discarded. The contents of several bulbs were combined and sublimed under vacuum. This product gave a positive test for iodide and gave on analysis 3.39% by weight beryllium, to be compared with 3.43% calculated for BeI_2. No optical or X-ray evidence of inhomogeneity of the product was observed.

Properties.—Most preparations examined consisted of colorless, anhedral grains without pronounced cleavage. One preparation, however, contained some euhedral crystals which were tetragonal dipyramids {112} with basal pinacoid {001} and prism {100}. Lack of suitable material made it impossible to obtain single-crystal X-ray data. The powder X-ray diffraction pattern (Table I) was indexed in terms of a primitive tetragonal cell with dimensions $a_0 = 6.12 \pm 0.01$ Å., $c_0 = 10.63 \pm 0.02$ Å., $c/a = 1.73_7$. All observed diffraction lines of type $0kl$ had k even and $(h + k)$ was even for all lines of type $hk0$, suggesting space group $P4/nbm$ (D^3_{4h}) in which the number of formular units per cell must be an integral multiple of two. Assuming four formular units per cell gives a volume per formular unit of $99._5$ Å.^{3} and a calculated density (formula weight 262.85; weight of unit atomic weight 1.6602×10^{-24} g.) of 4.38 g. per cc. For beryllium diiodide prepared in like manner and purified by sublimation, and therefore probably corresponding to form I of the present paper, Messerknecht and Biltz[3] reported a measured density of 4.325 g. per cc.

The crystals were optically uniaxial positive with very low birefringence and refractive indices for the ordinary and extraordinary rays near 1.99. The Lorentz–Lorenz refraction is $29._8$ cc.

Although samples for powder X-ray diffraction were prepared in an inert-atmosphere box with dew point below −60°, this form of beryllium diiodide exhibited a tendency to decompose on grinding in a mortar. Extreme care had to be exercised to avoid such decomposition which was evidenced by development of brown color in streaks corresponding to the more vigorous strokes of the pestle. No such tendency to decompose on grinding was observed with form II described below.

Beryllium Diiodide Form II

Preparation.—Beryllium diiodide form I and beryllium metal chips were sealed in borosilicate-glass tubes and heated for various lengths of time at various temperatures. When heated above 350° for a few hours form I was converted to form II. Attempts to separate form II from the metal chips by sublimation proved unsuccessful; when heated to about 450° form II sublimed, form I appearing as the condensation product. Although this might appear to indicate that form I is the high-temperature modification, the temperature at which crystal growth took place on condensation was believed to be well below 350°, the approximate temperature at which form I changed to form II on heating. Therefore form II is regarded as the high-temperature polymorph.

Beryllium diiodide form I and iodine sealed in borosilicate-glass tubes and heated to about 300° overnight gave form II and iodine. Most of the excess iodine was removed on heating this product under vacuum at about 150°. Analysis of the material thus purified gave 3.60% by weight beryllium. If the remainder is assumed to be iodine this corresponds to an iodine-to-beryllium ratio of 1.9. The fact that the same crystal species resulted from heating beryllium diiodide form I with excess beryllium and with excess iodine makes it highly improbable that this deviation from the stoichiometric ratio of 2 is significant; it is believed attributable to difficulty in analyzing such extremely hygroscopic materials. As will be shown, the two beryllium iodides have nearly identical molecular volumes and Lorentz–Lorenz refractions, this lending further support to the contention that they do not differ in composition.

Properties.—Calibrated Weissenberg and precession photographs indicate, with the exception of two faint reflections, diffraction symbol mmmB-ab, otherwise diffraction symbol mmmP-an, and give cell dimensions $a_0 = 16.48 \pm 0.02$ Å., $b_0 = 16.702 \pm <0.01$ Å., $c_0 = 11.629 \pm <0.01$ Å.; volume per formular unit 100 Å.^{3}; $a:b:c = 0.987:1:0.696$. The density calculated assuming 32 formular units per cell is 4.36 g. per cc.

The crystals exhibit prominent cleavage parallel to {010} and less prominent cleavage parallel to {001}. They are colorless and optically biaxial positive with optic axial angle 25° for sodium light and very weak dispersion $r < v$. The principal refractive indices for sodium light are 1.952 ± 0.005, 1.954 ± 0.005, 1.988 ± 0.005; geometric mean 1.965; Lorentz–Lorenz refraction 29.4 cc. The optic orientation is $X = c$, $Y = b$, $Z = a$.

Structural Considerations.—All prominent X-ray diffraction spots appearing in single-crystal photographs, and all the diffraction lines appearing in the powder pattern (Table II), have indices satisfying the conditions $h = 4n$, $k = 4n$, $h/4 + k/4 + l/2 = 2n$. This indicates a monomolecular orthorhombic pseudocell with dimensions $a_0' = 4.120$, $b_0' = 4.176$, $c_0' = 5.815$ Å. (obtained from the true cell by the transformation 1/4, 0, 0/0, 1/4, 0/0, 0, 1/2) with an

Chemistry of the Group VB Pentoxides. VI. The Polymorphism of Nb_2O_5

BY FREDERIC HOLTZBERG, ARNOLD REISMAN, MARGARET BERRY AND MELVIN BERKENBLIT

RECEIVED SEPTEMBER 21, 1956

The polymorphism of Nb_2O_5 has been reinvestigated. Experimental results indicate the definite existence of two modifications and the possible existence of a third. The δ-modification recently reported has been shown to be a poorly crystallized state of the γ-phase. It is proposed that the α- and β-phases are identical, with the β-modification existing as a two-dimensional array. Transformation temperatures were found to be: amorphous to γ 435°, γ to α 830°. The densities are: amorphous 4.36 g./cm.^{3} at 25°, γ, 5.17 g./cm.^{3} at 25° and α, 4.55 g./cm.^{3} at 25°. None of the transformations was reversible. The α-phase was reindexed on the basis of a monoclinic unit cell with a = 21.34 Å., b = 2.816 Å., c = 19.47 Å. and $\sphericalangle \beta$ = 120°20′ having 14 molecules/unit cell and an X-ray density of 4.52 g./cm.^{3}. The freezing point of Nb_2O_5 obtained in the study was 1491°.

Previous investigations pertaining to the chemistry of the Group VB pentoxides and their reactions with alkali oxides and carbonates have included studies of the polymorphism of Ta_2O_5[1] and V_2O_5.[2] Examination of the temperature–phase relationships of Nb_2O_5, in addition to completing the study of the comparative polymorphism of the pentoxides, may help explain the non-model behavior exhibited by the systems K_2O–Ta_2O_5[1] and K_2O–Nb_2O_5.[3]

In 1941, Brauer[4] reported that Nb_2O_5 existed in three crystalline modifications having the following transformations: amorphous to γ 500°, γ to β 1000° and β to α 1100°.[5] In 1951 Hahn[6] published X-ray data for an unspecified form of Nb_2O_5. The pattern did not correspond to Brauer's α-, β- or γ-forms. Subsequently Schäfer, *et al.*,[7,8] presented the results of a partial X-ray investigation of the system Nb_2O_5–Ta_2O_5 in which a study of the polymorphism of Nb_2O_5 was included. This work confirmed the α-, β- and γ-polymorphs reported by Brauer: however, the transformation temperatures were significantly different. Furthermore, contrary to evidence given by Brauer, the γ to β transformation was found to be reversible. The reversibility of the α to β transformation was not clarified. Schäfer also observed that the crystallization of the amorphous oxide sometimes results in a mixture of β- and γ-Nb_2O_5. Lapitskiĭ, *et al.*,[9] showed with thermal analysis that the amorphous pentoxide exhibited an exotherm at 609°. The temperature of this heat effect is not coincidental with any of the reported transition temperatures. Recently, Frevel and Rinn[10] reported a δ-form which was indexed on the basis of a pseudohexagonal unit cell. The δ-form is apparently converted to the γ-phase at 700°, a contradiction of Brauer's results. The method of preparation of the δ-form was not specified.

In order to resolve the uncertainties concerning the number of polymorphs of Nb_2O_5, and the temperatures and reversibilities of transformations between phases, it was felt that a complete re-evaluation of previously reported data was in order.

Experimental Procedure

Preparation of Reagents.—Sublimed $NbCl_5$ prepared from high purity niobium[11] was used for the preparation of Nb_2O_5. The pentachloride was hydrolyzed in distilled water and the precipitated Nb_2O_5 was washed until the filtrate was free of chloride ion. The washings, with intermediate digestions at boiling temperatures, were continued through five further cycles. After drying for 24 hours at 100° the pentoxide was found to be amorphous to X-rays. The excessive washing and digestion treatment was employed because, as will be shown, the transformation temperatures of the different pentoxide phases were impurity sensitive.

"High Purity"[12] Nb_2O_5 was used in experiments designed to determine the reversibility of phase transformations. Prior to use the oxide was heated at 1200° for 24 hours to ensure complete conversion to the high temperature form. A portion of the Nb_2O_5 was fused with K_2CO_3, dissolved in water and amorphous hydrated Nb_2O_5 was precipitated as described in an earlier paper.[13] X-Ray analysis indicated that this material was also amorphous.

Differential Thermal Analysis.—A large number of furnaces specifically designed for heating curve analysis have been described in the literature. The general construction involves the use of a mobile furnace which rolls into position over a fixed sample holder and thermocouple assembly. The holder and thermocouple assembly are often difficult to clean and frequently require refabrication for each analysis. In addition the apparatus is costly, requiring elaborate engineering. The problems inherent in the standard

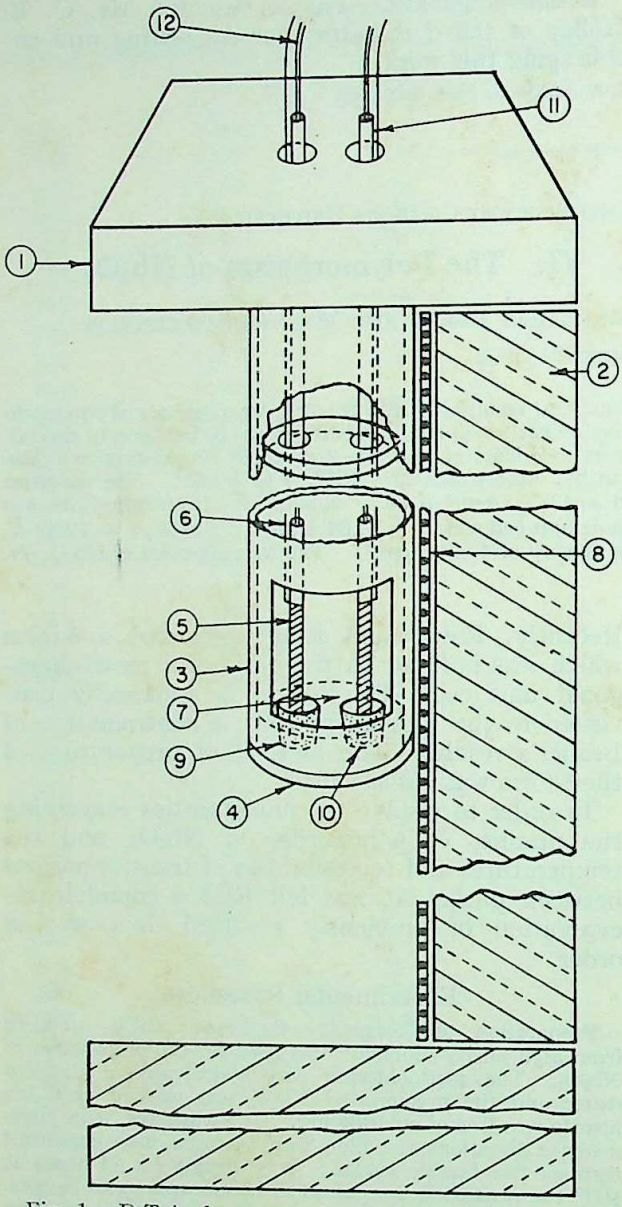

Fig. 1.—D.T.A. furnace and sample assembly: 1, firebrick, air-dry cement coated; 2, firebrick; 3, alumina; 4, alumina; 5, platinum protecting capsule; 6, platinum 20 mil ground wire; 7, firebrick crucible seat; 8, alumina 1/6″ pitch furnace tube; 9, 1-cc. platinum crucible with 90-mesh Alundum powder; 10, 1-cc. platinum crucible with sample; 11, 1/8″ 2-hole thermocouple tubing; 12, Pt–10 Rh B & S #28 wire.

design have been eliminated with the construction of a new D.T.A. apparatus, Fig. 1. A stationary furnace consisting of a 12 in. Kanthal wound $1^1/_2$ in. i.d. core set into 4 in. × 8 in. firebrick is mounted vertically. The sample holder and thermocouple assembly are mounted in a $1^3/_{16}$ in o.d. ceramic hollow cylinder which slides into the furnace and seats at the appropriate height. The thermocouples are supported in 1/8 in. two-hole alumina insulating rods that are guided through centering holes located in two parallel ceramic discs. Such an arrangement permits removal of the thermocouples after a heating curve. 0.2–0.5 g. charges contained in 1-cc. platinum crucibles are easily loaded into the holder through a port cut in the alumina cylinder. The time required for manipulation of the equipment prior to a run is approximately 1 minute. The electronic components of the D.T.A. apparatus have been previously described.[1-3] Heating rates were of the order 0.5–2°/minute with 5–34 × amplification of the differential signal.

The freezing point of Nb_2O_5 was determined using cooling curves as previously described.[1-3]

Sensitivity of D.T.A. Equipment.—In order to evaluate the smallest spontaneous heat change that could be detected with D.T.A. apparatus, potassium metaniobate was used as a calibrant. $KNbO_3$ has two solid state transformations, one at 215° and the other at 425°. The latent heat associated with the orthorhombic to tetragonal transformation at the lower temperature is 69 ± 5 cal./mole and that of the tetragonal to cubic transformation is 134 ± 5 cal./mole.[14] Consequently a 0.5-g. sample would absorb 0.2 cal. at 215° and 0.4 cal. at 425°. The signal-to-noise ratio for the lower endotherm was approximately 3 and thus it is estimated that a spontaneous heat change of 0.1 cal. can be readily detected.

Heat Treatments and X-Ray Analysis.—Samples contained in platinum crucibles were placed in furnaces whose temperatures were controlled to within ±5° throughout the heating period. Temperatures were measured with Pt–10 Rh thermocouples. All X-ray traces were obtained with a General Electric XRD-5 diffractometer using nickel filtered copper radiation.

Single crystals of α-Nb_2O_5 were obtained by cooling the molten oxide. The resulting crystals were twinned, strained and exhibited poor external morphology; however, sufficient X-ray data were collected with a precession camera to establish the crystal class and unit cell size. It was not possible to obtain single crystals of lower temperature phases because, as will be shown, the transformations are not reversible.

Discussion of Experimental Results

A. The Amorphous to Crystalline Transformation.—Figure 2 is a D.T.A. heating curve starting with the amorphous Nb_2O_5 prepared by the hydrolysis of $NbCl_5$ as previously described. The first broad endotherm corresponds to the evolution of surface water. The endotherm extends from room temperature to 400°. Although very slow heating rates were used, static experiments were

necessary in order to more nearly approximate equilibrium conditions. Constant temperature weight loss experiments showed that surface absorbed water is completely removed at 400°; Table I, part A.

[a] A, amorphous Nb_2O_5. [b] γ' refers to poorly crystallized γ. [c] α', 2-dimensional α.

The second heat effect is exothermal and coincides with the first appearance of crystallinity. It should be noted that the conversion temperature of amorphous to crystalline Nb_2O_5 obtained with D.T.A. is a function of heating rate. Thus, at 5°/minute the transformation occurred at 580°. At 3°/minute the transformation temperature was 520°. The exotherm is probably the same one observed by Lapitskii[9] at 609°. It is evident that D.T.A. serves only to indicate the presence of a latent heat associated with the amorphous–crystalline transition, and not the true temperature of the phase change. In addition to being rate dependent the inversion temperature was found to be impurity sensitive. For example, if the amorphous Nb_2O_5 prepared by precipitation from carbonate solution is not thoroughly washed, NH_4Cl remains as a contaminant. Approximately 0.5 wt. % NH_4Cl lowered the transition temperature amorphous to crystalline about 200°. This behavior, which is not uncommon, necessitated the excessive washing and digestion procedure used in the preparation of the amorphous oxide.

The "equilibrium" transformation temperature was determined using static methods. Table I, part B, describes the results. The samples of amorphous oxide were heat-treated at the different temperatures for varying lengths of time and then air-quenched. X-Ray diffractometer and Debye Scherrer techniques were then used to determine the phase present. It is seen that 64 hours at 440° showed conversion amorphous–crystalline, 96 hours at 430° showed no conversion. Within the time limits specified the transformation temperature could not be lowered and the "equilibrium" temperature was chosen at 435 ± 5°. It would appear, on the basis of the thermal and X-ray evidence, that the precipitated Nb_2O_5 has no rudimentary crystallinity. If some degree of periodicity were present, heating would serve only to increase crystallite size, and any heat effect would ex-

tend over a large temperature interval making the exotherm undetectable.

What is most interesting about Fig. 2 is that no further heat effects are observed above the exotherm. However, successive heating experiments with fresh samples up to given temperatures, at rates of 1–2°/minute, followed by X-ray examination of the quenched samples, indicated the appearance of new phases. The absence of latent heat concurrent with the appearance of new phases probably indicates that the transformations are second order. It was only possible to isolate the "pure" β-form characterized by Brauer[4] during these relatively non-equilibrium heating experiments. This behavior will be discussed more fully below.

B. Question of the Existence of δ- and γ-Polymorphs.—Above 440° the δ-modification reported by Frevel and Rinn[10] was found by X-ray analysis. The apparent temperature of transition of the δ form[15] to Brauer's γ-form was lowered by successively longer heat treatments at lower temperatures. These results are listed in Table I, part C. It is seen that progressively longer treatment at each of the transformation temperatures finally results in simultaneous appearance of γ- and δ-phases. On the basis of these results, it is believed that the δ-modification is a less crystalline state of the γ-phase. Examination of X-ray diffractometer traces shows that all of the maxima of the δ-form are characteristic of a material with poorly defined crystallinity. All of the δ-reflections occur as the major lines in the γ-form with increased sharpness, and the additional diffraction lines of the γ-form are all of low intensity. Low intensity maxima would not be observable in the diffuse pattern given by a poorly crystallized material. For example, as shown in Fig. 3, the broad maxima at 2θ equals 28.34 and 36.53° become resolved into sharp peaks at 28.32, 28.88, 36.52 and 36.98°, respectively. In fact upon careful inspection of the diffractometer traces of the δ-form, it is possible to see evidence of overlap of two diffraction maxima, Fig. 3, points a and b. It is evident, therefore, that the δ- and γ-modifications represent different degrees of crystallinity of the same polymorph.

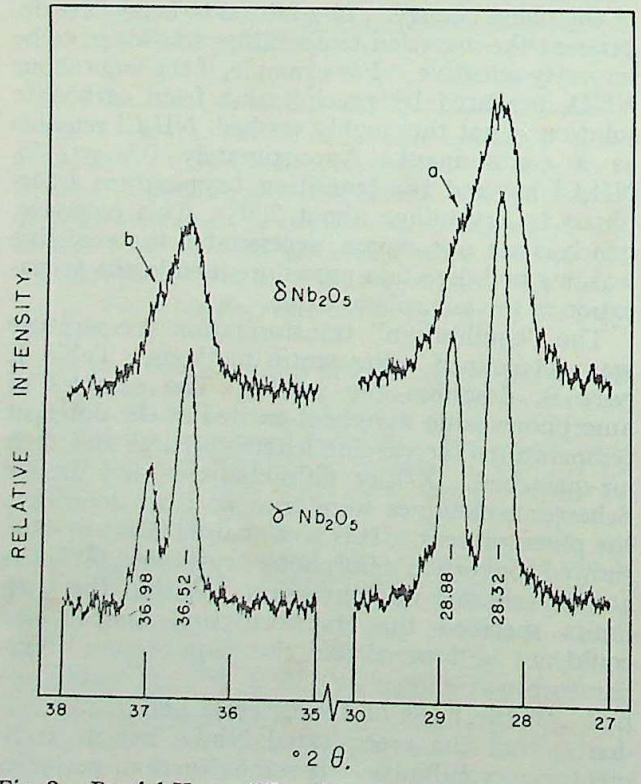

Fig. 3.—Partial X-ray diffraction pattern of γ- and δ-Nb_2O_5.

C. Question of the Existence of β- and α-Polymorphs.—Table I, part D, indicates that the γ-polymorph undergoes a transformation at 830 ± 5°. This temperature is in agreement with the upper limits reported by Schäfer, *et al.*, for the appearance of Brauer's β-phase. In the transition of γ to the next modification, one observes the phenomenon of a highly crystalline substance transforming into a material of low crystallinity. As pointed out, the transformation occurs in the absence of an observable latent heat. What is of greatest import is that under equilibrium conditions the γ-polymorph always transformed into a mixture of Brauer's β- and α-forms and, although these modifications appeared simultaneously, further treatment at approximately 1000° for 18 days did not result in complete conversion to the α-form. At 1095°, however, complete conversion of the β- or α'-phase to α was observable.

The question arises as to whether this is the same type of behavior observed for the development of crystallinity in the lower temperature polymorph or whether two crystalline forms exist. From the point of view of X-rays the apparent equilibrium transformation involves the simultaneous formation of two crystalline entities. As previously pointed out pure β-Nb_2O_5 was obtained only under non-equilibrium conditions. The characteristic pattern of the β-form shows broad as well as sharp maxima, and the sharp peaks are identical with peaks occurring in the α-form. The broad maxima can be traced into the formation of sharp doublets in the α-form, and it is difficult to attribute the doublet formation to the same phenomena observed in the lower temperature case because of the large displacement of the center of gravity of the broad maxima in the formation of doublets. One might postulate the occurrence of a two-dimensional periodicity in the apparent drastic structural changes in the transformation γ to α' and α. In such a situation the α'-polymorph might be thought of as a transitional phase. In view of the fact that all of the sharp lines that occur in the α'-form are also present in the α-form, it is conceivable that the sharp lines represent the two-dimensional periodicity of the α-form in the transitional phase. The broad maxima would then be attributable to a disordered structure in the third dimension. Such a hypothesis appears to reconcile the apparent paradox presented between heat treatment data which indicate identity of forms, and X-ray data which indicate two distinct forms.

D. Reversibility of Phases.—It can be seen from Table I, part E, that prolonged heat treatment of the various forms and mixtures of them at

(15) In Table I the δ-phase is referred to as γ'.

varying temperature increments beneath their transformation temperatures did not result in reversal of transformations, which is in agreement with the results obtained by Brauer.

In view of the inability to invert higher to lower temperature polymorphs, the term "equilibrium" as employed in this paper refers only to the results obtained within the limits of the experiments tabulated in Table I.

The densities of the polymorphs of Nb_2O_5, determined using the method previously described,[1] are as follows: amorphous 4.36 g./cm.^{3} at 25°, γ, 5.17 g./cm.^{3} at 25°, α 4.55 g./cm.^{3} at 25°.

The freezing point obtained in this study using D.T.A. cooling curve techniques was 1491 ± 2° which is slightly higher than the value originally reported.[3]

Magneli and Lagergren[16] indexed α-Nb_2O_5 on the basis of a monoclinic unit cell using data obtained with a Guinier focusing camera. They reported a = 21.50 Å., b = 3.825 Å., c = 20.60 Å. and $\sphericalangle\ \beta$ = 121°45′. Using these parameters the cell was found to contain 14 molecules with an X-ray density of 4.29 g./cm.^{3}. Apparently an error is present in the A.S.T.M. card since the indices recorded are not consistent with the above lattice constants. Using the data obtained from single crystal precession photographs the powder lines listed in Table II were reindexed. The monoclinic cell was found to have a = 21.34 Å., b = 3.816 Å., c = 19.47 Å. and $\sphericalangle\ \beta$ = 120°20′ with 14 molecules/unit cell. The X-ray density is 4.52 g./cm.^{3}.

Frevel and Rinn indexed the γ-phase on the basis of a monoclinic unit cell with a = 7.31 Å., b = 15.72 Å., c = 10.75 Å., $\sphericalangle\ \beta$ = 120°41′ with 12 molecules per unit cell. The X-ray density calculated from their data is 4.99 g./cm.^{3}, which is in poor agreement with the pycnometric density reported above. Attempts to reindex the γ-form directly from powder data were unsuccessful. Although heat treatment of the γ-phase for a month just below the γ- to α-transformation temperature appreciably improved the sharpness of diffraction maxima, the resolution was still insufficient to enable unequivocal indexing of this form. Consequently until a method is devised for growth of single crystals of this phase, the choice of unit cell is questionable.

The difference between the high temperature Nb_2O_5 and Ta_2O_5 phases indicated that the mixed oxide system would probably not form a continuous series of solid solutions. Preliminary investigation of this system, contrary to Schäfer's observations, showed a miscibility gap at approximately 25 mole % Ta_2O_5.

A complete investigation of the heterogeneous equilibria in the system Ta_2O_5–Nb_2O_5 is presently in progress and will be reported at a later date.

Heats of Combustion and Formation of Metal Carbonyls. II. Nickel Carbonyl[1]

BY A. K. FISCHER, F. A. COTTON[2] AND G. WILKINSON

RECEIVED DECEMBER 10, 1956

The heat of combustion of liquid nickel carbonyl, $Ni(CO)_4$, has been determined as $\Delta H°_{298} = -282.2 \pm 0.5$ kcal./mole. For the reaction Ni(s) + 4CO (g, 1 atm.) = $Ni(CO)_4$ (g, 1 atm.) a value of -39.1 ± 0.5 kcal./mole is calculated for $\Delta H°_{298}$ (the error does not include errors in auxiliary data). The relation of these values to the various highly divergent results previously reported is discussed.

Introduction

The unsatisfactory status of the value of $\Delta H°$ for the reaction Ni(s) + 4CO(g) = $Ni(CO)_4$(g) was recently emphasized by Spice, Staveley and Harrow,[3] who surveyed the field, checked some of the earlier calculations, and tabulated the values which they recalculated so as to be consistent among themselves in respect to the various supplementary quantities. They indicated that values for $\Delta H°$, as determined by several methods, ranged from -26.0 to -52.6 kcal./mole, with the more recent values tending to center toward -35 kcal./mole, and this figure was accepted as the best then available. Because of possible uncertainties attending equilibrium studies involving finely divided nickel metal, it seemed that combustion calorimetry might assist a resolution of the difficulties. Shortly after the paper by Spice, *et al.*, there appeared a report of a combustion study by Smagina and Ormont[4] giving the value of $\Delta H°$ as -47.3 ± 1 kcal./mole. This Russian work appeared to be of doubtful reliability not only because of a paucity of experimental data and inadequately described experimental technique, but also because of the rather large deviation of their result from the region in which the value might be expected to lie as a result of the discussion by Spice, *et al.* The discordance therefore remained, and a redetermination of the heat of combustion of nickel carbonyl was included in the present series of combustion studies.

Experimental

The nickel carbonyl used in this work was obtained from a cylinder bottled by The Matheson Co., Inc., and was purified by repeated bulb-to-bulb distillation *in vacuo*. The purified nickel carbonyl was shown not to contain iron by testing with thiocyanate. Immediately before use, the samples were distilled into thin-walled Pyrex bulbs about 1.5 cm. in diameter. Two types of bulb (see below) were used, and the stems of either type were fused to a standard taper joint fitting into the vacuum system. After degassing the sample by means of thawing followed by freezing and pumping, the bulb was sealed by touching a small flame to the constricted stem about 1.5 cm. above the bulb at the same time that the bulb was drawn aside with tweezers. During this operation the sample was kept frozen by having the bulb just immersed in liquid nitrogen; also, the space above the sample was evacuated. Heat was further kept away from the sample by several layers of slotted asbestos paper slipped around the bulb stem. Nevertheless, slight decomposition of carbonyl vapor occurred just at the point of sealing, but analysis showed that the resulting nickel mirror weighed only 0.1 to 0.2 mg.; in a 1 to 2-g. sample the error thus introduced is negligible.

The calorimetric apparatus and technique were the same as described previously.[1] In the first of two series of combustions which were performed, the sample was fired with the aid of a benzoic acid pellet placed next to the bulb. In the second series, bulbs with 4.0 cm. of electrically heated no. 32 platinum wire sealed in (Fig. 1) were used in order to check on the hydration effect of the water present in the first set.[5]

Although incomplete combustion represented by unburned nickel metal in the final state was the rule, in a few preliminary runs a more serious difficulty was encountered in the form of residual nickel carbonyl; this was evident from the abnormally small temperature rises and spontaneous ignition upon venting the bomb gases. Subsequently, therefore, all runs were checked for residual nickel carbonyl and for unburned carbon monoxide by slowly releasing the bomb gases into a train consisting, in order, of a Dry Ice trap, an iodine pentoxide tube maintained at 150°, and two carbon tetrachloride traps. The Dry Ice trap serves to condense out any nickel carbonyl, and any carbon monoxide reacts in the iodine pentoxide tube: $5CO + I_2O_5 = I_2 + 5CO_2$.[6] Carbon dioxide and oxygen from the bomb then sweep any liberated iodine into the carbon tetrachloride traps where the characteristic violet color should develop. Nickel carbonyl was tested for by removing the Dry Ice and adding bromine water to the still cold trap; after debromination by boiling, the resulting solution was tested with dimethylglyoxime. Any run which revealed residual nickel carbonyl or unburned carbon monoxide was rejected. Three of the twenty-one runs done failed this test; none in the internally fired series did so.

The solid combustion products consisting of NiO and some unburned nickel metal were found in the combustion cup and on the bomb walls with the nickel metal concentrated as a black underlying layer almost exclusively on the lower half of the walls and in the cup. The solids were brushed out so as to recover all of the nickel metal and most of the nickel oxide, weighed and dissolved in concentrated nitric acid. To recover any traces of nickel metal occluded in fused glass, the glass was pulverized and leached with concentrated hydrochloric acid. The total nickel in these solutions was determined gravimetrically with dimethylglyoxime. To calculate the quantity of unburned metal, it was assumed that a fraction x of the solid material is nickel metal and a fraction $1 - x$ is nickel oxide; the nickel content expressed in terms of x was equated to the total nickel determined and the operation solved for x. The weight of unburned nickel metal was used to calculate a correction for incomplete combustion of nickel, using -57.3 kcal./mole as the enthalpy of formation of nickel oxide.[7]

No X-ray studies were made on the solid combustion products, but the presence of significant amounts of higher oxides of nickel was unlikely. Smagina and Ormont,[4] in runs made under conditions similar to those employed here, reported that X-ray powder patterns of the products of combustion were consistent with the presence of only NiO and

Ni. Moreover, higher oxides of nickel are said not to exist in the anhydrous state.[8] Hence, although the non-anhydrous final state resulting in the runs fired with benzoic acid might conceivably permit slightly higher oxide formation, the borderline significance of the difference between this series of runs and the internally fired series would belie this; indeed, the difference can in greater likelihood be ascribed to hydration effects.

The heat input (*e.i.t.*) correction for the internally fired series was estimated in control runs with an empty sample bulb and its enclosed fuse wire in the following way. The slopes of the time *vs.* resistance curves for the fore- and after-periods, together with an allowance of an average time of 7 minutes for attainment of maximum temperature rise in a combustion run, permitted calculation of the correction, using the method of Dickenson.[9] This heat effect is such as to raise the resistance of the platinum resistance thermometer 0.0004 ohm and is included in the corrected temperature rise in Table II. Washburn corrections were calculated in one case by the original method of Washburn[10] which applies to 20° and also by the modified method of Hubbard, *et al.*,[11] which applies to 25°. The difference between the two values was insignificant for the present purposes, and all subsequent calculations were made by Washburn's simpler method. It was found that the correction differs negligibly from run to run and the same value, +0.50 kcal./mole, was applied to all.[12]

In Table I, run no. 2, and in Table II, run no. 4 were rejected as being obviously out of line with the other values. Thus, the remaining values in Table I give a mean value for $\Delta E^{comb.}_{298°}$ of −284.00 kcal./mole with an average deviation from the mean of ±0.61 kcal./mole and a standard deviation of the mean of ±0.34 kcal./mole. The mean of the remaining values in Table II is −282.06 kcal./mole with an average deviation from the mean of ±1.41 kcal./mole and a standard deviation of the mean of ±0.87 kcal./mole.

(11) W. N. Hubbard, D. W. Scott and G. Waddington, *J. Phys. Chem.*, **58**, 152 (1954).

(12) For the benzoic acid fired series, the fuse correction was calculated from the heat of combustion of benzoic acid under the standard conditions specified by the National Bureau of Standards. The actual conditions here, however, differed from the standard ones in that 1 ml. of water was omitted from the bomb. It can be calculated that this gives rise to a correction of −0.060% of the fuse correction. This has been included in Table I with the general Washburn corrections thus lowering them from 0.50 to the values listed. The effect is seen to be practically negligible, but has been treated to avoid uncertainty in the matter.

Results

An analysis of errors in the various operations leads to a maximum expected random error of ±0.80 kcal./mole in the benzoic acid ignited runs, and an error of ±0.90 kcal./mole in the internally fired series. In the latter case, the error is larger because of uncertainties in the *e.i.t.* correction. The error in the determination of unburned nickel metal is taken as ±0.006 g., leading to an error in ΔE of ±0.50 kcal./mole for an average 2-g. sample. The percentage of nickel metal in the solid combustion products varies from 16 to 21% in the benzoic acid fired series, and from 9 to 21% in the internally fired series; this is also about the range reported by Smagina and Ormont.[4]

Initial temperatures for the accepted runs ranged from 21.6° for run no. 1 in Table I to 27.9° for run no. 5 in Table II, but calculation of the temperature coefficients of these runs showed that neglecting to reduce the data to 25° introduced an error of −0.15 kcal./mole for the former and only 0.02 kcal./mole for the latter. Therefore, the temperature being assigned to the measured reaction is 25°, run no. 1 in Table I being corrected to this temperature and the other runs standing as they are.[13]

Discussion

If the means are expressed as −284.0 and −282.1 kcal./mole for the series with and without benzoic acid, respectively, and if allowance is made for the expected maximum random error, these values fail to coincide by 0.2 kcal./mole, and the separation is 0.7 kcal./mole if the standard deviations are considered. It is doubtful if much significance can be attributed to or explanation given for this difference at the present time, save ascribing it to slight, exothermic hydration of the NiO by the water produced from the combustion of benzoic acid, and/or, less likely, to the formation of a small amount of a higher oxide of nickel in the same runs. If it is assumed that the two series do indeed measure the same thing, then together they have a mean of $\Delta E^{comb.}_{298°}$ = −283.1 kcal./mole with a standard deviation of the mean[14] of ±0.5 kcal./mole; this grand average was used in the subsequent calculations.

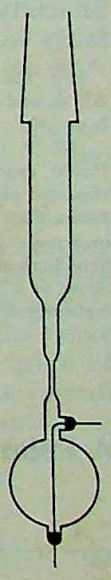

Fig. 1.

For the reaction

$$Ni(CO)_4(l) + 5/2O_2\ (g,\ 1\ atm.) = NiO(s) + 4CO_2\ (g,\ 1\ atm.)$$

$$\Delta H°_{298} = -282.2 \pm 0.5\ kcal./mole$$

(13) Calculation of the correction utilized heat capacity data from National Bureau of Standards Circular 500, except for $Ni(CO)_4$, for which the value $C_p^{298°}$ = 48.9 cal./mole was taken from reference 2.

(14) In part I a typographical error occurred in the definition of this quantity. The reported standard deviations of the means were calculated from the correct expression involving Σd_i^2.

For the reaction

$$Ni(s) + 4CO(g, 1 atm.) = Ni(CO)_4(g, 1 atm.),$$
$$\Delta H°_{298} = -39.1 \pm 0.5 \text{ kcal./mole}^{15}$$

The enthalpies of formation used in the calculations are from reference 13 for CO and CO_2 and from reference 7 for NiO. The heat of vaporization of $Ni(CO)_4$ was taken as 6.5 kcal./mole.[3] From the foregoing, $\Delta Hf°_{298} = -145.1$ kcal./mole was calculated for the reaction Ni(s) + 4C (graphite) + $2O_2$ (g, 1 atm.) = $Ni(CO)_4$ (g, 1 atm.). Taking $S°_{298}$ of nickel carbonyl as 96.0 cal./°mole,[16] $\Delta Ff°_{298} = -140.0$ kcal./mole was calculated for the same reaction. The values quoted for Mittasch's work are those recalculated by Spice, *et al.*, from the corrected mathematical expressions; Reicher's value had also been recalculated by the same authors using more modern values for the relevant heats of formation and for the heat of vaporization of $Ni(CO)_4$. Of the listed figures, Reicher's is the most divergent and since the technique used is of doubtful reliability, this value perhaps need not be considered further.

The results obtained from equilibrium studies involving finely divided nickel metal may, as Spice, *et al.*, pointed out, suffer from an effect demonstrated by Giauque,[22] namely, that sometimes it may be impossible to identify equilibrium data obtained with finely divided solids with the equilibrium obtaining with the macrocrystalline phase, presumably because of the higher energy content of the more open structure of the finer material. The direct determination and the heat of combustion studies should be free from this difficulty. Mittasch's direct determination agrees fairly well with Smagina and Ormont's combustion value, but Mittasch's result conflicts markedly with the more modern direct determinations by Tomlinson and by the Mond Nickel Company, the latter agreeing well and contrasting with Mittasch's 30% higher figure. Smagina and Ormont's value was based on only three combustion runs, the average of which can be expressed to only two-figure significance and the result appears to be of doubtful reliability. In the present work, pains were taken to eliminate systematic errors, one noteworthy source of which could be incomplete detection of unburned nickel metal; an error of this sort would lead to a high value for $\Delta H°$. Consequently, it appears reasonable to regard previous values greater than −40 kcal. as erroneous.

(15) The ±0.5 kcal. represents the standard deviation of the mean in $\Delta E°_{298}$ and does not include errors in the auxiliary data from refs. 3, 7 and 13.

(16) B. L. Crawford, Jr., and P. C. Cross, *J. Chem. Phys.*, **6**, 525 (1938), report a spectroscopically determined value of 97.0 e.u. The expected error was stated as not greater than 2%. Recently L. H. Jones, *ibid.*, **23**, 2448 (1955), reinvestigated the infrared spectrum and in a preliminary report suggests some reassignments of bands in the neighborhood of 300–400 $cm.^{-1}$ which may lower the entropy value. Spice, *et al.*,[3] found 95.4 (probably ±2 e.u.) calorimetrically, the uncertainty arising in a long low temperature extrapolation.

A Polarographic Study of the Formate Complexes of Cadmium, Copper, Lead, Thallium and Zinc[1]

BY HERBERT M. HERSHENSON,[2] RUTH THOMPSON BROOKS AND MARY E. MURPHY

RECEIVED OCTOBER 8, 1956

Cadmium, lead and zinc have been found to form weak but definite complexes of the types $M(HCOO)^+$, $M(HCOO)_2$, $M(HCOO)_3^-$ and $M(HCOO)_4^=$ with formate ion concentrations ranging from 0 to 1.98 *M* in solutions held at a constant ionic strength of 2.00 with perchlorate. Copper forms similar complexes which appear to be more stable, while thallium shows no complexing tendency except at very high formate concentrations. The formation constants at 25° for the $M(HCOO)^+$, $M(HCOO)_2$, $M(HCOO)_3^-$ and $M(HCOO)_4^=$ complexes, respectively, were determined to be 3, 13, 22 and 16 for cadmium, 6, 23, 27 and 15 for lead, 4, 9, 3 and 6 for zinc and 37, 116, 112 and 283 for copper. No constants could be determined for thallium.

Introduction

The formate complexes of metal ions have not been investigated extensively; however, a few complex formates of iron and chromium have been

known for some time.[3-5] Brintzinger and co-workers[5] employed dialysis measurements to establish the existence of the following complexes: $Cd(HCOO)_4^=$, $Cu(HCOO)_4^=$ and $M(HCOO)_6^{-4}$ where M may be Co^{++}, Ni^{++} or Zn^{++}.

As part of a program involving the complexing tendencies of certain anions in aqueous solution, the formate complexes of cadmium, copper, lead, thallium and zinc have been studied using the polarographic technique developed by DeFord and Hume.[6]

Experimental

Half-wave Potential Measurements.—A Sargent Recording Polarograph, Model XXI, was used throughout this study. The span voltage was normally set at 0.5 volt, the sensitivity at 0.040 μa./mm. and no damping was employed. The initial and final applied voltages were measured to ±0.1 mv. with a Rubicon potentiometer and the resistance of the cell system was determined by means of an Industrial Instruments conductivity bridge. A Beckman Model G *p*H meter was used to determine the acidity of all solutions. Nitrogen was bubbled through the sample solution before each run in order to remove dissolved oxygen. All polarograms were run at 25.0 ± 0.2°. The method employed for determining the half-wave potential, slope and diffusion current for each polarogram was essentially that described by Hume and co-workers.[7]

Electrode Assembly.—The dropping mercury electrode, made from Corning marine barometer tubing, served as cathode. Because of the possibility of precipitation of potassium perchlorate,[8] it was decided to avoid the use of a conventional saturated calomel reference electrode. Instead a reference solution saturated with quinhydrone and hydroquinone was used. The sample solution, containing 0.001 *M* metal ion, 0.01 *M* perchloric acid, and various concentrations of sodium perchlorate and sodium formate, was placed in one arm of a U-shaped cell. The other arm, separated by a sintered-glass disk, contained the reference solution and 100 cm. of 0.0014″ platinum wire wound into a 3″ coil. The reference solution consisted of the same concentrations of perchloric acid, sodium perchlorate and sodium formate as in the sample solution, but contained no metal ion, and was saturated with quinhydrone and hydroquinone by shaking with the solids immediately before use. This assembly had the advantage of reducing to a minimum the unknown junction potential. Since the *p*H of the reference solution varies with the sodium formate concentration, it was necessary to measure the *p*H of each solution in order to calculate the potential of the reference electrode in each case. The standard potential of the quinhydrone–hydroquinone electrode was taken as +0.6123 volt *vs.* hydrogen.[9] Half-wave potential values were converted to S.C.E. as reference.

Chemicals.—All chemicals were reagent grade except for C.P. quinhydrone and hydroquinone. The nitrate salts were used to supply the metal ions, sodium formate to supply the formate ions and sodium perchlorate to adjust the ionic strength.

Results and Discussion

It is generally true that, if the half-wave potential of a metal ion shifts in a more negative direction as the concentration of ligand is increased, formation of complexes is indicated. Experiments were performed, therefore, to discover the direction and magnitude of the half-wave potential shift for each metal as the concentration of formate was increased. The results are shown in Fig. 1. It may be seen that in each case except thallium, there was a pronounced shift to more negative potentials with increasing formate concentration. Thus it appeared that complex formation does occur with

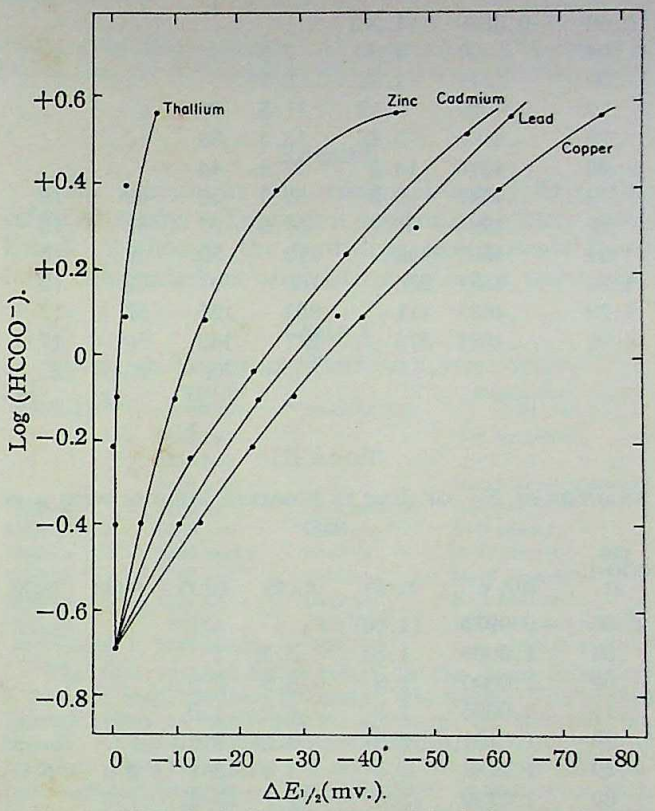

Fig. 1.—Shift in half-wave potential of the metals as a function of sodium formate concentration (based arbitrarily on the half-wave potential in 0.20 *M* formate as the initial value).

cadmium, copper, lead and zinc. However, the observed shift in half-wave potential is due to two factors: the increased amount of complex formation at higher formate concentrations and the change in activity coefficients due to changing ionic strength. In order to obtain quantitative results, another series of determinations was performed for each metal during which the ionic strength was maintained at a constant value of 2.00 while the formate concentration was varied. The data obtained were calculated and plotted as directed by DeFord and Hume.[6] The analysis of the data is shown in Tables I, II, III and IV.

Plots of the calculated values of $F(X)$ against the formate ion concentration for each of the elements resulted in straight lines for $F_3(X)$ and $F_4(X)$. This indicates the presence of complexes of the forms $M(HCOO)^+$, $M(HCOO)_2$, $M(HCOO)_3^-$ and $M(HCOO)_4^=$ in each case.

The formation constants for the formate complexes and their estimated uncertainties are summarized in Table V. These uncertainties are primarily the result of the difficulty in determining very precisely half-wave potential shifts ranging from 10 to 100 mv. Examination of the data in

			37	166	112	283

Table V will show that the order of complexing with formate is Cu >> Pb > Cd > Zn >> Tl. This agrees with the order predictable from the results of the preliminary experiment shown in Fig. 1.

TABLE V

CALCULATED FORMATION CONSTANTS FOR FORMATE COMPLEXES AT 25°

Complex type	Zinc	Cadmium	Lead	Copper
$M(HCOO)^+$	4 ± 1	3 ± 1	6 ± 1	37 ± 8
$M(HCOO)_2$	9 ± 2	13 ± 1	23 ± 4	166 ± 22
$M(HCOO)_3^-$	3 ± 1	22 ± 7	27 ± 10	112 ± 40
$M(HCOO)_4^-$	6 ± 3	16 ± 4	15 ± 4	283 ± 23

Burns and Hume[10] have reported recently that lead forms only the $Pb(OAc)^+$, $Pb(OAc)_2$ and $Pb(OAc)_3^-$ complexes with acetate under comparable conditions. However, the evidence for the presence of the tetraformato complex at high formate concentrations is quite definite. Also, the $Cd(HCOO)_4^=$ and $Cu(HCOO)_4^=$ complexes identified by Brintzinger and co-workers[5] have been confirmed but no indication of a $Zn(HCOO)_6^{-4}$ complex was observed.

The formate complexes of cadmium, lead and particularly zinc are obviously very weak. The validity of the constants is therefore somewhat questionable. Nevertheless, the data presented strongly suggest the tendency for complex formation with formate and represent at least a reasonable measure of the magnitude of this tendency.

Infrared Spectra of the Salts of the Dinitrososulfite Ion (Nitrosohydroxylaminesulfonates)

BY RUSSELL S. DRAGO

RECEIVED NOVEMBER 30, 1956

The infrared spectra of the sodium, potassium and ammonium salts of the dinitrososulfite ion are reported. Differences in the spectra of these three salts are interpreted. It is also concluded that the N–N bond in this ion has considerably more single bond character in it than previously proposed.

The synthesis of several materials containing the dinitrososulfite ion can be accomplished by passing nitric oxide into a basic solution containing sulfite ion.[1,2] The reactions that the dinitrososulfites undergo are very complex and, as a result, attempts to deduce a structure from the chemical behavior led to conflicting results.[2–5] A single crystal, X-ray diffraction investigation was undertaken and the structures of the potassium, ammonium and thallium salts were determined.[6] An accurate determination of the bond orders could not be ascertained from these studies and recently there have been attempts[7,8] to explain the electronic structure of the dinitrososulfites from chemical behavior. Evans and Gergeley[9] have also proposed a structure based upon a molecular orbital system of bonding throughout the N_2O_2 group. The infrared spectra were obtained in order to gain additional information concerning the structures of these salts.

An X-ray study of the sodium salt was not undertaken by Cox, *et al.* Difficulties were encountered[5] in attempts to prepare single crystals of this salt because of its much greater solubility. In view of this surprising solubility, the infrared spectrum of the sodium salt also was studied in order to obtain evidence concerning its structure.

Experimental

The sodium and potassium salts were prepared by methods described by Weitz and Achterberg.[2] The ammonium salt was prepared by a metathesis reaction based on the insolubility of ammonium dinitrososulfite relative to the sodium salt. In this procedure excess ammonium chloride and ammonium hydroxide are added to the reactants used to prepare the sodium salt. The crude ammonium salt precipitates out as the reaction proceeds. The salt is purified by methods previously described.[2] The potassium salt can also be prepared by a similar type reaction. The purity of the salts employed in this study are indicated by the following analyses: Calcd. for $K_2SO_3N_2O_2$: N, 12.83; K, 35.84. Found: N, 12.74; K, 35.67. Calcd. for $Na_2SO_3N_2O_2$: N, 15.01; Na, 24.73. Found: N, 14.38; Na, 24.73. Calcd. for $(NH_4)_2SO_3N_2O_2$: N, 31.82. Found: N, 31.80.

Nujol mulls of the compounds were examined using a Perkin–Elmer model 21 infrared spectrometer with sodium chloride optics. The potassium salt was also examined in perfluorokerosene mull.

Results

Table I contains the results obtained from the infrared study. Tentative assignments have been listed. Although the tentative assignments have been designated as originating within a particular bond, it should be pointed out that the group frequency vibrations in the 1300–650 region are not completely localized within the bond designated. There is only limited information available to support the assignment of the bond at 925 cm.$^{-1}$. Fortunately the doubtful assignment does not seriously affect the conclusions that can be drawn regarding the structure of these salts.

TABLE I

INFRARED BANDS AND TENTATIVE ASSIGNMENTS[a]

$K_2SO_3 \cdot 2NO$	$(NH_4)_2SO_3 \cdot 2NO$	$Na_2SO_3 \cdot 2NO$	Assignments and lit. ref.
	3250 i,s		NH stretch[10]
	3110 i,m		
	1435 i,m		NH_4^+ bending mode[10]
1322 i,s	1330 i,s	1345 med,m	NO stretch[12]
1265–85 i,m	1282 i,m	1280 i,m	S–O stretch[11]
1230 i,s	1202 med,s	1240 i,s	N–O stretch[12]
1130 i,s	1132 i,s	1147 i,s	N–N stretch[12]
1055 i,s	1057 i,s	1060 i,s	S–O stretch[11]
922 i,s	925 i,s	934 i,s	(S–N–N) vibration[b]
625 med,br	625 med,br	625 i,br	S–O bending mode[11]

[a] The first symbol listed refers to the bond intensity: i, intense; med, medium intensity; wk, weak. The second symbol refers to band width: s, sharp, m, medium, br, broad. [b] Very little information is available on this type of linkage. This bond does not occur in compounds that contain only one nitrogen on the sulfur.[11,13] It does occur both in the compounds reported above and in hydrazinosulfuric acid.[13] The parentheses indicate this assignment is questionable and requires further investigation.

Discussion

The following structures are possible for the dinitrososulfite ion. (Resonance forms for the $-SO_3$ group are not included.)

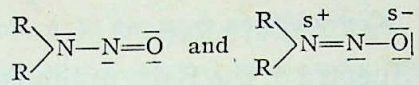
The actual structure undoubtedly is a resonance hybrid consisting of most of these forms. From the X-ray study it was concluded that structure III is of greatest significance in contributing to the final structure and in other publications[7] structure III was the only one indicated.

The absence of absorption in the 1500 cm.$^{-1}$ region indicates that the N–N bond has a considerable amount of single bond character in it. This would indicate that other structures (I or I and II) are quite significant in determining the final state of the molecule. The Raman and infrared spectra of hyponitrite ion have been reported[14] and absorption at 1392 cm.$^{-1}$ was attributed to the N–N bond. The authors interpreted this as indication of a considerable amount of single bond character in the N–N bond. Using similar arguments these studies indicate that the N–N bond in the dinitrososulfite ion has more single bond character than the N–N bond in hyponitrite for the spectra of the potassium salt in perfluorokerosene shows the absence of absorption up to 1322 cm.$^{-1}$.

The tentative assignments have been made for N–O and N–N absorption by considering the bond types to be similar to those in the dialkyl nitrosamines.[12] The following assignments have been reported for N–O and N–N vibrations in these compounds[12]: two vibrations for N–O stretch: 1315–1165 and 1265^{-1} cm.$^{-1}$; the N–N vibration between 1135–1190 cm.$^{-1}$. The structures of the nitrosamines were regarded as a hybrid of the forms



Absorptions from N=O do not occur at higher frequencies because of this resonance.

It should be kept in mind that in this study the spectra were obtained on Nujol mulls of the solid dinitrososulfites. It would be most desirable to check these measurements with Raman data on these compounds in solution to evaluate further the above assignments.

The spectra of the potassium, ammonium and sodium salts are all similar enough to indicate that the structure of the sodium salt is similar to that of the potassium and ammonium salt. With the exception of the NH_4^+ vibrations and the absorption at 1230 cm.$^{-1}$, the spectra of the potassium and ammonium salts are very much alike. The difference in the N–O vibration at 1230 cm.$^{-1}$ can be attributed to effects caused by hydrogen bonding in the ammonium salt. The existence of hydrogen bonding is further substantiated by the splitting of the N–H stretching vibration in the 3200 cm.$^{-1}$ region.

The shifts observed in the infrared spectra of the sodium salt compared to the other salts is interesting in view of the larger solubility of the sodium salt. The shifts probably arise from differences in crystal stability resulting from either anion–anion contact or from a different kind of crystal lattice in the case of the sodium salt.

Near Ultraviolet Absorption Spectra of the Pyridine Monocarboxylic Acids in Water and Ethanol Solutions[1,2]

BY HAROLD P. STEPHENSON[3] AND H. SPONER

RECEIVED DECEMBER 26, 1956

The near ultraviolet absorption spectra of picolinic, nicotinic and isonicotinic acids (2-, 3- and 4-pyridinecarboxylic acids) have been measured in 95% ethanol and distilled water solutions, and for isonicotinic acid, also for several mixtures of these two solvents. Changes in the spectra which occur when the solvent is changed from ethanol to water have been interpreted to show that the pyridine monocarboxylic acids exist primarily in the neutral, undissociated form in ethanol, and in the anion and zwitterion forms in water.[4] The spectra of the several species are discussed with regard to rather limited theoretical information concerning the effects of a carboxyl substituent on the spectrum of benzene or pyridine.

Introduction

Recently the near ultraviolet absorption spectra of the three pyridine monocarboxylic acids in aqueous solution have been reported in a number of papers,[5–7] the spectra having been observed in order to determine the acid and base dissociation constants of these substances. In each of these papers the possible zwitterion forms of the molecules were considered unimportant for an interpretation of the observed spectra. However, Jaffé[8] has discussed the tautometric equilibria of a number of substituted pyridines and their 1-oxides in aqueous solution and has concluded that nico-

(4) For external reasons, the publication of this paper was much delayed. Before finally sending it off, a recent article by R. W. Green and H. K. Tong on "The Constitution of the Pyridine Monocarboxylic Acids in their Isoelectric Forms" (THIS JOURNAL, **78**, 4896 (1956)) has come to our attention, in which these authors came to the same conclusions about the species of these acids in aqueous solutions as are presented in this paper. However, since our approach to this problem came more from the spectroscopic side, this paper contains additional spectroscopic information which supplements the paper by Green and Tong.

tinic acid and isonicotinic acid exist predominantly in the zwitterion form at the isoelectric point and that the thermodynamic constants K_a and K_b for these substances have been misinterpreted in the previous papers. Platt[9] has included nicotinic acid in a study of the "spectroscopic moments" of a large number of substituent groups and has suggested that observed anomalous intensities in the ultraviolet spectra of nicotinic acid may be due to zwitterion formation. In part, Platt based his conclusions on data from a spectrum which was reported to have been measured in isoöctane solution (non-polar solvent) but has since been found to have been taken in water solution instead.[10]

In this paper the near ultraviolet absorption spectra of picolinic, nicotinic and isonicotinic acids (2-, 3-, 4-pyridinecarboxylic acids) measured in this Laboratory in both ethanol and water solutions[11] will be reported which augment and clarify the arguments of Jaffé and Platt and afford an opportunity to discuss the spectra of what we think are the truly neutral species of these substances.

Experimental

The picolinic acid (melting point designated as 136°) was kindly given to us by Mr. L. Szabo of the Wyeth Institute of Applied Biochemistry. Since only a small quantity of the acid was available, it was found impossible to recrystallize any useful amount of the sample on account of the very high solubility of picolinic acid in cold water. Both the nicotinic and isonicotinic acids were purest-grade Eastman Kodak products and were used after recrystallization. In water solution where the extent of dissociation of these acids appears not to be the same for all observers, it is difficult to judge the purity of the samples by a comparison of the spectra. The absorption strength of both picolinic[12] and nicotinic[10] acid as reported by previous authors is somewhat smaller than that reported here. We have measured the spectrum of nicotinic acid both before and after recrystallization and have observed that low molar extinction values are characteristic of an unpurified sample. Better agreement between the results of different laboratories is to be expected for spectra measured in ethanol solutions, but apparently an ethanol solution spectrum has been published elsewhere only for nicotinic acid. In this case there is excellent agreement between our measured maximum molar extinction value of 2840 and an earlier value of 2820 reported by Miller.[13] All the spectra recorded in the previously mentioned papers[6-7] were measured in solutions of controlled *p*H and may not therefore be used to judge the purity of our samples.

The solutions used in this research were prepared from distilled water or 95% ethanol by ordinary procedures, and the spectral measurements were made at room temperature with a Beckman quartz spectrophotometer. Readings were taken over the wave length range from about 210 mμ up to about 320 mμ. For the concentrations used to cover most of this range (4×10^{-3} to 4×10^{-4} mole/l.) there appeared to be no significant concentration effects which could not be attributed to non-linearity of the optical density scale. The results of this paper indicate, however, that a careful study of such effects over a much wider range of concentrations in water solution would undoubtedly be very worthwhile for the pyridine carboxylic acids. For isonicotinic acid an interesting band shifting effect was discovered which seemed to warrant our taking measurements in various mixtures of ethanol and water. The proportions of 95% ethanol and water were in this case measured volumetrically.

Molar extinction coefficients ϵ were calculated from the usual equation $I = I_0 \times 10^{-\epsilon cl}$, where c refers to the total concentration of the solute in moles per liter and l is the absorbing path length, absorption cells 1 cm. long being used throughout this research. The spectra are plotted in Figs. 1, 2 and 3 with wave numbers ν (reciprocal centimeters) as the abscissae and molar extinction coefficients as the ordinates. For convenient comparison the spectra of

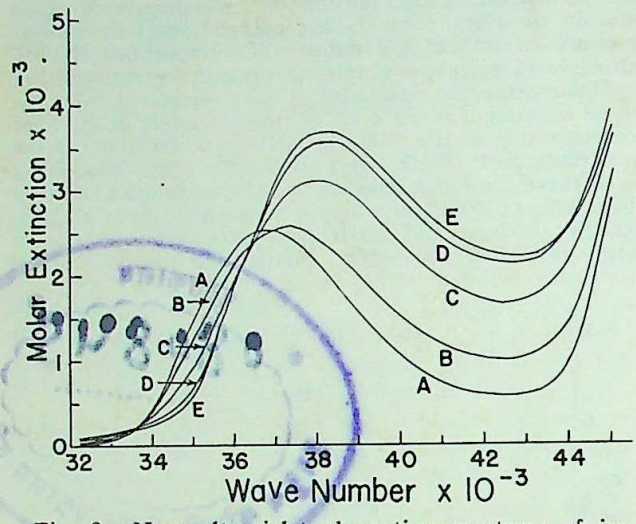

Fig. 3.—Near ultraviolet absorption spectrum of isonicotinic acid in: (A) 95% ethanol; (B) three-fourths 95% ethanol–one fourth water by volume; (C) half-and-half ethanol and water; (D) one-fourth, three-fourths mixture; (E) distilled water.

pyridine in isoöctane and ethanol solutions[14] have been included with those of picolinic acid in Fig. 1.

Recently the spectrum of pyridine in a non-polar solvent such as isoöctane (see Fig. 1D) has been interpreted as consisting of two overlapping electronic transitions, a weak n-π^* transition between 35,000 and 38,000 cm.$^{-1}$, and a strong π-π^* transition from about 37,000 to 45,000 cm.$^{-1}$, the latter transition being derived from the well-known forbidden transition of benzene.[14,15] The weak transition is due to the excitation of a non-bonding electron from the ring nitrogen,[16] and this transition shifts to higher wave numbers (shorter wave lengths) in a solution where hydrogen-bonding occurs (see Fig. 1C). Since the exact location of the shifted n-π^* transition cannot be determined, the near ultraviolet absorption spectrum of pyridine in either ethanol or water solution[17] is assumed, therefore, to be due to a single π-π^* transition of a ring π-electron.

It is likewise very probable that the single strong band appearing with a maximum at about 38,000 cm.$^{-1}$ in the spectra of the pyridine carboxylic acids is also primarily due to a single π-π^* electronic transition. The oscillator strength (f-value) of this transition is proportional to the area under the ϵ *vs.* ν graph and may be determined from the well-known equation

$$f = 4.32 \times 10^{-9} \int_0^\infty \epsilon d\nu$$

The f-values for the π-π^* transitions of the pyridine carboxylic acids were determined in this research by measuring areas from Figs. 1, 2 and 3 which were arbitrarily determined on the high wave number side by drawing a vertical line through the minimum of absorption around 43,000 cm.$^{-1}$. The results of the f-value determinations are listed in Table I together with the wave numbers, wave lengths and molar extinction coefficients of the band maxima.

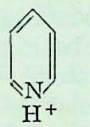
TABLE I

BAND MAXIMA AND OSCILLATOR STRENGTHS OF THE π-π^* TRANSITIONS IN THE SPECTRUM OF THE PYRIDINE MONOCARBOXYLIC ACIDS

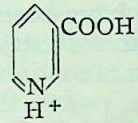
Compound	Max. wave no., cm.$^{-1}$	λ_{max}, mμ	ϵ_{max}	f	Solvent
Pyridine	38,900	257	2630	0.049	Ethanol
Picolinic acid	37,900	264	3900	.071	Ethanol
(2-position)	37,000	265	6600	.120	Water
Nicotinic acid	38,000	263	2840	.052	Ethanol
(3-position)	38,200	262	4230	.073	Water
Isonicotinic acid	36,800	272	2520	.055	Ethanol
(4-position)	38,200	262	3650	.093	Water

Discussion

Molecular Species in Solution.—Earlier authors[5] have called attention to the fact that the spectrum of nicotinic acid is very similar to that of pyridine and not to benzoic acid.[18] Especially impressive is the similarity of the spectra of the cations



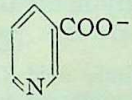
I, λ_{max} = 256 mμ
ϵ_{max} = 5320[19]
= 5290[20]



II, λ_{max} = 262 mμ
ϵ_{max} = 5500[5]
= 5000[6]

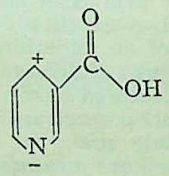
The spectra of the neutral and anion species existing in a highly basic aqueous solution (0.1 *N* NaOH) are likewise very similar

III, λ_{max} = 256 mμ
ϵ_{max} = 2660[19]
= 2750[20]



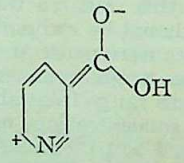
IV, λ_{max} = 262 mμ
ϵ_{max} = 2960[5]
= 3100[6]

This comparison between the spectra of pyridine and nicotinic acid indicates that the nature of the π-π^* transition in the acid is determined largely by the ring nitrogen and not by the carboxyl group. Using the symbolism of valence-bond theory, one concludes that ionic resonance structures with migration of charge to the nitrogen atom, *viz.*



V

characterize the π-π^* transition to a much larger extent than do resonance structures with migration of charge to the carboxyl group, *viz.*



VI

That structure VI plays some role in the absorption is indicated by the red shift of about 6 mμ in the maximum of the acid spectrum relative to the pyridine spectrum.[21] The corresponding red shift is particularly pronounced for isonicotinic acid and will be discussed further in the last section of this paper.

Since there is the possibility that the observed enhancement of intensity for nicotinic acid cation over that of the anion is primarily due to the addi-

tion of the proton to the carboxyl group rather than to the ring nitrogen, comparison data for all three of the pyridine carboxylic acids and a number of other simple pyridine derivatives not possessing a carboxyl substituent are given in Table II. The data for the fluoropyridines and picolines demonstrate that the nitrogen protonation effect is not only approximately independent of the nature of the pyridine ring substituent, but is also approximately independent of the initial degree of binding of the nitrogen non-bonding electrons. Spectral evidence[14] as well as dissociation constant measurements[22] have proved that for the *ortho*-substituted halopyridines the nitrogen non-bonding electrons are very tightly bound by an inductive effect. Whether these electrons are tightly bound or loosely bound as in the picolines,[14,20] the addition of a proton to the ring nitrogen of a pyridine derivative generally has the effect of approximately doubling the absorption intensity of the π-π^* transition in the near ultraviolet.

What the independent effect of adding or removing a proton from the carboxyl group alone would be may be estimated from the recent work of Ungnade and Lamb on benzoic acid.[18] They found that the ionization of benzoic acid in 95% ethanol solution is negligible and that ϵ_{max} is 900 at λ_{max} of 272 mμ for the π-π^* transition corresponding to the transition under discussion for the pyridine compounds. In 0.01 *N* HCl aqueous solution ϵ_{max} is 1020 at λ_{max} of 274 mμ, and in 0.01 *N* NaOH solution, where the molecule is entirely in the anion form, ϵ_{max} is 490 at λ_{max} of 268 mμ. In water solutions for which the *p*H is determined by the dissociation of the acid itself, the maximum extinction coefficient varies from 940 at a concentration of 1.748×10^{-3} mole/l. to 780 at a concentration of 0.0715×10^{-3} mole/l., for which there is considerable ionization. Thus for benzoic acid, in which the carboxyl group causes about a 5-fold intensification of the originally forbidden benzene spectrum, the relative effect of removing the proton from the carboxyl group is rather large. The relative effect will not be expected to be nearly as large for the pyridine monocarboxylic acids, however, because the *f*-value of pyridine itself is already some 50 times as large as that for benzene,[14] and the *f*-values in Table I show that the addition of the carboxyl group to pyridine serves only to increase slightly the absolute degree of absorption intensity, not its order of magnitude. One might estimate that the effect of removing a proton from the carboxyl group of the pyridine carboxylic acids would be to decrease ϵ_{max} by several hundred, possibly 200 to 500.

With a comparison of Tables I and II it becomes clear that the spectra of the pyridine carboxylic acids in ethanol solution are very similar to the spectra of the aqueous-solution anions (species IV, for example) of these substances. In spite of the fact that nearly all the carboxyl groups would, therefore, have to be dissociated, the ethanol solutions appear to be highly basic, not acidic. At first this situation seemed puzzling. It is well known that the acidity of the carboxyl group is reduced by as much as 5 pK_a units whenever many acids are dissolved in ethanol rather than water,[24] and therefore the spectral evidence of Ungnade and Lamb that benzoic acid is negligibly dissociated in ethanol, as well as other alcohols, is not surprising. In consequence of these facts for benzoic acid, it seems reasonable that the pyridine carboxylic acids would likewise be negligibly dissociated in ethanol solutions and that the corresponding spectra in Figs. 1, 2 and 3 actually represent the spectra of the completely neutral forms of these substances, not the anion forms. The reason the spectra are so similar to the anion spectra in all

cases is simply that the π-electron systems of picolinic, nicotinic and isonicotinic acids are very little affected by the presence of a proton on the carboxyl group. In fact, we see that the ϵ_{max} values for all the neutral molecules in ethanol solution are actually somewhat smaller than the ϵ_{max} values for the corresponding anions in basic water solution, rather than larger as we would have predicted. A similar situation prevails for all the other pyridine compounds listed in Table II except 4-picoline.

In water solution where some ionization of the pyridine acids is now expected, one sees from Figs. 1, 2 and 3 that the intensity of absorption of these acids increases with carboxyl dissociation rather than decreases as does the intensity of the benzoid acid spectrum.[18] Consequently it becomes clear why it is necessary to have established the primary importance of proton attachment at the ring nitrogen as the determining factor in the intensity changes. Every proton that detaches itself from a carboxyl group must decrease the intensity of absorption by a much smaller extent than it subsequently increases the intensity when it becomes attached to a ring nitrogen. Furthermore, there must be a large percentage of such attachments in water solution, a situation which agrees with the opinion of Jaffé[8] that these acids must exist primarily as zwitterions in water solution. According to Jaffé the neutral uncharged forms of the molecules contribute only about 5% to the equilibrium mixtures at the isoelectric points, which in each case are mixtures of rather high acidity: picolinic acid, pH 3.21; nicotinic acid, pH 3.42; isonicotinic acid, pH 3.31.[6] The pH of the water solutions used in this research will be expected to be somewhat higher than those values.

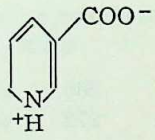
By making measurements near the isoelectric points, Evans, Herington and Kynaston[6] were able to derive spectral curves for what they called the undissociated molecular species of the acids. The curves are closely similar to the water spectra given in Figs. 1, 2 and 3, with the following values for ϵ_{max}: 7400 for picolinic acid; 4800 for nicotinic acid; 4500 for isonicotinic acid. It is significant that these ϵ_{max} values are just 200 to 300 less than the ϵ_{max} values of the corresponding cations listed in Table II, a difference corresponding to the change expected with the removal of a proton from the carboxyl group. Thus the evidence is rather convincing that the dissociated molecular species is formed by removing a carboxyl proton, not the ring nitrogen proton, from the cation species II. Evans, Herington and Kynaston realized that the undissociated molecular species might be an admixture of the neutral form and the zwitterion form, but they stated that it is unnecessary to discriminate between them. Such a point of view is permissible for the measurement of the apparent dissociation constants of these dibasic compounds, but the work of Jaffé shows that some discrimination is necessary for the interpretation of these constants in order to calculate the thermodynamic dissociation constants K_a and K_b.

In each of the papers[5-7] on the dissociation constants of pyridine and its derivatives the following

stants which were determined experimentally were defined by the equations

$$K_1 = \frac{a \times [HA]}{[H_2A]} \text{ and } K_2 = \frac{a \times [A]}{[HA]}$$

where "a" is the hydrogen ion concentration, [HA] the concentration of the undissociated molecular species, [H_2A] the concentration of the cation species, and [A] the concentration of the anion species. If the species HA is predominantly represented by the neutral, uncharged molecule, then K_1 would be referred to as the apparent dissociation constant of the conjugate acid of the base, and K_2 would be referred to as the apparent dissociation constant of the acid. These constants were thought of in these terms by the previous authors.[5-7] On the other hand, if the species HA is predominantly represented by the zwitterion form of the molecule, for example



VII

then K_1 must be referred to as the apparent dissociation constant of the acid and K_2 as the apparent dissociation constant of the conjugate acid of the base.

From their assumptions about K_1 and K_2 the previous authors have further calculated the thermodynamic constants K_a and K_b. The most accurate results seem to be those of Evans, Herington and Kynaston, and these are summarized in Table III. According to these values of K_a and K_b, the carboxyl groups of these acids donate a proton with slightly less facility than does benzoic acid, $K_a = 6.86 \times 10^{-5}$,[18] and the basic property of the ring nitrogen is greatly reduced with respect to pyridine itself, $K_b = 1.44 \times 10^{-9}$.[25] That the basic property of the ring nitrogen appears so weak for nicotinic acid, as well as in the other two acids is the reason why Hughes, Jellinek and Ambrose[5] were the first to conclude that nicotinic acid cannot exist as a zwitterion in water solution.

TABLE III

DISSOCIATION CONSTANTS OF THE PYRIDINE MONOCARBOXYLIC ACIDS ACCORDING TO EVANS, HERINGTON AND KYNASTON[6]

Compound	pK_1	pK_2	10^5K_a	$10^{12}K_b$
Picolinic acid	1.08	5.32	0.403	0.102
Nicotinic acid	2.09	4.72	1.50	1.04
Isonicotinic acid	1.82	4.78	1.46	0.59

Jaffé has pointed out that one must know the extent of zwitterion formation before the correct values of K_a and K_b may be determined precisely from the measured K_1 and K_2 values, even when the correct interpretation of the constants is made. He finds that for nicotinic acid and isonicotinic acid the corrections are quite small because of the predominant formation of the zwitterions. With the altered interpretation of K_1 and K_2, new values of K_a and K_b may now be determined from the

same equations used by Evans, Herington and Kynaston, namely

$$pK_a = pK_2 - \log_{10} \gamma^-$$
$$pK_b = 13.997 - pK_1 - \log_{10} \gamma^+,$$

where the values used for the activity coefficient terms were about −0.10. When the apparent dissociation constants K_1 and K_2 are interchanged in the equations, the results listed in Table IV are obtained. For example, in the case of picolinic acid

$$pK_a = 1.08 + 0.10 = 1.18$$

and consequently

$$K_a = 6.61 \times 10^{-2}$$

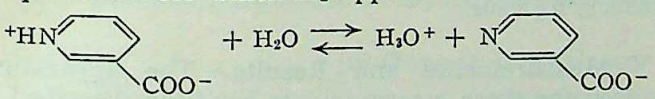
TABLE IV

DISSOCIATION CONSTANTS OF THE PYRIDINE MONOCARBOXYLIC ACIDS WITH THE ASSUMPTION THAT ZWITTERION FORMATION IS PREDOMINANT IN WATER SOLUTION

Compound	pK_a	10^2K_a	pK_b	10^9K_b
Picolinic acid	1.18	6.61	8.78	1.66
Nicotinic acid	2.19	0.646	9.38	0.417
Isonicotinic acid	1.92	1.20	9.32	0.479

These results show that the basicity of the ring nitrogen is changed very little by the introduction of the carboxyl group, but that the acidity of the carboxyl group itself is greatly enhanced by the presence of the nitrogen. These conclusions are in agreement with the spectral evidence that the ring nitrogen acts almost independently of the carboxyl substituent, preventing large migration of negative charge on to the carboxyl group as shown in resonance structure VI.

Because of the almost complete dissociation of the carboxyl groups, the pH of the water solutions used in this research must have been determined chiefly by the value of the dissociation constant K_2. That is, we are chiefly concerned with the equilibrium for which K_2 applies. Under this as-



VII IV

sumption it is possible to use the data from the paper of Evans, Herington and Kynaston to calculate theoretical values for the molar extinction coefficients of the pyridine acids in water solution. The results of these calculations are summarized in Table V. The maximum molar extinction values for the zwitterions were taken to be identical with the coefficients for the "undissociated molecular species."[6] There is good agreement between the calculated and observed values of ϵ_{max}, but for each acid the observed molar extinction coefficient is lower than the calculated value, a fact which indicates that the neutral undissociated molecular species is making a small contribution to the absorption. By assigning ϵ_{max} values to these neutral species corresponding to those obtained in ethanol solution (the values in water solution must still be considered uncertain), it appears that the neutral form makes up about 10, 5 and 15% of the *total* solute mixture in the case of picolinic, nicotinic and isonicotinic acids, respectively.

Comparison of the Spectra.—It is well known that, because of their strong electron attracting character as illustrated by the resonance structures V and VI, both a carboxyl group and a ring nitrogen are *meta*-directing substituents in benzene and pyridine. Sklar[26] has studied the effects which

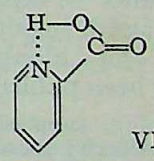
TABLE V

THEORETICAL CONCENTRATIONS OF VARIOUS SPECIES AND ϵ_{max} VALUES FOR WATER SOLUTIONS OF THE PYRIDINE ACIDS AT A TOTAL CONCENTRATION OF 2×10^{-4} MOLE/L.

Compound	Zwitterion concn., $\times 10^4$, mole/l.	Anion concn., $\times 10^4$, mole/l.	pH	Calcd. ϵ_{max}	Measd. ϵ_{max}
Picolinic acid	1.71	0.29	4.54	6910	6600
Nicotinic acid	1.48	.52	4.28	4360	4230
Isonicotinic acid	1.50	.50	4.30	3980	3650

electron-attracting or electron-donating substituents have on the near ultraviolet π-π^* electronic transition in benzene, and was able to predict the relative intensities of the spectra of a number of isomeric disubstituted benzenes for which first-order calculations applied. While neither a ring nitrogen nor the carboxyl group fits the theoretical restrictions of the Sklar theory, Platt[9] has noted that these groups do act in a manner expected of *meta*-directing substituents in all observed cases except nicotinic acid. According to the simple Sklar treatment, one expects the oscillator strengths of the *o*- and *m*-pyridine carboxylic acids to be equal to each other and to be slightly smaller than that of pyridine itself, while the oscillator strength of *p*-pyridine monocarboxylic acid is expected to be larger than any of the other two or of pyridine itself. The equality of the oscillator strengths of the *ortho*- and *meta*-substituted compounds is predicted by the theory also for the case where the orienting powers of the substituents are different.

Now it is significant that the oscillator strength of the electronic transition in picolinic acid should be so much larger than that of nicotinic and isonicotinic acids, regardless of whether the molecules are in their neutral forms or in the zwitterion forms characteristic of water solutions (*cf.* Table I). It is tempting to say that picolinic acid occurs predominantly in the chelated[27] form



VIII

in alcohol solution, but then it is not understandable why the oscillator strength of picolinic acid cation should continue to be so much more intense than that of nicotinic or isonicotinic acid cations. The addition of a proton to the ring nitrogen of the latter substances ought to have the effect of evening up the discrepancies between the intensities.

That the oscillator strength of isonicotinic acid should be slightly larger than that of nicotinic acid in ethanol agrees qualitatively with the results expected from the Sklar theory for two *meta*-directing substituents. This agreement must be considered very inconclusive, however, in view of the difficul-

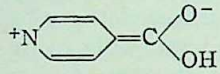
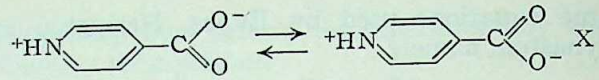
ties with the picolinic acid intensity. The observed violet shift of about 1700 cm.$^{-1}$ (*cf.* Fig. 3) which occurs for isonicotinic acid when the solution is changed from ethanol to water bears a close resemblance to the type of blue shift expected for an n-π^* transition,[14,28] but it is highly probable that the correct explanation for this blue shift is one that involves a discussion of π-electrons only. Kumler and Strait[21a] have pointed out in a discussion of the spectra of benzoic acid and *p*-aminobenzoic acid that resonance (migration of negative charge) between the carboxyl group and the ring is restricted whenever internal carboxyl resonance itself is enhanced by removal of the proton. Whereas, therefore, one expects some contribution from ionic resonance structures such as



IX (similar to VI)

in ethanol solutions, such structures will be restricted in water solution because of the added importance of the resonance



That is, one expects a greater migration of charge out of the ring in the neutral isonicotinic acid species than for the corresponding zwitterion species. The greater migration in the former case is a well-known explanation for the resulting shift of the π-absorption band to longer wave lengths.[21b] Since the shifts for picolinic and nicotinic acids are not so large, it can be assumed that the ionic structure IX is more important in determining the absorption by isonicotinic acid than is the corresponding structure VI for nicotinic acid (and picolinic acid). In the *ortho* and *meta*-positions the nitrogen atom undoubtedly restricts the degree of electron migration to the carboxyl group. A theoretical treatment of the perturbation effect of the carboxyl group when substituted on simple aromatic rings like benzene and pyridine is evidently very desirable.

Low Temperature Heat Capacities and Entropies at 298.15° K. of Cryolite, Anhydrous Aluminum Fluoride and Sodium Fluoride

BY E. G. KING

RECEIVED NOVEMBER 28, 1956

Heat capacities of cryolite (Na_3AlF_6), sodium fluoride and aluminum fluoride were measured in the temperature range 51 to 298°K. All showed normal behavior. The 298.15°K. entropies are: cryolite, 57.0 ± 0.4 cal./deg. mole; sodium fluoride, 12.26 ± 0.07 cal./deg. mole; and aluminum fluoride, 15.89 ± 0.08 cal./deg. mole.

This paper reports the results of heat capacity measurements throughout the temperature range 51–298°K., with derived entropies, for cryolite and its constituent fluorides. Thermodynamic values for these substances are of importance in the usual electrolytic process for aluminum production. No similar data have been published previously.

Materials.—The cryolite, supplied by the Aluminum Company of America Research Laboratories, New Kensington, Pa., consisted of hand-picked crystals of natural Greenland cryolite. The analysis by ALCOA showed 32.76% sodium (theoretical, 32.85%) and 13.01% aluminum (theoretical, 12.85%). As impurities there were 0.036% potassium and 0.007% lithium. For the purpose of the present work, the substance was considered as $Na_{2.959}AlF_{5.959}$, and the heat-capacity results were corrected to stoichiometric composition. This correlation ranged from 0.1 to 0.2%.

The sodium fluoride was Mallinckrodt analytical reagent powder meeting A.C.S. specifications. No treatment of the sample was made other than heating to 700° immediately before use.

The aluminum fluoride was a vacuum-sublimed product, prepared especially for this work by the Reduction Research Laboratory, Kaiser Aluminum and Chemical Corp., Permanente, Calif. The sample analyzed 32.12% aluminum (theoretical, 32.13%). Impurities, measured spectrographically by the Kaiser Laboratories, were: Si, 0.008%; Fe, 0.008%; Mg, 0.005%; Na, 0.05%; Ti, 0.003%; and Ca, 0.06%. All other impurities were present in amounts less than 0.003%.

Measurements and Results.—The apparatus used for these measurements has been described.[1] Sample masses employed were: cryolite, 214.48 g.; sodium fluoride, 130.08 g.; and aluminum fluoride, 241.49 g.

The heat capacities are expressed in defined calories (1 defined calorie = 4.1840 absolute joules). The measured values are given in Table I. Molecular weights accord with the 1953 International Atomic Weights.[2]

All three compounds showed normal behavior over the entire measured temperature range. It is of interest to compare the heat capacity of cryolite with that of the stoichiometric summation of sodium and aluminum fluorides. Cryolite has 60% greater heat capacity at 50°K. However, the difference decreases rapidly with temperature, becoming 7% at 100°K., less than 0.2% at 200°K., and less than 0.2% for the entire range from 200 to 298.15°K.

Entropies at 298.15°K.—The entropy increments for the measured range, 51–298°K., were obtained by Simpson-rule integrations of C_p *vs.* log T plots.

Infrared Spectra of Cyclopentamethylenedialkylsilanes[1] in the 2–35–Region

BY GORDON D. OSHESKY AND FREEMAN F. BENTLEY

RECEIVED NOVEMBER 28, 1956

The infrared absorption spectra of 21 cyclopentamethylenedialkylsilanes have been obtained from 2–35 μ and empirical assignments made for specific vibrations. The series begins with cyclopentamethylene-silane and ends with cyclpentamethylenedioctadecylsilane. Absorption bands at 10.93 to 11.00 and 20.20 to 20.85 μ are tentatively assigned to vibrations arising from the heterocyclic ring. All the observed absorption bands are given in a table showing their position and relative intensities.

This paper presents infrared absorption spectra of a series of cyclopentamethylenedialkylsilanes in the liquid state from 2 to 35 μ. This series of compounds was studied by this Laboratory for the purpose of correlating various physical properties with molecular structure.[2] This paper will deal solely with the infrared absorption bands of this and mainly with the tentative band assignment of the organosilicon ring vibration.

Experimental

Apparatus and Technique.—The infrared spectra in the 2 to 15 μ region were obtained with a Baird Associates, Model B, automatic recording spectrophotometer equipped with a sodium chloride prism. This instrument was calibrated to within ±0.05 μ by using ammonia and polystyrene. The liquid samples were recorded in a 0.028 mm. cell with sodium chloride windows. The thin capillary thicknesses were obtained by placing a drop of liquid between two rock salt plates, which were then fastened tightly together.

The spectra in the 15–35 μ region were obtained on a Perkin–Elmer Model 21, double beam recording spectrophotom ter equipped with cesium bromide optics. This prism was calibrated by using atmospheric carbon dioxide and water vapor bands. The accuracy of the wave lengths as recorded here is probably better than ±0.05 μ, which in this region of the spectrum is equivalent to about ±1.5 cm.$^{-1}$. The liquid samples were measured in 0.510 and 0.053 mm. cells with cesium bromide windows. All measurements in the 2 to 35 μ region were made at 24.0 ± 0.5° and at a relative humidity of 35 ± 5%.

Due to insufficient sample the spectra of the diethyl and 2-ethylbutyl derivatives could not be obtained in the 15 to 35 μ region.

(1) Opinions expressed are those of the authors and do not necessarily express the official opinions of the U. S. Air Force or the Wright Air Development Center.

(2) This series of compounds was prepared by Dr. Christ Tamborski, Dr. Harold Rosenberg and Mr. James Groves, and the details of their physical properties and preparation will be published elsewhere.

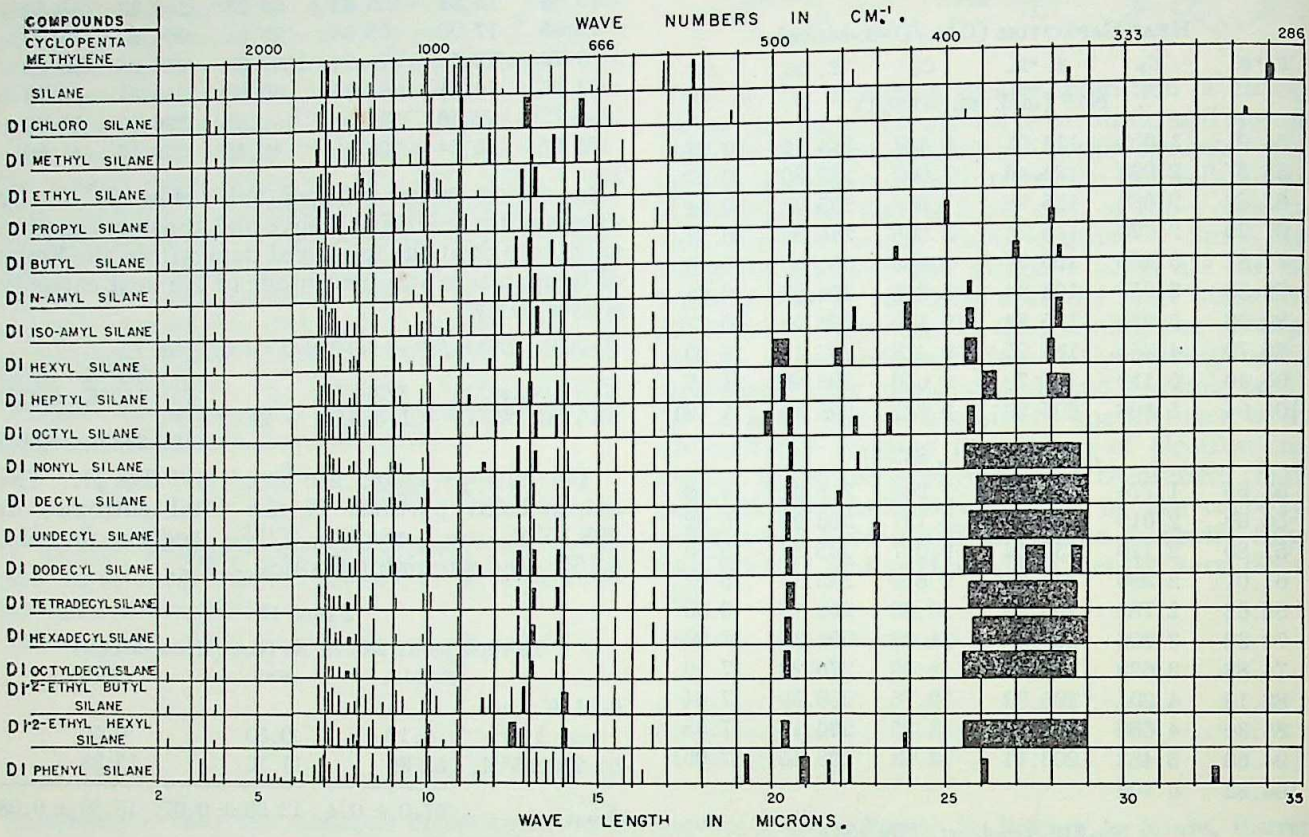

Fig. 1.—Tabulated absorption frequencies of 21 cyclopentamethylenedialkylsilane derivatives.

Materials.—The cyclopentamethylenedialkylsilanes used in this study were fractionated through a 30-cm. short-path Vigreux column. Carbon, hydrogen and silicon analyses were performed on each compound of this series and they were found to be 99% pure. The compounds were analyzed by the Schwarzkopf Microanalytical Laboratory.

Results and Discussion

The difficulty in establishing the presence of a ring in organic molecules by chemical means has promoted interest in identifying the presence of cyclic structures by infrared techniques. Saturated cyclic systems have characteristic frequencies arising from the bond stretching and valence angle modes which occur in the fundamental region. There is a great number of articles in the literature dealing with attempts to characterize alicyclic systems, particularly cyclopropane and cyclobutane, from the infrared spectra, but the situation is still obscure.[3-5] With the possible exception of cyclopropane[6] no certain means of identifying ring systems by the out-of-plane and torsional bending modes beyond 20 μ has so far been realized. A few band assignments for some of the saturated cyclic hydrocarbons are given in Table I.

Tentative frequency assignments have been made for the cyclopentamethylenedialkylsilanes investigated in these studies. Figure 1 lists the 21 compounds recorded and pictorially indicates the band positions and their relative intensities. The infrared spectra of eight of the derivatives of this series are shown in Figs. 2 to 5, inclusively.

Carbon–Hydrogen Deformation Frequencies.—Absorption arising from the CH deformation frequencies of these molecules present some interesting correlations. Absorption bands at 6.85 μ in the spectra of cyclopentamethylenesilane and cyclopentamethylenedichlorosilane are apparently due to the CH_2 bending modes of the heterocyclic ring. The position of this band remains constant throughout the series. It is masked to a degree by the CH_2 deformation and CH_3 asymmetrical deformation absorption of the large alkyl substituents on the silicon atom. Absorbance due to the sym-

metrical bending vibration of the CH_3–C group at 7.23 μ is clearly present in the spectra of all the molecules of this series containing this group. The intensity of this absorption band gives some indication as to the number of methyl groups present in the molecule. In the spectrum of cyclopentamethylenediisoamylsilane the absorption band is split due to the isopropyl group.[17,18] As would be expected the absorption band at 7.23 μ is not present in the spectrum of cyclopentamethylenedimethylsilane where the methyl group is linked to a silicon atom.

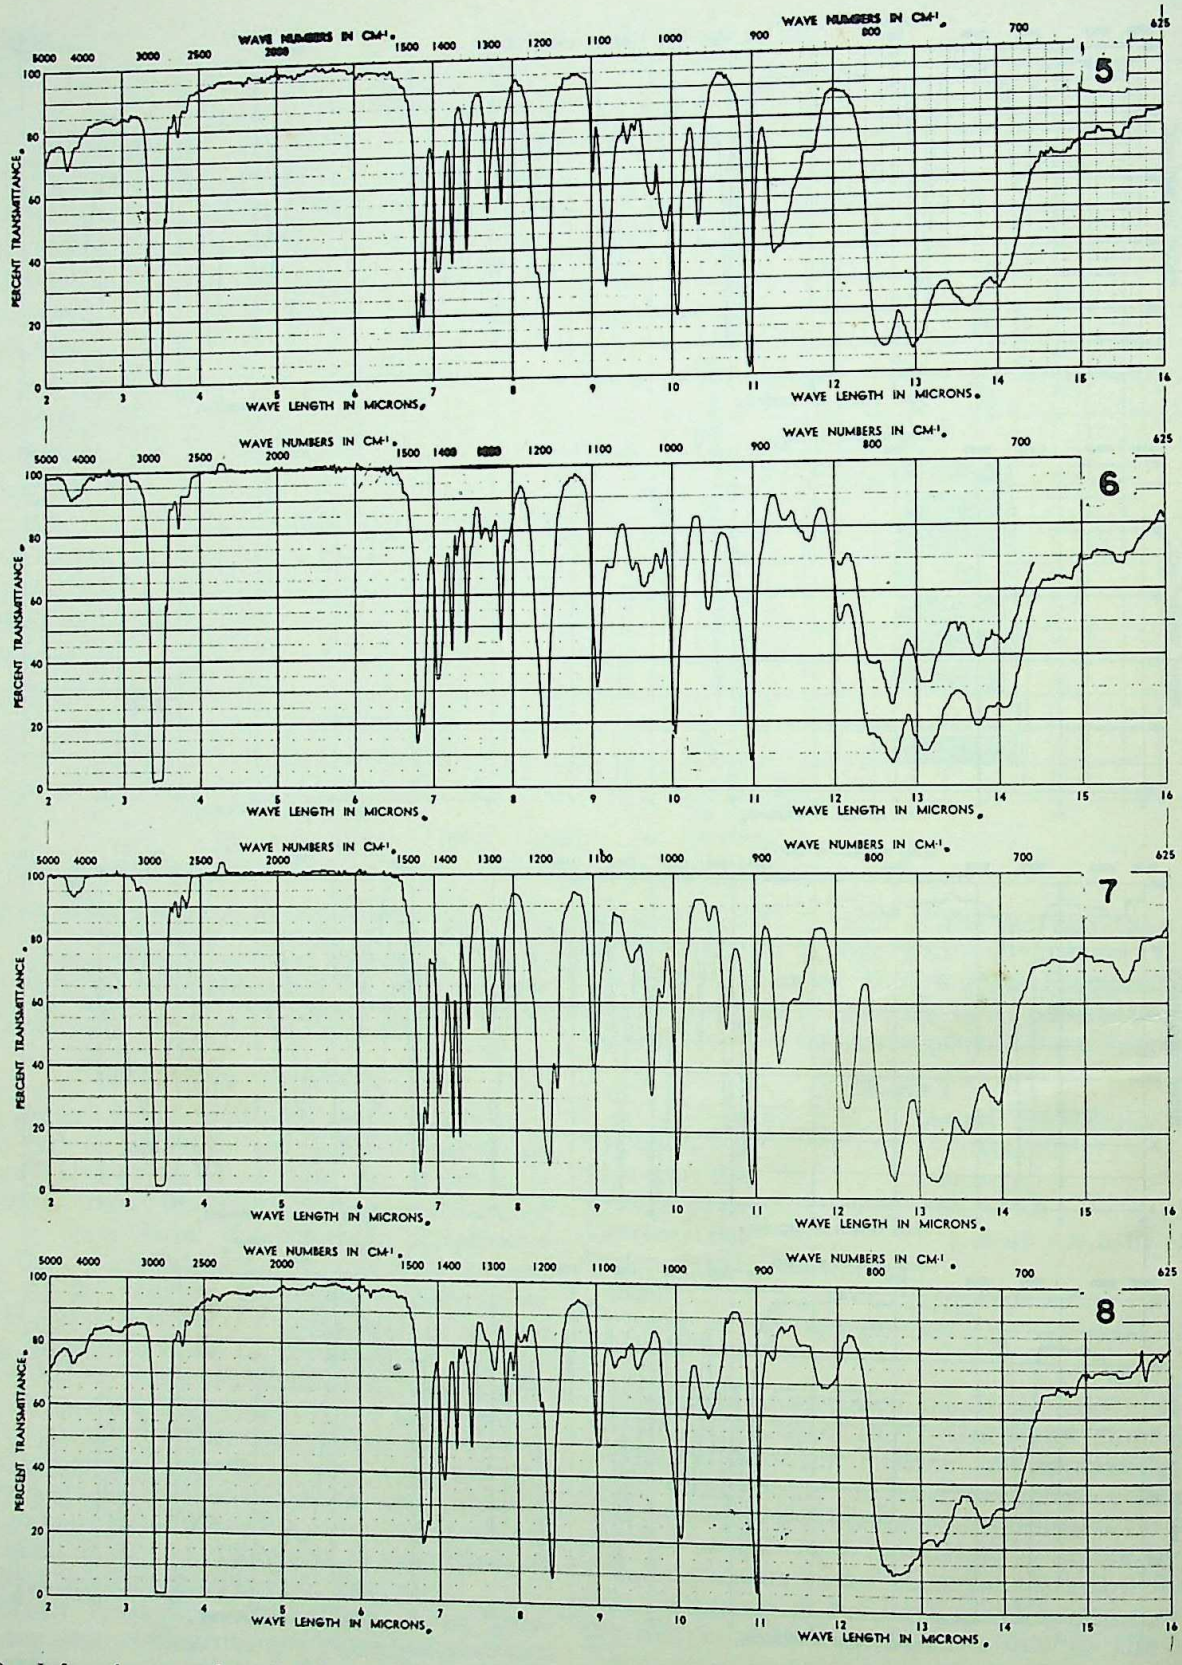

Fig. 3.—Infrared spectra from 2–16 μ of cyclopentamethylene silanes: 5, di-*n*-butyl; 6, di-*n*-amyl; 7, diisoamyl; 8, di-*n*-hexyl.

The strong absorption in the 7.03 to 7.10 μ region is attributed to the deformation vibrations of the CH_2 group linked to the silicon atom. The CH bending vibration of the $Si–CH_3$ group was observed by Wright and Hunter[19] and all the tetraalkylsilanes (more than 30) studied in this Laboratory absorb in this region. Young and co-workers[20] also observed an absorption band at 7.08 μ in the spectra of cyclic disubstituted siloxanes containing $Si–CH_3$ and $Si–CH_2CH_3$ linkages. They tentatively assigned this band to the carbon–hydrogen

bending vibrations of the methylene group linked to the silicon atom.

Vibrations Attributed to the Heterocyclic Ring.—Analysis of the spectra of the cyclic silanes led to empirical assignments for the characteristic vibrations of the heterocyclic ring. Absorption bands at 10.93 to 11.00 μ and 20.20 to 20.85 μ in the spectra of these compounds are tentatively assigned to this structure. The sharp absorption band at 10.93 to 11.00 μ appears to be the most promising band for determining the presence of the heterocyclic ring. It is a strong band and is very constant in wave length position throughout this series of compounds. The second band absorbs strongly at 20.20 to 20.85 μ and is present in the spectra of all the cyclic silanes except cyclopentamethylenesilane and cyclopentamethylenediphenylsilane. In the latter spectrum the band is at 21.00 μ, just outside the above range, but in the spectrum of the silane it has shifted to longer wave lengths at 22.30 μ. This band is attributed to the out-of-plane bending mode of the heterocyclic ring.

Several other absorption bands in the spectra of these cyclic silanes appear to be characteristic of the cyclopentamethylene silicon ring, and serve to identify this class of compounds. A weak absorption band at 3.70 to 3.75 μ is present in the spectra of all the cyclic silanes in this series, and most of the cyclopentane and cyclohexane derivatives in the API spectra. It appears to be a characteristic feature of these aliphatic ring systems. A study in the 3 to 4 μ region with a lithium fluoride prism would probably disclose a band characteristic of the C–H vibration of the heterocyclic ring.

The weak absorption band at 7.83 to 7.90 μ is present in the spectra of all the cyclic silanes in this series and appears to be characteristic of the heterocyclic ring. Since Si–CH_3 always absorbs in this region, however, this band is a risky one for other correlations. Cyclohexane has an absorption band at 7.95 μ and most of its derivatives absorb in this region. The 7.83 to 7.90 μ band appears to be associated with the vibrations of the methylene linkage in the heterocyclic ring.

The strong absorption band at 9.95 to 10.05 μ decreases in intensity as heavier alkyl substituents are linked to the silicon atom. The relative position of this band is constant throughout the series. Marrison[15] has noted that most of the published spectra of cyclohexane derivatives show bands in

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

the 9.95 to 10.50 μ and 9.48 to 10.00 μ region, and cyclopentane and cyclopropane[8,9] derivatives absorb in the 10 μ region. Absorption in the 10 μ region also appears to arise from vibrations of the methylene group in the heterocyclic ring.

Vibrations Attributed to the Alkyl-Silicon Linkage.—There has been some dispute over the assignment of absorption bands arising from vibrations of the methylene groups bonded to a silicon atom as to whether it should be assigned to the 11.6 or 8 μ region[21,22] and as to whether it is a deformation or rocking vibration.[19,20] A strong absorption band at 8.42 μ was observed in the spectra of all the cyclic silanes studied. The relative intensity and position of this band is constant throughout the series. This band was also observed in the spectra of alkyl silanes by Kaye and Tannenbaum[23] and it was attributed to the symmetrical deformation vibration of the methylene groups attached alpha to the silicon atom.

An absorption band in the 11.6 μ region was not observed in the cyclopentamethylenedialkylsilane series, but strong bands in the 12 to 13 μ region were observed. These bands are attributed to the methylene groups in the alkyl radical which are bonded to the silicon atom. Young, Koehler and McKinney[24] observed an absorption band at 11.5 μ in the spectrum of tetramethylsilane and assigned this band to a methyl rocking vibration. A strong absorption band is observed at slightly longer wave lengths, 11.90 μ, in the spectrum of cyclopentamethylenedimethylsilane. This band is attributed to a methyl rocking vibration. Absorption bands at 7.97 μ in the latter spectrum and at 8.03 μ in the spectrum of cyclopentamethylenediethylsilane apparently are due to symmetrical deformation vibrations of the methyl and ethyl groups bonded to the silicon atom.

Absorption Characteristic of Disubstituted Silanes.—An absorption band in the 10.6 to 10.7 μ region, characteristic of disubstituted silanes, was observed and reported by West and Rochow,[25] but no frequency assignments were made in that paper. A strong band in this region was also observed by Opitz[26] in the spectra of monosubstituted silanes. He assigned the 10.60 to 10.90 μ region, which is common to disubstituted silanes, to a deformation mode of the SiH_2= group. An absorption band has been observed at 10.58 μ in the spectrum of cyclopentamethylenesilane. This band is in agreement in frequency and intensity with the band for the SiH_2= bending frequency occurring at 10.50 μ for dichlorosilane[27] and 10.62 μ for dibromosilane.[28] This band has been observed to remain essentially constant throughout the spectra of 38 compounds containing two and three hydrogens on silicon.[29,30]

Two strong absorption bands are present in the spectra of the cyclic silanes at 10.0 and 11.0 μ. These bands occur at wave lengths which have been assigned to the terminal vinyl linkage, —C=CH_2, in the litarature.[31,32]

Spectra of the Cyclic Silanes in the Long Wave Length Region.—The infrared spectrum of most materials in the wave length region beyond 8 μ is quite sensitive to change in structure, as pointed out many times in the literature.[33] The spectra of this series of cyclopentamethylenedialkylsilanes exhibits this sensitivity to a degree. A noticeable change can be observed in the spectra up to the dinonyl derivatives. Beyond the dinonyl derivative the change may be considered negligible.

Several absorption bands in the wave length region beyond 15 μ are of interest. The medium band at 15.4 to 15.8 μ is very consistent in wave length position in the dialkyl derivatives, and may be related to vibrations of the heterocyclic ring. The medium band at 16.6 μ and the strong broad band at 26 to 29 μ in the spectra of the dialkyl silanes are apparently due to vibrations arising from the alkyl substituents linked to the silicon atom. Similar absorption bands are observed in the spectra of long chain esters studied in this Laboratory. The presence of these bands gives some indication as to the size of the alkyl groups in this type of molecule. The strong band at 29.9 μ in the spectra of cyclopentamethylenedimethylsilane is observed in the spectra of toluene and other cyclic systems containing methyl groups and may be indicative of this group.

Acknowledgments.—The authors wish to thank Dr. C. Tamborski, Dr. H. Rosenberg and Mr. J. Groves of this Laboratory for preparing the samples used in this investigation.

Equilibria and Spectra of Aqueous Chlorine Solutions

BY G. ZIMMERMAN AND F. C. STRONG[1]

RECEIVED DECEMBER 20, 1956

The thermodynamic equilibrium constants for the reactions: $Cl_2(aq) + H_2O = HOCl(aq) + H^+(aq) + Cl^-(aq)$, $Cl_2(aq) + Cl^-(aq) = Cl_3^-(aq)$, have been determined by a spectrophotometric method which involved accurate determinations of the absorption spectra of aqueous Cl_2, HOCl and Cl_3^- from 2000 to 3900 Å. The second, shorter wave length absorption bands observed for aqueous Cl_2 and Cl_3^- (in the former case, absent in the gas spectrum) can be interpreted as excitation to an "ionic" excited state, or, less likely, as a "charge transfer to solvent" spectrum.

We have determined spectrophotometrically the equilibrium constants for the reactions

$$Cl_2(aq.) + H_2O(l) \overset{K_1}{=} HOCl(aq.) + Cl^-(aq.) + H^+(aq.) \quad (1)$$

$$Cl_2(aq.) + Cl^-(aq.) \overset{K_2}{=} Cl_3^-(aq.) \quad (2)$$

and have obtained precise absorption spectra for HOCl(aq.), Cl_2(aq.) and Cl_3^-(aq.). The work was undertaken partly because of interest in the nature of the absorption spectra and partly to verify the presently accepted values of the two equilibrium constants, namely, $K_1 = 3.90 \times 10^{-4}$,[2] and $K_2 = 0.176$.[3] Several other recorded values of K_1 [(4.75×10^{-4}),[4] (2.09×10^{-4})[5] at 25° and (1.55×10^{-4})[6] at 0°] show only fair agreement. Our results ($K_1 = 3.35 \times 10^{-4}$, $K_2 = 0.191$) support Jakowkin's value for K_1 and are consistent (*vide infra*) with Sherrill and Izard's value for K_2. The absorption spectra for Cl_2(aq.) and Cl_3^-(aq.) have not been separated properly hitherto; in pure water and even in concentrated H_2SO_4 there is a considerable contribution to the net absorption spectrum of chlorine by Cl_3^-, especially at short wave lengths (<2800 Å.).

TABLE I

ABSORPTIVITIES

Wave length, Å.	a_{HOCl}	a_{Cl_2}	$a_{Cl_3^-}$
2537	59.0 ± 0.4	5.0 ± 0.5	3311 ± 78
2885	27.0 ± .2	26.3 ± .2	180.4 ± 1.7
3250	11.0 ± .2	75.3 ± .3	192.9 ± 5.0

Experimental

Absorbancies[7] were measured with a Beckman D.U. spectrophotometer for solutions of HOCl, OCl^- and Cl_2 in pure water and for solutions of Cl_2 in HCl–$HClO_4$ solutions of constant ionic strength (μ = 1.000) and varying HCl concentration. In order to prevent loss of Cl_2 during absorption measurements and analysis, two techniques giving identical results were used. In one case, a hypodermic syringe was connected, through a stopcock and ground joints, to a standard, Beckman, 1 cm. path quartz absorption cell; in the other case, a cell was designed to trap (below a ground joint) an exactly known volume of solution in the absorption cell and, subsequent to absorption measurements, to release the solution under the surface of a KI solution. In both cases liberated I_2 was titrated with carefully standardized thiosulfate solution. In this way highly reproducible (0.5% average deviation) values were obtained for A/bc[7] (c = total chlorine concentration in moles per liter of solution at 25°). During absorption measurements, solutions were held at 25.0 ± 0.1° in a thermostated cell holder. Pure commercially available HCl (Baker Analyzed), $HClO_4$ (G. F. Smith, triple distilled) and Cl_2 (Ohio Chemical Co.) were used; all chlorine solutions were made up immediately before using, and never kept for more than 1 or 2 hours. No detectable decomposition of the chlorine solutions was found, however, over considerably longer periods of time in strong artificial light. Pure HOCl solutions were prepared[8] by adding the stoichiometrically correct amount of NaOH solution to an aqueous chlorine solution, vacuum distilling on to Ag_2SO_4, and redistilling. The spectrum of this solution agreed with that of the original half-neutralized solution. As an additional check, the spectrum of OCl^- (prepared by adding the correct amount of chlorine to pure, carbonate-free NaOH solution) was determined carefully and compared with the spectra of HOCl–OCl^- mixtures. The longer wave length, weaker band in the HOCl spectrum definitely belongs to HOCl

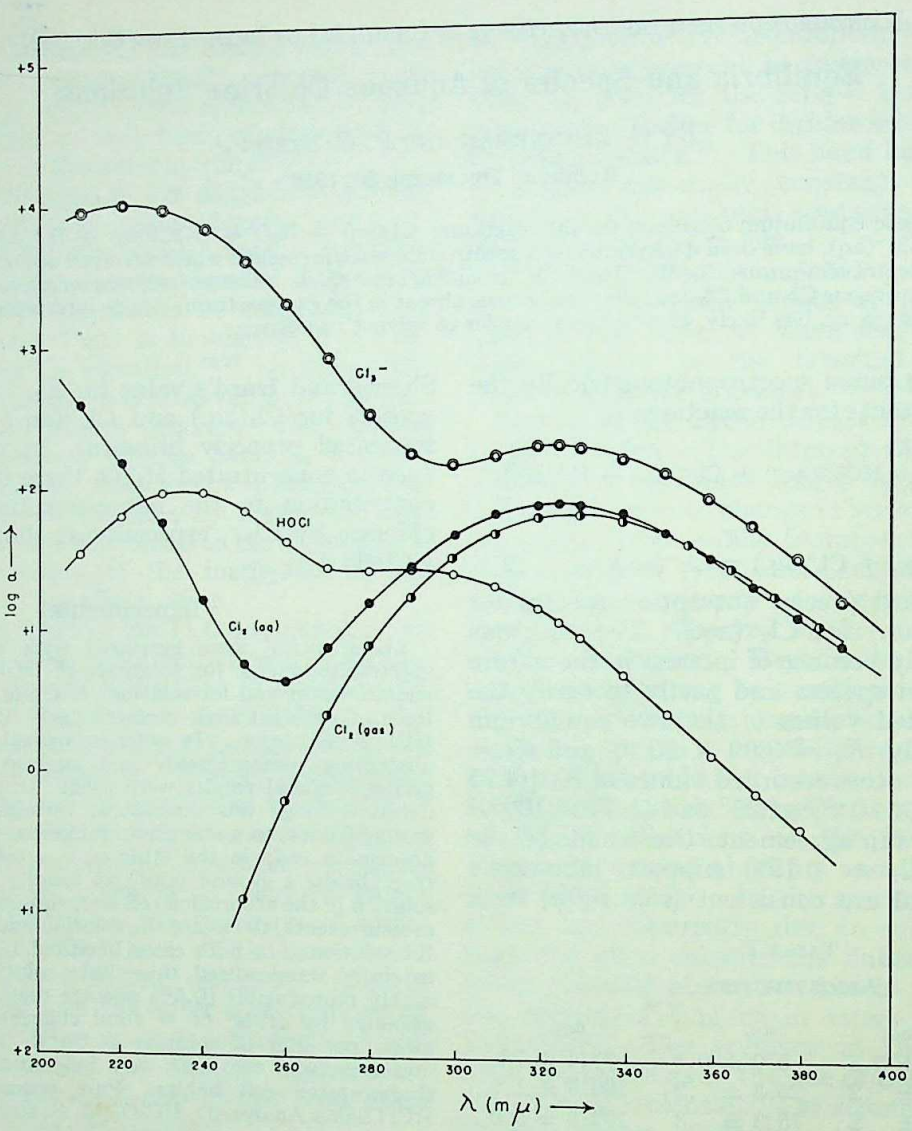

Fig. 1.—Absorption spectra.

and not to OCl^-, which happens to have a maximum absorption at the same wave length.

Results

The absorption spectrum of HOCl(aq.) shown in Fig. 1) (precise data for several wave lengths are given in Table I) is essentially the same as previously obtained[8,9,10] and was repeated mainly in order to obtain more precise values of the absorption coefficients. For solutions of chlorine in HCl–$HClO_4$ mixtures of ionic strength unity and with the initial concentration of HCl (U_0) larger than 0.02 molar, the concentration of HOCl becomes negligibly small and assuming Beer's law to hold for the two species, Cl_2(aq.) and Cl_3^-(aq.), it can be shown easily that (to better than 0.1%) the relation holds

$$A/bc = a_{Cl_2} + K_2(a_{Cl_3^-} - a_{Cl_2})\frac{U_0}{1 + K_2'(U_0 + c)}$$

where the a's are molar absorptivities[7] and $K_2' = (Cl_3^-)/(Cl_2)(Cl^-)$ for $\mu = 1.000$; parenthesis ( ) indicate molar concentrations. Figure 2 shows some typical plots of A/bc against $U_0/[1 + K_2' \cdot (U_0 + c)]$ for three wave lengths, and Table I gives the values and probable errors for a_{Cl_2} and $a_{Cl_3^-}$ obtained from least square calculations. All of the points for the corresponding spectra in Fig. 1 were obtained in the same way. For these calculations the value of 0.176 for K_2' from Sherrill and Izard's work[3] was used as representing the best value of K_2' for an ionic strength of 1.000.

Absorbances of solutions of Cl_2 in pure water are given in Fig. 3 and Table II. From the former there appears to be an isosbestic point at 2885 Å. ($A/bc = 27.02$) for $0.015 < c < 0.034$ mole/liter. It is not a true isosbestic point since all three species, HOCl, Cl_2 and Cl_3^- contribute significantly to the absorption (see Table I). However for the above limited range of c values and with no added electrolytes, A/bc for this "isosbestic" wave length is constant to within the limits of experimental accuracy and can be used conveniently to determine c from absorption measurements. In order to determine K_1 and K_2 from the data in Table II the three equations

$$A/bc = a_{HOCl}(HOCl) + a_{Cl_2}(Cl_2) + a_{Cl_3^-}(Cl_3^-) \text{ for the 2 wave lengths 2537 and 3250 Å.}$$

$$c = (HOCl) + (Cl_2) + (Cl_3^-)^{11}$$

were solved for the three concentrations, and the K's calculated using accurate values for the activ-

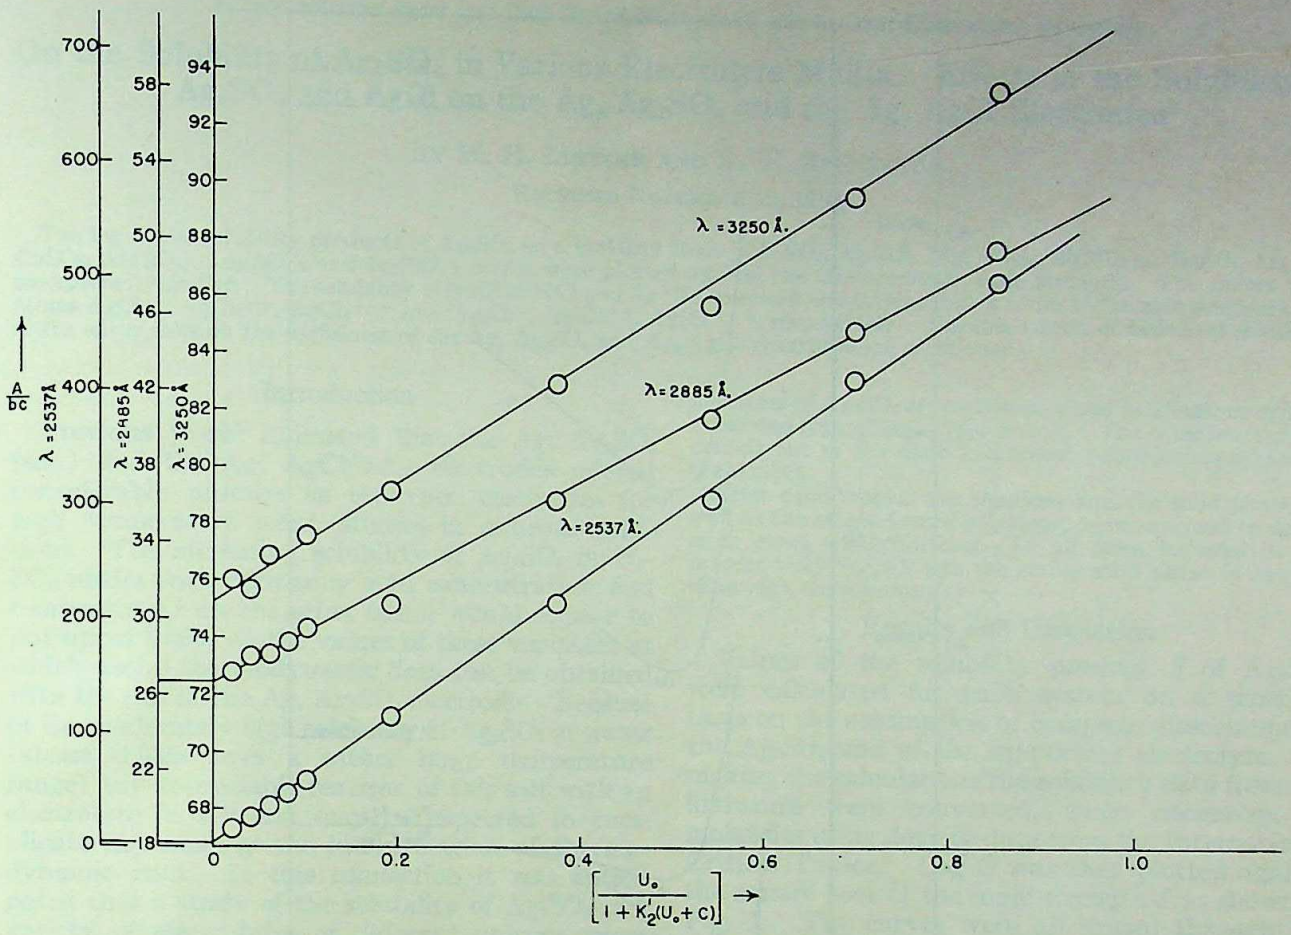

Fig. 2.—Absorption of chlorine in HCl–$HClO_4$ solutions.

ity coefficient of aqueous HCl[2] and making all other activity coefficients unity. The uncertainties (probable errors) in the individual K's in Table II are all essentially the same and result mainly from the uncertainties in the a's in Table I; the uncertainties in the a's also mainly determine the uncertainty in the average K's.

Aqueous Chlorine and Trichloride Ion Spectra.—In the Cl_2(aq.) absorption spectrum (see Fig. 1) the longer wave length band clearly corresponds to the similar known $^1\Pi_{Lu} \leftarrow {}^1\Sigma_g^+$ band for the gas[12,13]; the band which begins to appear at shorter wave lengths and which must involve fairly strong solvent-excited state interaction (since it differs greatly from the gas spectrum) probably represents either a transition to an "ionic" excited state of Cl_2[14–16] or to an excited state involving neighboring solvent molecules roughly similar to the case of aqueous halide and certain other ions.[17–19] This latter sort of excitation has been referred to frequently as "electron transfer" to solvent molecules. A semi-quantitative explanation can be based on the first assumption. Thus Fig. 4 shows the various possible levels for the separated nuclei and potential curves for (a) the ground ($^1\Sigma_g^+$) state, (b) the $^1\Pi_{1u}$

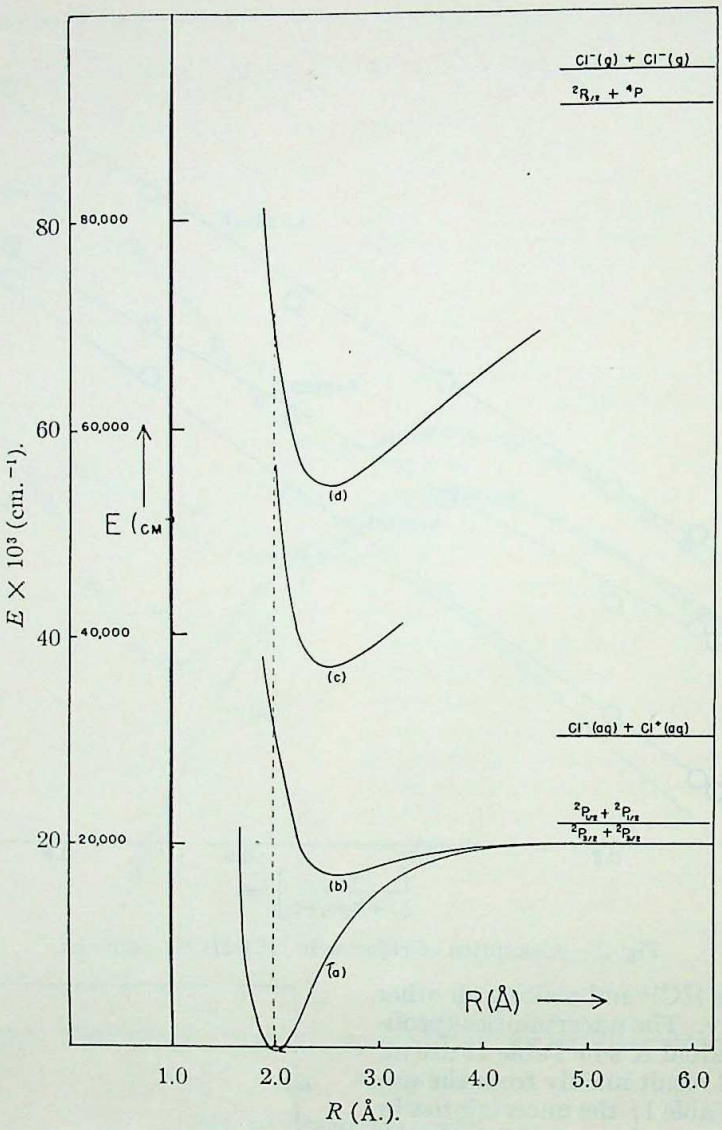

Fig. 4.—Potential energy curves for Cl_2.

state presumably giving rise to the longer wave length band,[12,13] (d) the state[20] formed from gaseous Cl^- and Cl^+ ions. The last curve was calculated assuming that Cl^+ behaves approximately as does Na^+ with respect to ion-pair formation and hydration energy. Curve (c) is obtained from a rough estimate of the hydration energy of the gaseous Cl^+Cl^- ion pair, assuming a dipole moment equal to that of NaCl(g) and a continuous dielectric medium; the dipole–solvent interaction would presumably also increase slightly the equilibrium internuclear separation. This estimate predicts an absorption maximum at 1700–1800 Å. and a long wave length limit of about 2700 Å. This admittedly very rough estimate is at least consistent with the observations, and it is hard to find any other excited state of the Cl_2 molecule which would both lie as low in energy and show a large solvent interaction. The interpretation suggests the possibility of dissociation into ions in solution by the absorption of the shorter wave lengths. In Cl_3^- the interaction of the Cl_2 and Cl^- is so weak (about 2 kcal.)[21] that one can think of the spectrum as that of Cl_2 perturbed by a close Cl^- neighbor. Thus absorption within the longer wave length band would lead to dissociation into $Cl_2 + Cl^-$ as suggested by existing photochemical evidence,[22,23] while in the lower band the upper state would be an ion triplet, $Cl^-Cl^+Cl^-$, the additional ion–dipole interaction shifting the maximum further toward the red. It would be interesting to see whether the photochemical behavior of Cl_2(aq.) for wave lengths less than about 2200 Å. would contribute to the present picture.

We wish to acknowledge the advice and suggestions of the late Professor J. L. Crenshaw under whose direction the work was begun.

BRYN MAWR, PA.

(20) From the lowest states of the ions $Cl^-(^1S)$, $Cl^+(^3P)$ one would expect a triplet state of the molecule and hence a low intensity of absorption. It is hard to draw definite conclusions from the present data concerning the intensity; more knowledge could prove to be a serious objection to the above suggested explanation.

On the Solubility of Ag_2SO_4 in Various Electrolyte Media. Effects of the Solubility of Ag_2SO_4 and AgCl on the Ag, Ag_2SO_4 and the Ag, AgCl Electrodes[1]

BY M. H. LIETZKE AND R. W. STOUGHTON

RECEIVED NOVEMBER 19, 1956

The log of the solubility products of Ag_2SO_4 on a molality basis in KNO_3, $AgNO_3$, $Mg(NO_3)_2$, $Al(NO_3)_3$, Na_2SO_4, $MgSO_4$, $CuSO_4$, $Al_2(SO_4)_3$, $La_2(SO_4)_3$ and $In_2(SO_4)_3$ media were plotted against the stoichiometric ionic strength. The curves were unexpectedly similar. The solubility of AgCl in HCl and $AgNO_3$ solutions was interpreted in terms of the mononuclear complexes $AgCl_2^-$, $AgCl_3^{--}$, $AgCl_4^{---}$ and Ag_2Cl^+, Ag_3Cl^{++}, Ag_4Cl^{+++}, respectively. Possible effects of increased solubility of the silver salts on the usefulness of the Ag, Ag_2SO_4 and Ag, AgCl electrodes are mentioned.

Introduction

Previous work[2] indicated that the Ag, Ag_2SO_4 (sat.) and the Ag, AgCl(sat.) electrodes offered considerable promise as reference electrodes for high temperature e.m.f. studies in aqueous solutions. The increasing solubility of Ag_2SO_4 in H_2SO_4 media with increasing acid concentration and temperature,[3] on the other hand, would appear to put upper limits on the values of these variables at which useful thermodynamic data can be obtained with the use of the Ag, Ag_2SO_4 electrode. Because of the moderately high solubility of Ag_2SO_4 in water (about $0.03m$ over a rather large temperature range) any appreciable reaction of this salt with an electrolyte in solution may be expected to complicate significantly the interpretation of thermodynamic data. In this connection it was anticipated that a study of the solubility of Ag_2SO_4 in a variety of electrolytes of different valence types even at room temperature might elucidate the general problem of such interpretations.

Data for the solubility of Ag_2SO_4 in $AgNO_3$, $Al(NO_3)_3$, $Al_2(SO_4)_3$ and $La_2(SO_4)_3$ solutions at 25° were obtained experimentally for this study, while data for the solubility of Ag_2SO_4 in $Mg(NO_3)_2$,[4] Na_2SO_4,[5] $MgSO_4$,[6] $CuSO_4$[6] and $In_2(SO_4)_3$[7] solutions were obtained from the literature. The determinations in $AgNO_3$ solutions were made because, as will be shown later, the literature values for this system[4] appeared to be inconsistent with the other data. Solubility data for AgCl in HCl, $AgNO_3$ and HNO_3 media were also obtained from the literature in order to compare the common ion effect on this salt with that on Ag_2SO_4.

Experimental

The Ag_2SO_4 used in the solubility measurements was prepared according to the method described by Archibald.[8] The $La_2(SO_4)_3$ was prepared from Fisher Scientific Company $La(NO_3)_3 \cdot 6H_2O$ by treating the nitrate with Baker analyzed concentrated H_2SO_4, fuming off the excess H_2SO_4, and igniting the $La_2(SO_4)_3$ in a muffle furnace at 500°. The $Al(NO_3)_3$, $Al_2(SO_4)_3$ and $AgNO_3$ were all Baker Analyzed Reagent grade chemicals. In each case a series of stock solutions was prepared covering the desired concentration range. Ten-ml. aliquots of the stock solutions along with an excess of Ag_2SO_4 crystals were sealed in 15-ml. centrifuge tubes and rotated at 25° for 5 days. The equilibration was carried out in the dark to prevent photodecomposition of the Ag_2SO_4.

After equilibration the solutions and the solid phase, as well as the original stock solutions, were analyzed to determine exact concentrations. In all cases included in the present work Ag_2SO_4 was the stable solid phase in equilibrium with the solution.

Results and Discussion

Values of the solubility product S of Ag_2SO_4 were calculated for each system on a molality basis on the assumption of complete dissociation of the Ag_2SO_4 and of the supporting electrolyte. In making the calculations the solubility data from the literature were converted, when necessary, to molalities using density data from the International Critical Tables.[9] Log S was then plotted against the square root of the ionic strength I as shown in Fig. 1. The curves were all drawn through the value of the log of the solubility product of Ag_2SO_4 in pure water[6] (represented by the lowest point). The data obtained in the course of the present study are also given in Table I.

TABLE I

SOLUBILITY OF Ag_2SO_4 IN $AgNO_3$, $Al(NO_3)_3$, $Al_2(SO_4)_3$ AND $La_2(SO_4)_3$ SOLUTIONS AT 25°

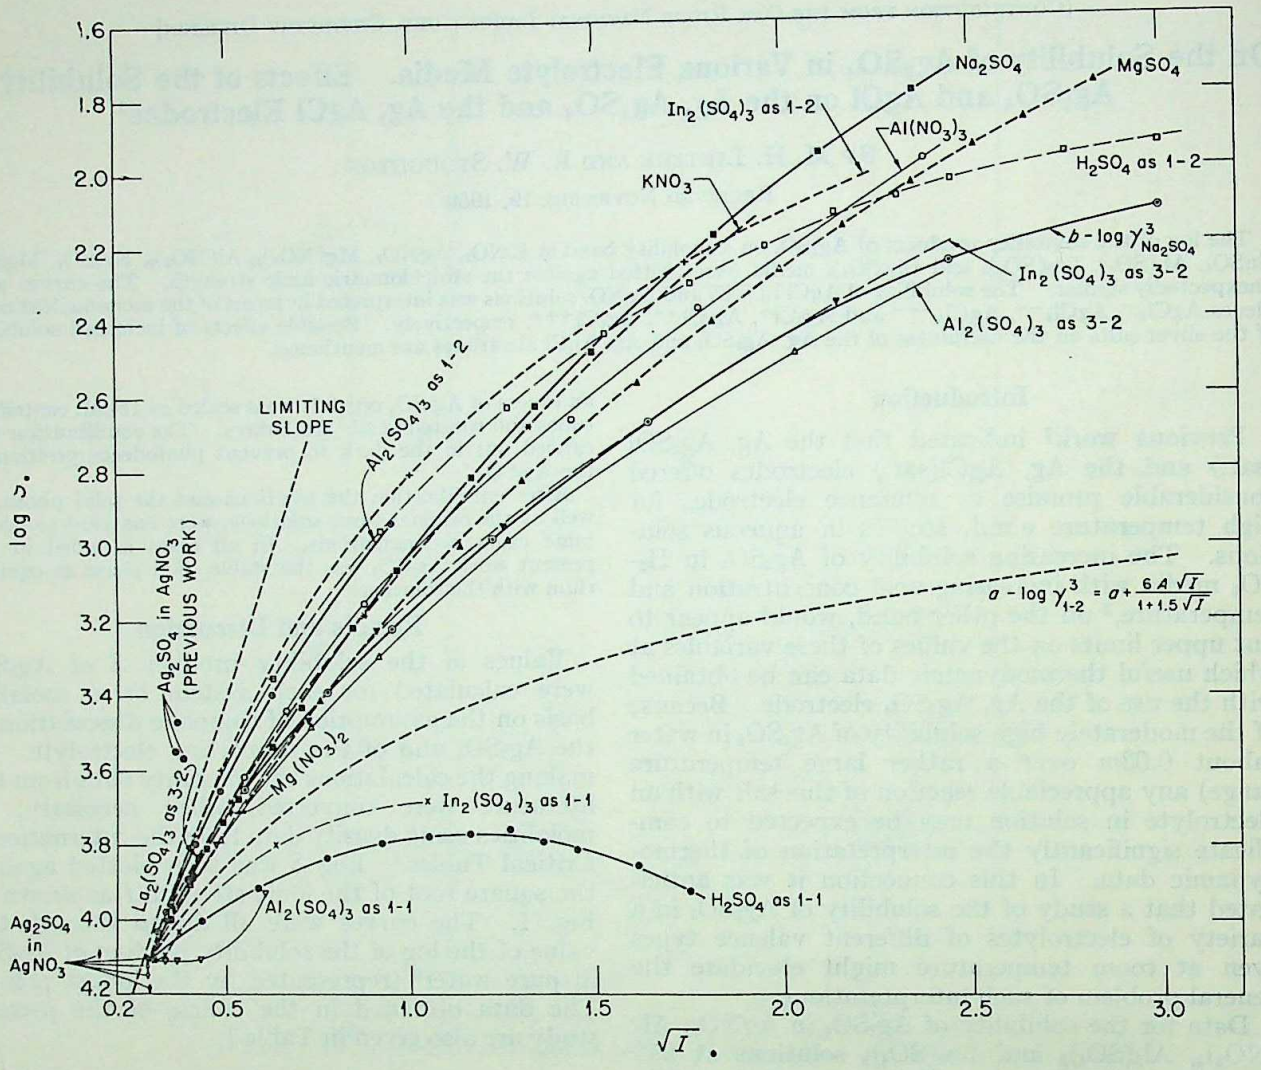

Fig. 1.—The apparent solubility product of Ag_2SO_4 in various electrolyte media.

As can be seen in Fig. 1 the solubility products on a molality basis vary in a surprisingly similar manner with the stoichiometric ionic strength whether or not the "supporting electrolyte" contains sulfate ions. The solubility data of Ag_2SO_4 in $AgNO_3$ solutions obtained in this study appear to be generally consistent with the other data, while the values obtained by Harkins[4] fall considerably above the limiting slope. It is interesting to note that the ionic strength in this case is essentially independent of $AgNO_3$ concentration.

For purposes of comparison, plots of log $\gamma_{\pm}^3$ for Na_2SO_4[10] and a generalized average activity coefficient function are also shown in Fig. 1. These two curves were shifted vertically to make them go through the point representing the solubility product of Ag_2SO_4 in pure water. The generalized average activity coefficient function (equation 2) was obtained by calculating log $\gamma_{\pm}^3$ for a 1–2 electrolyte from equation 1 which relates log γ of an ion to the ionic strength I, the charge of the ion Z_i, and the Debye–Hückel limiting slope A. The factor 1.5 in the denominator of equation 1 was suggested by Scatchard[11] as being more useful in many cases than the value unity used by Guggenheim.

$$\log \gamma_i = -\frac{AZ_i I^{1/2}}{1 + 1.5I^{1/2}} \qquad (1)$$

For a 1–2 electrolyte

$$\log \gamma_{\pm}^3 = -\frac{6AI^{1/2}}{1 + 1.5I^{1/2}} \qquad (2)$$

As can be seen the activity coefficient of Na_2SO_4 varies with its stoichiometric ionic strength in a manner very similar to that in which the activity coefficient of Ag_2SO_4 varies with the stoichiometric ionic strength in the various mixed electrolyte solutions. Two interesting conclusions can be drawn concerning all the curves based on the assumption of complete dissociation: (1) they all lie closer to the limiting law slope than do most activity coefficient curves, and (2) they are surprisingly close together compared to activity coefficient curves for strong electrolytes picked at random (after multiplication by the proper factors to correct for different valence types).

These two statements can be seen clearly to be true by noting the position of the hypothetical "average" 1–2 electrolyte curve, denoted as $a - \log\gamma^3_{1-2}$ in Fig. 1, or by an actual comparison with a plot of strong electrolyte activity coefficients.

Originally it had been hoped that some qualitative conclusions concerning the degree of dissocia-

tion of electrolytes such as the 3–2 sulfates might result from inspection of the curves in Fig. 1. For this reason the 3–2 sulfates were assumed to dissociate "completely" on three separate bases

$$\text{3–2} \quad M_2(SO_4)_3 = 2M^{+3} + 3SO_4^{--}$$
$$\text{1–2} \quad M_2(SO_4)_3 = 2MSO_4^{+} + SO_4^{--}$$
$$\text{1–1} \quad M_2(SO_4)_3 = MSO_4^{+} + M(SO_4)_2^{-}$$

Values of S and I were then determined on each of these three bases. As can be seen from Fig. 1, basis 3–2 gives the best agreement with the other curves. Basis 1–2 causes deviations from the other curves in a direction consistent with greater association or complexing of either the Ag^+ or SO_4^{--} (or both) up to an ionic strength of about 2.3 (*i.e.*, an $I^{1/2}$ of about 1.5). Basis 1–1 shows effects entirely unlike the 1–1 salt KNO_3. At least in the case of $In_2(SO_4)_3$ it is surprising that the three different bases do not cause more widely differing curves. Apparently the ionic strength effect and the common ion effect approximately cancel each other when a comparison of the three bases is made. It is not believed that the fact that basis 3–2 gives best agreement with the other curves should be interpreted as indicating that the principal species in solution are M^{+3} and SO_4^{--}. For example, in a previous paper,[7] evidence was presented to show that $In_2(SO_4)_3$ is by no means completely dissociated into In^{+3} and SO_4^{--} ions in the concentration range indicated.

In the case of the solubility of Ag_2SO_4 in H_2SO_4 media two bases of dissociation were considered

$$\text{1–2} \quad H_2SO_4 = 2H^+ + SO_4^{--}$$

and

$$\text{1–1} \quad H_2SO_4 = H^+ + HSO_4^-$$

It is known that the second equation more nearly represents the principal species in H_2SO_4 solutions in the concentration range of interest than does the first. According to Fig. 1 basis 1–2 indicates an activity coefficient for Ag_2SO_4 which varies with ionic strength almost exactly as it does in $Al_2(SO_4)_3$ and $In_2(SO_4)_3$ media on basis 1–2. Such a close similarity in these three different cases is surprising. When H_2SO_4 is treated as a strong 1–1 electrolyte the plot of the Ag_2SO_4 activity coefficient varies with ionic strength in a manner distinctly different from the other curves in Fig. 1 and similar to some of the 1–1 halide curves.

It would be interesting to calculate S and I for the Ag_2SO_4–H_2SO_4 system on an actual ionic basis using the data of T. F. Young[12] for the values of the concentration quotient K for HSO_4^- dissociation as a function of ionic strength calculated from the actual ionic concentrations in pure H_2SO_4 solutions. However, both the calculation and its interpretation would be complicated since the ionic strength on this basis must be calculated by a reiterative process; the equilibrium quotients vary, in general, with species in solution as well as with ionic strength (especially at higher values of the latter); and, as shown in Fig. 1, log S appears to be to a good approximation a function of the stoichiometric ionic strength alone. The calculation may be even further complicated by the existence of Ag^+-SO_4^{--} complex ions.

A calculation similar to the one just discussed was carried out in an attempt to calculate Ag_2SO_4 solubilities in H_2SO_4 media more accurately than was done previously.[3] The previous calculation involved the assumptions that (1) only the species Ag^+, H^+, HSO_4^- and SO_4^{--} existed in solution, (2) that S and K varied with ionic strength (calculated from actual ionic concentrations) in a manner predictable by equation 1, and (3) that only A in equation 1 varied with temperature or dielectric constant. In the current calculation assumption (2) was altered in that log S was assumed to vary with I (in this calculation I being determined by the actual ionic concentrations) in a manner represented by the average of the curves in Fig. 1 where the supporting electrolytes were assumed to dissociate completely into their simple ions, *i.e.*, basis 1–2 for H_2SO_4, basis 3–2 for $Al_2(SO_4)_3$, etc. The log S curve at any other temperature was assumed to be given in terms of that at 25° by equation 3

$$\log S(t,I) = \frac{A(t)}{A(25°)} \log S(25°, I) \qquad (3)$$

The variation of K with I (on an ionic concentration basis) at 25° was obtained from the data of Young[12] and the relation given by equation 3 was also assumed to hold for log K, *i.e.*

$$\log K(t,I) = \frac{A(t)}{A(25°)} \log K(25°,I) \qquad (4)$$

These calculations were carried out for 25 and 150° and for 0.1, 0.5 and 1.0m H_2SO_4 based on the solubilities in pure water. Contrary to expectation the agreement with the experimental values was not noticeably better than in the previous calculations. Nor was better agreement obtained when similar calculations were made in which I was calculated from the stoichiometric concentrations of the ions.

In contrast to the Ag_2SO_4 system where possible complexing of Ag^+ or SO_4^{--} with ions of the supporting electrolyte cannot be deduced definitively from the solubility data, the solubility of AgCl in electrolyte solutions containing a common ion shows a dramatic behavior. From the data of Forbes[13]; Pinkus and Timmermans[14]; Pinkus, Frederic and Shepmans[15]; and Pinkus and Shepmans[16] for the solubility of AgCl in HCl, $AgNO_3$ and HNO_3, respectively, the solubility products were calculated on a molality basis and on the basis of complete dissociation into simple ions. A plot of log S was then made against the square root of the stoichiometric ionic strength as shown in Fig. 2. In the case of HNO_3 media log S approaches the Debye–Hückel limiting slope at low ionic strengths and deviates at higher ionic strengths in a manner expected from the behavior of strong 1-1 electrolyte activity coefficients. In the cases of HCl and $AgNO_3$ media the deviations from the limiting law slope clearly show strong complexing. Further the two curves are, surprisingly enough, almost coincident which strongly implies complexing

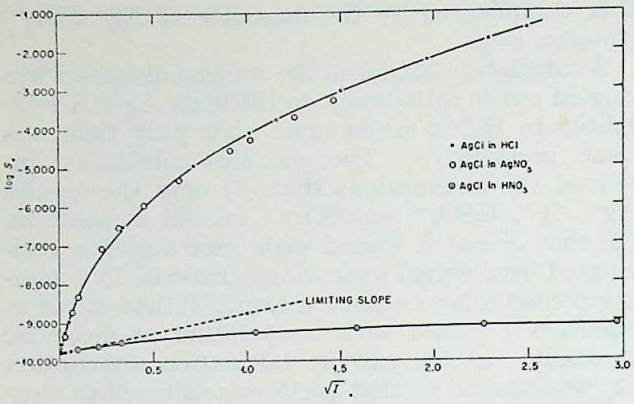

Fig. 2.—The apparent solubility product of AgCl in HCl, HNO_3 and $AgNO_3$ media.

(with excess Ag^+ or Cl^-) that is both symmetrical and that takes place to the same degree in both cases.

Some idea of the extent of complexing may be obtained in the AgCl–HCl system by making the assumption that only mononuclear complexes exist and then plotting the data in the form of log S *vs.* log m_{HCl}. On the basis of this assumption the observed S in terms of the molal solubility s and the species assumed to exist is given by

$$S = (m + s)s \qquad (5)$$

when $m \gg s$

$$S = ms = m([Ag^+] + [AgCl]_{(aq)} + [AgCl_2^-] + [AgCl_3^-] + \ldots) \qquad (6)$$

Letting S_i (where $i = 1, 2, \ldots n$) represent the molality solubility quotients for the assumed ionic equilibria

$$\underline{AgCl} = Ag^+ + Cl^- \quad S_0$$
$$\underline{AgCl} = AgCl_{(aq)} \quad S_1$$
$$\underline{AgCl} + Cl^- = AgCl_2^- \quad S_2$$
$$\ldots\ldots\ldots\ldots\ldots\ldots \quad \ldots$$
$$\underline{AgCl} + (n-1)Cl^- = AgCl_n^{-n+1} \quad S_n$$

equation 6 becomes

$$S = S_0 + mS_1 + m^2S_2 + \ldots m^nS_n \qquad (7)$$

If a single silver species predominates in any HCl concentration range then the slope of a log S *vs.* log m curve in that region gives the number of chlorides in the predominant species, and an extrapolation of that slope to $m = 1$ gives the appropriate log S_i. For an accurate treatment of the data corrections would have to be made for activity coefficient changes throughout the region under consideration. However, for a qualitative interpretation it may be assumed that activity coefficient changes are of the order of magnitude of the changes in the AgCl–HNO_3 curve with ionic strength and hence may be neglected.

In general, more than one species may exist to an appreciable extent in any region and hence the slope will give an average of i. The simplest interpretation where the slope lies between i and $i + 1$ is to assume that $AgCl_i^{-i+1}$ and $AgCl_{i+1}^{-i}$ are the principal species. If such an interpretation is made it appears that $AgCl_2^-$, $AgCl_3^{--}$ and $AgCl_4^{---}$ become significant species above about 0.002, 0.1 and 1 m HCl, respectively. Since there is no extended region where the slope is equal to a single integral value of i it appears that more than one species is important throughout the whole range studied except perhaps at the lowest ionic strength values. Consistent with the interpretation given here is that of Barney, Argersinger and Reynolds[17] who interpreted their solubility data to give a $Ag^+/AgCl_2^-$ ratio of about unity at 0.0015 m KCl.

The similarity between the AgCl–HCl and AgCl–$AgNO_3$ curves suggests the existence of species like Ag_2Cl^+, Ag_3Cl^{+2} and Ag_4Cl^{+3} in the presence of excess Ag^+ at approximately the same ionic strength values where $AgCl_2^-$, $AgCl_3^{--}$ and $AgCl_4^{---}$ appear to exist in the presence of excess Cl^-. Actually, in either or both systems polynuclear complexes may exist. Additional information is needed to settle the question definitively.

Berne and Leden[18] interpreted the solubility data for AgCl in chloride media and in $AgNO_3$ media in a manner consistent with that given above. Moreover, MacDougall[19] has shown impressive solubility evidence for the existence of the positive silver acetate complex $Ag_2(C_2H_3O_2)^+$ in solutions containing excess silver ion.

While the effect of the complexing described above on the solubility of AgCl at room temperature is not sufficiently great to alter appreciably an HCl or a $AgNO_3$ medium, the situation may be much more unfavorable to interpretation of Ag, AgCl (sat.) electrode results at elevated temperatures. It is known, for example, that the solubility of AgCl in pure water increases about tenfold in raising the temperature from 25 to 100°. If then the complex formation constants were temperature independent the solubility in HCl or $AgNO_3$ media would be about 10 times higher at 100° than it is at 25°. Actually the complex formation tendency may increase with temperature, and the solubility probably continues to increase with temperature above 100°. Thus it will be necessary to investigate the solubility of AgCl in water and in media containing a common ion at elevated temperatures before interpretation of e.m.f. data under such conditions can be taken seriously.

Conclusions

The molality solubility product of Ag_2SO_4 appears to a good approximation to be a function of the stoichiometric ionic strength alone. The fact that this is true to an ionic strength of over unity in widely different media and in the presence or absence of a common ion is difficult to explain. Nothing can be concluded definitively concerning the existence of complex ions from the solubility data alone, although at least in the case of $In_2(SO_4)_3$ considerable complexing was previously shown to obtain. Reasonable and surprisingly similar curves are obtained whether $In_2(SO_4)_3$ is assumed to dissociate "completely" as a 3-2, a 1-2, or a 1-1 electrolyte. Apparently, in this case, the common ion effect and the ionic strength effect

cancel each other to a first approximation. In contrast, the solubility of AgCl in the presence of either common ion clearly shows complexing. Interestingly enough the complexing of Ag^+ by Cl^- and of Cl^- by Ag^+ appear to be remarkably similar. The large extent of this complexing at room temperature combined with the known increasing solubility of AgCl in water with temperature suggest the necessity of obtaining AgCl solubilities in media containing a common ion before making definitive interpretations concerning thermodynamic data involving the Ag, AgCl (sat.) electrode in such media.

Some Phase Relationships in the Three-component Liquid System CO_2–H_2O–C_2H_5OH at High Pressures

BY LOUIS C. W. BAKER[1] AND THOMAS F. ANDERSON

RECEIVED JUNE 15, 1956

Phase diagrams for the liquid system CO_2–H_2O–C_2H_5OH are reported covering the temperature range 10 to 50° at pressures from 3000 lb./in.² down to the vapor pressures of the respective mixtures. Liquid–vapor critical data are included. In most respects the diagrams are typical of systems wherein one component (C_2H_5OH) is completely miscible with each of the other two components while the latter are only sparingly soluble in one another. However, for ternary mixtures containing a given C_2H_5OH:H_2O molar ratio, isobaric temperature rise causes first an increase and later a decrease in the extent of the region wherein only one liquid phase exists. The temperature of maximum extent of the region of one liquid phase increases with increasing pressure and decreases with increasing C_2H_5OH:H_2O molar ratio. These effects are attributable to temperature-dependent variation in the extent of molecular association.

The properties of liquid carbon dioxide solutions have received relatively little study[2] although the liquid has potentialities for considerable interest as a solvent. The linear CO_2 molecule has no over-all dipole moment and the liquid has a very low dielectric constant.[3] However, the ends of the molecule are undoubtedly considerably more negative than its center, offering opportunities for hydrogen bonding and other forms of molecular association. It is challenging to consider the following facts, for example: (1) water is practically insoluble in liquid CO_2, although the solid $CO_2 \cdot 8H_2O$ is stable, at elevated pressures, at temperatures up to 8° and perhaps higher[4–6]; (2) this paper shows ethyl alcohol to be miscible with liquid CO_2, marked diminution in total molal volume taking place upon mixing[4,7]; (3) measurements with the propyl and butyl alcohols indicate rapidly decreasing solubility with increasing carbon chain length[7]; but (4) glycerol is practically insoluble in liquid CO_2.[8] Several examples of minimum critical solution temperatures have been reported for liquid CO_2 solutions of organic substances.[7]

This paper reports phase diagrams, determined with moderate accuracy, for the liquid system CO_2–H_2O–C_2H_5OH, at temperatures from 10 to 50° and at pressures from 3000 lb./in.² down to the vapor pressures of the mixtures. Liquid–vapor critical data, within that range of conditions, are included. The results are potentially useful in the "critical point drying method" for electron microscope specimens.[9] The experimental approach has novel features.

Pure water and pure liquid CO_2 exhibit very limited mutual solubility. However, the latter was found to be completely miscible with absolute ethyl alcohol, as anticipated on the basis of frag-

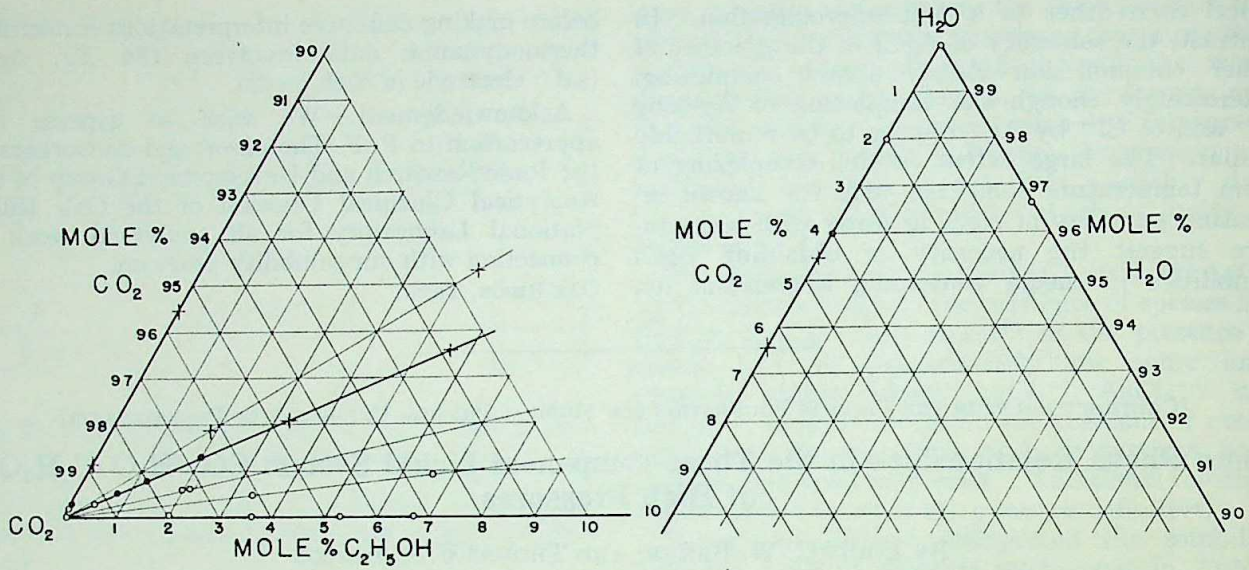

Fig. 2.—Details of corners of Fig. 1: ×, points in area A; ●, points in area B; ○, points in area C. Critical conditions were determined for most of the latter in the CO_2-rich corner.

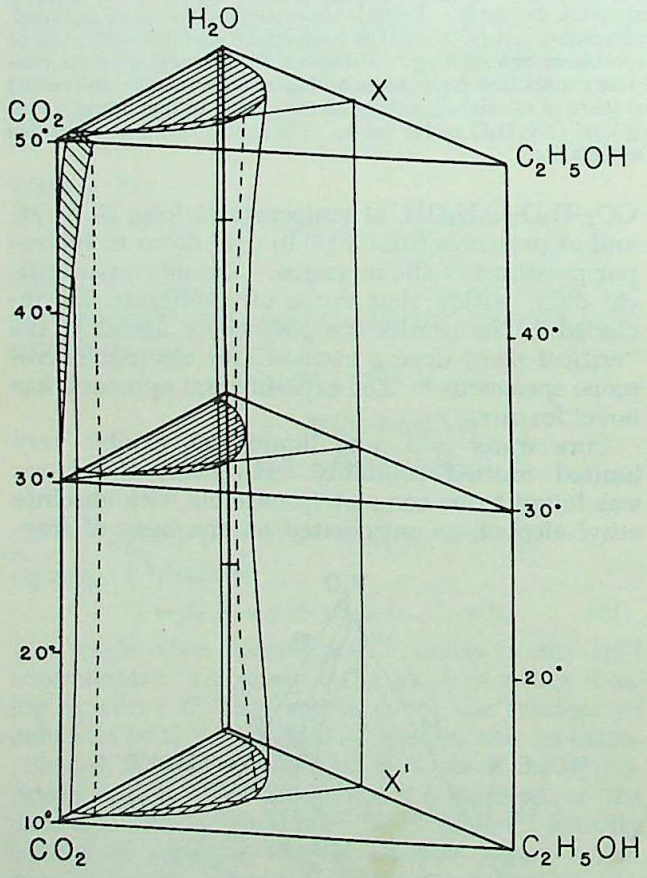

Fig. 3.—General form of diagram, see text below. The plane $XX'CO_2(10°)CO_2(50°)$ intersects the isobaric surface of the region of two liquids at the dotted lines. A portion of the heterobaric liquid–vapor critical envelope is shown in the CO_2 corner.

mentary older results.[7] Within the range of conditions cited, a 95 weight % solution of ethyl alcohol in water is also completely miscible with liquid CO_2.

The general findings are summarized by Figs. 1 and 2.

Figure 3 represents the general form of the phase diagrams of which Fig. 1 is a projection. The lower end of the liquid–vapor critical envelope is seen in the CO_2 corner. That envelope, of course, is not isobaric. It is composed of the "second critical points" of the mixtures[10] (*i.e.*, the points at which the distinction between the gaseous phase and the liquid phase vanishes). The vertical columnar volume represents the region of two liquids. One of the isobaric surfaces of that region is represented. A slight indentation in that surface, locating temperatures of maximum extent of the region of one liquid phase, runs as a broad shallow valley in a counterclockwise helical path up that surface. The valley's depth appears to be negligible near its ends. As the pressure is raised the region of two liquids is slightly decreased in size and the location of the helical valley is displaced upward, sometimes to temperature ranges higher than those illustrated.

Experimental

An extremely sturdy glass-and-steel liquid level gage,[11] manufactured for service on very high-pressure steam boilers, was adapted for use as a glass-walled bomb. The interior volume (about 35 cc.) was all visible between the two 1.0 inch-thick pre-strained Pyrex glass plates which formed opposite sides of the bomb. Each plate covered a 1.3 cm.-wide side of the interior chamber. The bomb, containing a large ball bearing, was mounted on a motor-driven rocking mechanism which was submerged in a well-stirred water-bath. As the bomb rocked slowly, the steel ball rolled from one end of the interior chamber to the other, providing efficient stirring. A powerful light was shone, by means of a submerged mirror, through the glass walls of the bomb chamber and toward the observer. The contents of the bomb could be watched through a window in the side of the water-bath. One end of the bomb was fitted with an aneroid high pressure gage, of negligible volume, which was calibrated in place and periodically checked against an hydraulic dead-weight balance. The other end of the bomb was fitted with a fine-bore high pressure valve of negligible volume.

Solutions were prepared, in relatively large amounts, from known weights of absolute ethyl alcohol and recently boiled distilled water.

A typical run was made as follows. The water-bath was emptied and the dried bomb-chamber was swept out with

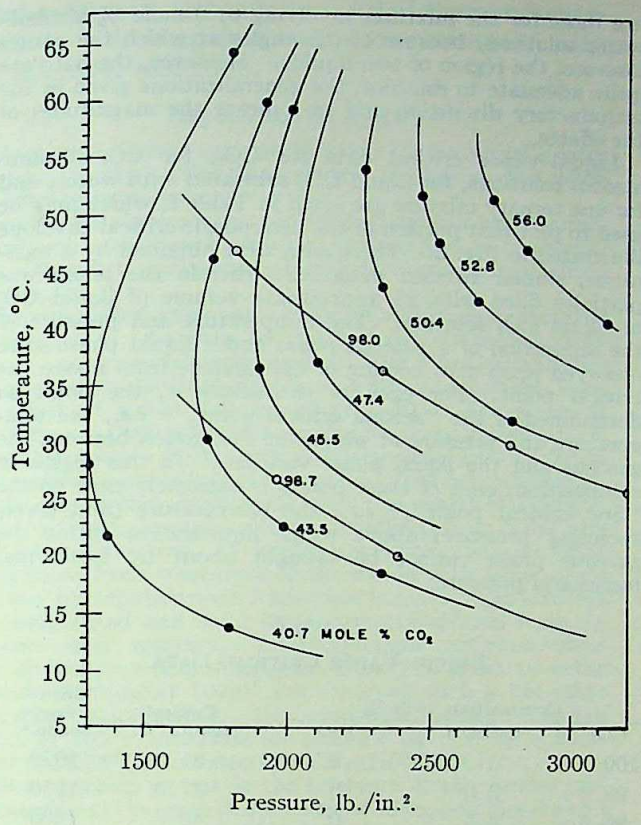

Fig. 4.—Temperatures and pressures of phase separations for various mixtures *made with* 61.0 mole % solution of alcohol in water. These mixtures all lie on line CO_2-X, Fig. 1. The mole % CO_2 is indicated for each. The two types of curves shown lie on opposite sides of the intersection of the line CO_2-X with area A, Fig. 1. (For mixtures containing about 50 mole % CO_2, the CO_2-rich liquid phase is the more dense of the two liquid phases below 10°; and it is the less dense liquid phase above that temperature.)

CO_2. Then a known weight of a given alcohol–water solution was injected with a calibrated syringe, the nozzle of which was temporarily inserted through the open valve into the bomb chamber. A high pressure stainless steel tube, running from an inverted cylinder of C.P. liquid CO_2, was swept out and connected to the valve on the bomb. The water-bath was then filled with ice-water. Liquid CO_2 (under its room temperature vapor pressure) was thereupon run into the bomb chamber, filling it at 0°. This procedure ensured that only liquid phases would be present after the temperature was raised as described below. The valve on the bomb was closed and the mixture was rocked to stir it at 0°. The pressure fell during this stirring, it being obvious that a marked decrease in total molal volume accompanied the dissolution.[4] More CO_2 was then admitted and the contents were stirred as before. The line to the CO_2 tank was then disconnected and, in its place, a rubber tube was fitted to the valve on the bomb. This tube led to a precision "wet test meter"[12] containing several liters of water through which CO_2 had just been bubbled for 20 minutes. While the bomb rocked, the temperature of the bath was rapidly raised until only one liquid phase was present, provided the temperature required was not over 60°. The temperature was then lowered fairly rapidly to determine roughly the temperature of separation of two liquid phases. The point of separation of the two phases was then determined accurately by covering again the appropriate portion of the temperature range very slowly. Reproducibility was consistently within 0.1°. The thermometer used was calibrated against one recently checked by the U. S. Bureau of Standards. The temperature and pressure at which the two phases separated were noted. The bath was then raised to 60°, and the valve on the bomb was cracked, allowing a little of the homogeneous mixture within the bomb to blow off very slowly through the wet test meter. The valve was closed again, and the temperature and pressure of separation of two liquid phases were again determined for that portion of the mixture remaining in the bomb. This partial blowing off procedure was repeated several times; and for each ternary mixture within area B, Fig. 1, several points were thus obtained. Observations were discontinued when the pressure was so low that a vapor phase appeared. The remaining CO_2 in the bomb was then blown off slowly through the wet test meter. The total reading on that instrument then showed the amount of CO_2 which had been in the bomb originally, measured as volume of water-saturated gas at the current atmospheric pressure and at the temperature of the water within the meter. Thus the over-all mole fraction could be calculated. Most of the alcohol and water generally remained in the bomb (not much being swept out during the final blow off); but the small amounts of these compounds which entered the wet test meter dissolved, when the gas was bubbled through it, in the large volume of water the meter contained. Excellent reproducibility was obtained on duplicate runs.

Construction of Diagrams

For a given run, the temperatures and pressures of liquid phase separations were plotted against one another and a smooth curve was drawn through the points (Fig. 4). Different runs involving varying proportions of CO_2 but the same C_2H_5OH:H_2O ratio (*e.g.*, 61.0 mole % alcohol) thus gave a family of curves (Fig. 4) from which temperatures of separation at a given pressure can be read. Alternatively one may ascertain pressures of separation at a given temperature.

The point X, Fig. 1, represents a specific (*i.e.*, 61.0 mole %) alcohol–water solution. All mixtures made by injecting varying quantities of that solution into the bomb, as described in the above procedure, have compositions falling on the line joining X and the CO_2 corner. In Fig. 3 these compositions coincide with the plane $XX'CO_2(10°)CO_2(50°)$. The dotted lines, Fig. 3, representing the intersections of this plane with an isobaric surface of the region of two liquids, may be plotted by reading temperatures from Fig. 4 at the pressure in question. Figure 5 represents the plane $XX'CO_2(10°)CO_2(50°)$, with such intersections plotted for three different pressures. The locations of temperatures of maximum extent of the region of one phase are obvious in Fig. 5.

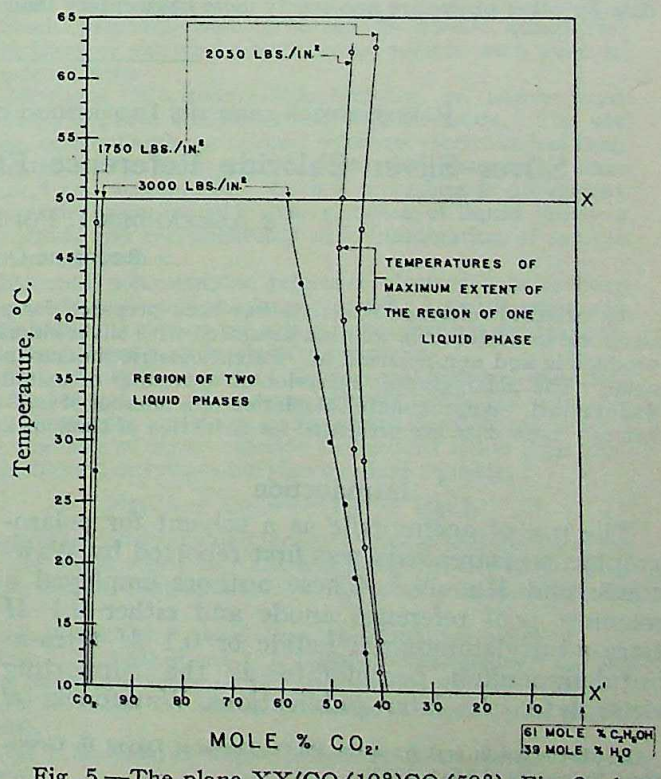

Fig. 5.—The plane $XX'CO_2(10°)CO_2(50°)$, Fig. 3, showing three of the isobaric intersections of the plane with the region of two liquids. Plotted with readings from Fig. 4.

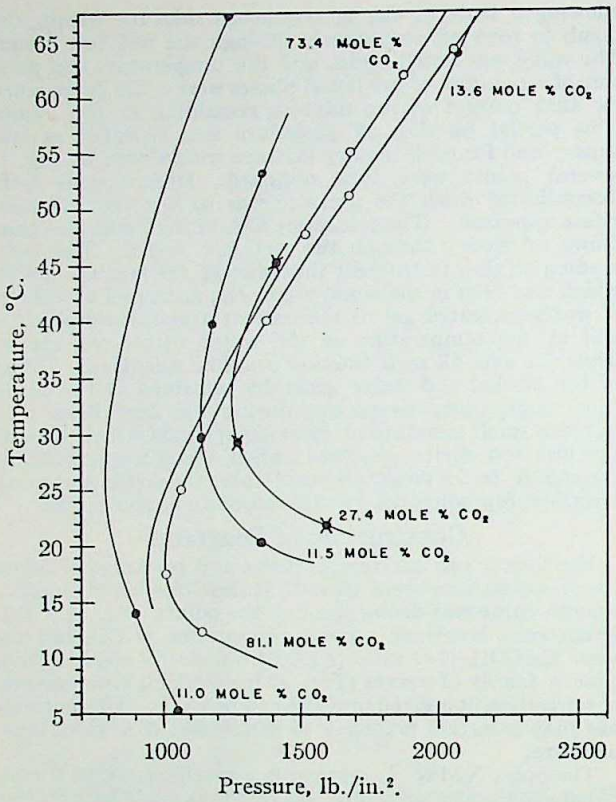

Fig. 6.—○, points on *PT* curves for mixtures *made with* 77.9 mole % alcohol–water solution; ●, points determined for mixtures *made with* 28.1 mole % alcohol–water solution; ✕, points determined for mixture *made with* 50.0 mole % alcohol–water solution.

The isobaric intersections of the region of two liquids with other planes, radiating from the CO_2 corner of Fig. 3, may be similarly plotted from the data obtained using other alcohol–water proportions (Fig. 6). An assemblage of such planes determines the surfaces of the region of two liquids. The data for other planes are necessarily more fragmentary than are those for the mixtures involving 61.0 mole % alcohol–water solutions, because of the angles at which the planes intersect the region of two liquids. However, the data are quite adequate to establish the generalizations given in the introductory discussion and to indicate the magnitudes of the effects.

Liquid–vapor critical data for CO_2, for CO_2–absolute alcohol solutions, for liquid CO_2 saturated with water, and for one ternary mixture are listed in Table I, which may be used to plot that portion of the heterobaric critical envelope illustrated in Fig. 3. These data were obtained by a technique, similar to that described, wherein the bomb was partially filled with an appropriate volume of liquid CO_2 or liquid CO_2 solution. The temperature and pressure of the separation of a gaseous phase and a liquid phase were observed upon slow cooling of the mixture from above the critical point. For each of the solutions, the point so determined is the "second critical point,"[10] *i.e.*, the temperature and pressure at which the distinction between the gaseous and the liquid phase vanishes. In this region of composition, each of these points is extremely close to the "first critical point",[10] *i.e.*, the temperature (and corresponding pressure) above which liquefication within the gaseous phase cannot be brought about by isothermal increase of pressure.

Silver–Silver Chloride Reference Electrode in Acetonitrile Polarography[1]

BY ALEXANDER I. POPOV AND DAVID H. GESKE[2]

RECEIVED OCTOBER 24, 1956

An external reference electrode has been prepared for polarographic studies in acetonitrile. A silver–silver chloride electrode in acetonitrile solution saturated with silver chloride and trimethylethylammonium chloride was found to be reproducible and non-polarizable. Potentiometric measurements were made to relate the reference electrode to Pleskov's scale. The polarographic behavior of a number of metallic perchlorates in 0.1 *M* tetra-*n*-butylammonium perchlorate was studied. Approximate calculation of a number of half-wave potentials was done and comparison made with observed values. New data are presented for reduction of thallous and stannous ions.

Introduction

The use of acetonitrile as a solvent for polarographic measurements was first reported by Wawzonek and Runner.[3] These authors employed a mercury pool reference anode and either 0.1 *M* tetra-*n*-butylammonium iodide or 0.1 *M* tetra-*n*-butylammonium perchlorate as the supporting electrolyte. In later publications Wawzonek, *et al.*,[4] reported polarographic measurements on some organic compounds in the same solvent. The study of hydrogen ion reduction in acetonitrile has been described recently by Vlcek.[5]

After the work reported in this paper was completed, a dissertation by Coetzee[6,7] reported a comprehensive polarographic study of a number of

metal cations in acetonitrile. All of these measurements were done against an aqueous saturated calomel reference electrode.

Experimental Part

Reagents.—Source and purification of acetonitrile were given previously.[8] The final solvent distillation was made in a nitrogen atmosphere.

Tetra-*n*-butylammonium iodide[9] and tetra-*n*-butylammonium perchlorate[10] were prepared as described in the literature. Reagent grade potassium iodide was recrystallized from water.

Trimethylethylammonium chloride was prepared in the following way. Aqueous sodium hydroxide is added dropwise to aqueous trimethylamine. The reaction mixture was warmed to distil trimethylamine into an alcoholic solution of ethyl iodide maintained at −50°. The alcoholic solution was then allowed to warm to room temperature. Since the reaction is exothermic it is necessary to moderate the reaction to avoid loss of reactants. The trimethylethylammonium iodide is filtered from the reaction mixture, rinsed with ethyl acetate and recrystallized from ethyl acetate–ethanol mixture. Trimethylethylammonium chloride is produced from treatment of the iodide with silver oxide followed by titration with hydrochloric acid. The solution was evaporated and solid material recrystallized from an acetone–water mixture. Trimethylethylammonium chloride undergoes a transformation from non-cubic to cubic crystal structure at 100.0° (as observed with a hot-stage polarizing microscope). Decomposition without fusion begins at 290°. Analysis for chloride gave 28.57% compared to 28.68% calculated for $(CH_3)_3N(C_2H_5)Cl$.

Silver chloride for use in the reference electrode was precipitated from acetonitrile solutions of silver perchlorate and tetra-*n*-butylammonium chloride and washed on the filter with acetonitrile.

Silver nitrate was purified from reagent grade material by recrystallization from water followed by fusion. Anhydrous potassium, sodium, barium, strontium and silver perchlorates (G. F. Smith and Co.) were dried *in vacuo* at 25°. Anhydrous lithium perchlorate was obtained by dehydration of lithium perchlorate trihydrate.

Anhydrous lead perchlorate was obtained by preparing the hydrated material from lead monoxide and 70% perchloric acid and then dehydrating in a vacuum oven at 180°.[11] No chloride was present after the dehydration. Analysis for lead by electrodeposition of lead dioxide gave 51.5% compared to 51.02% for $Pb(ClO_4)_2$.

Thallium perchlorate was prepared anhydrous by dissolving thallium metal in perchloric acid and drying the resulting crystals at 120°. Analysis for thallium by gravimetric chromate gave 66.5% compared to 67.27% for $TlClO_4$.

Anhydrous cadmium perchlorate was prepared by dissolving cadmium oxide in perchloric acid to obtain the hexahydrate, dehydrating to the dihydrate at 25° *in vacuo*, and finally to the anhydrous compound at 120° *in vacuo*.[12] Analysis for perchlorate by precipitation of potassium perchlorate in ethanol[12] gave 63.6% perchlorate compared to 63.89% for $Cd(ClO_4)_2$.

Calcium perchlorate was obtained anhydrous by dissolving calcium hydroxide in perchloric acid and dehydrating the resulting dihydrate by heating *in vacuo* at 180°.[12] Analysis for calcium by standard Versenate titration gave 16.5% calcium compared to 16.77% for $Ca(ClO_4)_2$.

Nickel, cobaltous, ferric, ferrous, cupric and chromic perchlorates (hexahydrate) and mercuric perchlorate trihydrate (all obtained from G. F. Smith and Co.) were dried over phosphorus pentoxide *in vacuo* at 25°. Compositions were checked by precipitation of potassium perchlorate in ethanol,[12] except in the case of the cupric salt where copper was determined electrometrically. The ferrous salt was found to be free of ferric by polarographic analysis. Zinc and manganese perchlorates (hexahydrate) were prepared by action of perchloric acid on the oxide. The zinc salt was analyzed by the gravimetric perchlorate method. The manganese salt was analyzed by gravimetric determination of manganese sulfate obtained by repeated fuming with sulfuric acid. Aluminum perchlorate hexahydrate (chloride free), was obtained by action of perchloric acid on aluminum dust and was analyzed by the gravimetric perchlorate method.

The compound stannous perchlorate diacetonitrile was prepared as described by Schmidt[13] but was found to detonate on handling. It was possible to prepare an acetonitrile solution of stannous perchlorate by electrolyzing an acetonitrile solution of silver perchlorate using a tin anode. Concentration was determined from the amount of silver replaced by tin.

The perchloric acid solution used for polarographic study was prepared by dilution of 70% stock followed by titration against standard base.

Tank nitrogen was purified by passage through concentrated sulfuric acid, barium oxide, hot copper turnings, another barium oxide column, and finally an acetonitrile presaturator.

Apparatus.—A Sargent Model XXI recording polarograph was used to obtain all data reported here. Calibration of current sensitivity was done as described by Kolthoff and Lingane.[14] Current measurements were made by using the average of the pen deflections with the instrument circuit undamped. Recorder lag was negligible with the circuit undamped. Potential settings for scanning were checked with a potentiometer. Polarograms were corrected for iR drop through the cell and instrument resistances.

The dropping mercury electrode had a drop time of t = 4.02 sec. and m = 1.75 mg. sec.$^{-1}$ at a pressure of 60.0 cm. Hg (uncor.) on open circuit in 0.1 M tetra-*n*-butylammonium perchlorate solution. Diffusion current constants were evaluated using m and t values obtained at the potential of the reduction wave.

Resistance measurements were made using a Wheatstone bridge powered by a 1000 cycle audio oscillator. Resistance of the cell circuit was taken at maximum mercury drop size.

Electromotive force measurements of circuits of high resistance were made using a Leeds and Northrup #7673 thermionic amplifier and a type K potentiometer.

Temperature of polarographic cell was maintained at 25.0 ± 0.1° by circulation of water from a constant temperature reservoir through a smaller auxiliary bath in which the cell was placed.

Stock solutions were prepared in 50-ml. quantities. Weighings of extremely hygroscopic solutes were done in stoppered vials.

Reference Electrode.—Polarography in non-aqueous solvents requires a suitable reference electrode. The use of an external aqueous calomel reference electrode has been reported with formamide,[15] acetamide–formamide mixtures,[16] and acetonitrile.[7] Such a procedure is convenient but nevertheless magnifies the question of liquid junction potentials and the possibility of contamination of sample system with water.

External polarographic reference electrodes have been prepared in acetone[17] and formic acid.[18] A search was made for a half-cell reaction suitable for use as an external polarographic reference electrode in acetonitrile.

An acetonitrile analog of the aqueous calomel electrode was investigated. Mercurous chloride, although insoluble in acetonitrile, undergoes a disproportionation reaction in the presence of excess chloride ion present either from lithium chloride or tetra-*n*-butylammonium chloride.

$$Hg_2Cl_2 + Cl^- \longrightarrow Hg^0 + HgCl_3^-$$

Particles of finely divided mercury appear and mercuric ion is detected in solution. The enhanced stability of the chloromercurate complex anion is apparently responsible for

this reaction in acetonitrile as well as in a number of other organic solvents. These observations agree with those reported by Ulich and Spiegel[19] and Cruse, Goertz and Petermoller.[20]

The mercury–mercurous sulfate electrode, with sulfate ion furnished by tetraethylammonium sulfate, was found to be entirely unsatisfactory.

A silver–silver nitrate electrode was unsatisfactory because of polarization when current flowed.

Janz and Taniguchi[21] comment that the tendency of silver chloride to form complexes in acetonitrile makes the silver–silver chloride electrode unsuitable as a reference electrode. A preliminary study in this Laboratory indicated that the solubility of silver chloride is indeed greatly increased in the presence of free chloride ion, thus indicating complex formation. This increased stability of silver polychloride anions in acetonitrile by comparison with water is in accord with observations by Kratohvil.[22] However it was found possible to achieve equilibrium conditions such that the potential of a silver–silver chloride electrode did not change.

A silver electrode was prepared by deposition of silver on a platinum cylinder with a surface area of 23.4 cm.^{2}. The silver deposition was done as described by Brown.[23]

The reference electrode consisted of the silver electrode placed in acetonitrile saturated with respect to silver chloride and trimethylethylammonium chloride. The solubility of silver chloride in acetonitrile is limited by the amount of free chloride ion present, which in turn is governed by the solubility of trimethylethylammonium chloride. It is this saturation condition that prevents the electrode potential from drifting as further complexation occurs. Equilibrium conditions for a 250-ml. quantity of reference electrolyte are achieved in approximately 80 hours at 25°.

Analysis of such solutions equilibrated at 25.0° was carried out by digesting an aliquot portion in aqueous nitric acid and filtering. This gave the amount of silver chloride present. Excess chloride was determined in the filtrate by the usual means. The composition of the reference electrolyte was found to be 0.015 *M* silver chloride and 0.118 *M* trimethylethylammonium chloride.

Performance of the electrode was tested by placing identical half-cells in the arms of an H cell with a fine sintered glass frit separating the arms. A linear current–voltage relationship was found from 0 to 2 volts and 0 to 100 μa. Polarization was less than 1 mv. on such a run, and less than 2 mv. when a current of 100 μa. was passed through the cell for 20 minutes. There was no variation of potential on shaking the cell. These results indicated that the electrode was suitable as a non-polarizable polarographic reference electrode.

Pleskov[11] has measured formal electrode potentials in acetonitrile using a silver–silver nitrate (0.01 *M*) half-cell as a primary zero reference. It seemed desirable to relate the saturated silver chloride electrode to this primary reference, thus allowing comparison of half-wave potentials with electrode potentials.

This measurement was made in an H cell whose arms were separated by a ground glass plug. Junction between the two half-cells formed around the plug. The high resistance of the cell necessitated the use of the amplified potentiometer circuit previously described.

Six measurements with different electrolyte preparations over a period of six months gave a value of 0.638 ± 0.001 v. for this cell at 25.0°.

$$-\text{Ag, AgCl (0.015 } M\text{), } Me_3NEt^+Cl^- \text{ (0.118 } M\text{)//AgNO}_3 \text{ (0.01 } M\text{), Ag} +$$

The temperature coefficient was 0.6 mv. deg.$^{-1}$. Half-wave potentials reported in this paper are all referred to the silver–silver nitrate scale by the above measurement.

Following completion of this investigation a publication by Hanselman and Streuli[24] reported use of a silver–silver chloride in saturated lithium chloride as a potentiometric reference electrode in acetonitrile. Pavlopoulos and Strehlow[25] found the solubility of lithium chloride in acetonitrile to be 0.14 g./100 ml. at 25°, corresponding to a 0.026 *M* solution. It appears reasonable that a silver chloride electrode saturated with lithium chloride could be adapted for use as a polarographic reference electrode. Such an electrode would undoubtedly have a higher resistance than the cell employing trimethylethylammonium chloride as electrolyte. On the other hand, lithium chloride is more readily available. Transference numbers for estimation of liquid junction potentials are not available for ionic species in the reference electrolyte. The following limiting ionic conductances were reported by Walden[26] and are of interest here: lithium, 59.3; chloride, 88.8; tetramethylammonium, 92.9; and tetraethylammonium, 86.1 (trimethylethylammonium limiting conductance assumed intermediate to tetraethyl- and tetramethylammonium ions). From these data it seems probable that the saturated solution of trimethylethylammonium chloride minimizes the liquid junction potential more effectively than a saturated solution of lithium chloride.

Cell Construction.—A satisfactory polarographic cell was obtained by modification of the design of Pecsok and Juvet.[27] Reference electrolyte and electrode are separated from a junction compartment by a sintered glass disk (fine porosity). The junction compartment is in turn separated from the test solution by another disk (coarse porosity).

Formation of the liquid–liquid junction in this manner proved quite successful. There was no contamination of the test solution by chloride ion from the reference electrolyte.

An external electrical contact into the test solution compartment was provided for the studies of the mercury pool reference electrode. Resistance of the cell using the external reference electrode was 1500 ohms.

A gravity-flow closed system was designed in which it was possible to distil solvent, prepare and dilute solutions and transfer into the polarographic cell under dry nitrogen. It was found unnecessary to use this apparatus since the solvent which had been distilled under nitrogen required only ten minutes of degassing to remove traces of oxygen. The minor effect of small amounts of water is described later.

Results

Polarographic data were obtained in acetonitrile using the reference electrode described above. These data are summarized in Table I, with half-wave potentials reported *versus* the silver–silver nitrate (0.01 *M*) electrode. Data presented represent the average of at least three determinations. Diffusion current was proportional to concentration in the range studied, 1 to 0.1 millimolar. All polarographic waves were examined by plotting log $i/(i_d - i)$ *vs.* the applied e.m.f. corrected for iR drop (except for ferrous ion reduction, where $\log(i_d - i)$ *vs.* ϵ was plotted). The slope of such lines gives $n\alpha/0.059$. Values of $n\alpha$ are listed in Table I for those waves which gave straight line plots. The effect of addition of 0.5% water on half-wave potential is also listed in Table I.

Previous workers[3] have obtained half-wave potentials of various cations in 0.1 *M* tetra-*n*-butylammonium iodide employing a mercury pool anode. It is of interest to correlate these data with those reported in this paper. Measurement of the half-wave potential of potassium ion (in iodide supporting electrolyte) *versus* both the mercury pool and silver–silver chloride reference electrodes showed a difference of 0.25 v. Combining this measurement with the potential of the cell, $Ag,AgCl,Me_3NEtCl(satd.)\ //\ AgNO_3$ (0.01 *M*), Ag, the half-wave potentials in 0.1 *M* iodide are referred to the silver nitrate electrode by addition of

[a] Metallic perchlorates in 0.1 M tetra-n-butylammonium perchlorate. [b] Metallic halides in 0.1 M tetra-n-butylammonium iodide. [c] Maxima. [d] Metallic perchlorate in 0.1 M tetraethylammonium perchlorate.

Half-wave potentials for a number of ions in 0.1 M tetra-n-butylammonium perchlorate measured with a mercury pool anode have been reported.[3] Comparison of these data with data in this publication did not show an exactly constant difference between the two sets of measurements. The possibility that the mercury pool anode was polarizable was verified by passing a current of 50 μa. for 2 minutes through the cell: Ag, AgCl reference / / 0.1 M Bu_4NClO_4, Hg. Polarization of 60 mv. occurred.

The potential of the mercury pool anode in iodide media is controlled by the activity of mercuric ion present largely as tetraiodomercurate, $HgI_4^=$. In the case of perchlorate media, the absence of mercury complexes may account for the polarizability of the pool electrode.

Polarographic measurements were made by Coetzee[7] using 0.1 M solutions of tetraethylammonium perchlorate and sodium perchlorate as supporting electrolyte. These measurements were related to Pleskov's electromotive force series[11] by measurement of the cell, saturated calomel-(aq.) / / $AgNO_3$(0.01 M)$_{CH_3CN}$ Ag; $E = 0.29$ volt.

Although both this measurement and the polarographic measurements involve an unknown liquid junction potential, if the junction potentials are assumed equal, the half-wave potentials obtained by Coetzee[7] are satisfactorily placed on the silver–silver nitrate (acetonitrile) scale. Thus comparison may be made between Coetzee's work (listed in Tables I and II) and the data in this paper.

Generally good agreement is found between the two sets of data, even though the supporting electrolytes were not the same.

Coetzee[7] reports a well-defined wave for the chromic–chromous reduction, while in this work the wave is ill-defined ($E_{1/2}$ approximate only) and the diffusion current plateau was not accurately measurable.

Difficulty was encountered in the study of nickel perchlorate. Two reducible species appeared to be present, since one wave occurred at -0.69 v. and another at -1.22 v. The total diffusion current was proportional to concentration but the height of the individual waves was not reproducible.

A systematic study has been made by Vlcek[5] of the effect of small amounts of water on the reduction of hydrogen ion. By using potassium as a pilot ion, hydrogen ion reductions were carried out in acetonitrile–water solutions of up to 6.2% water. The solution was saturated with tetramethylammonium iodide to provide supporting electrolyte. The reduction wave shifted to increasingly negative potentials with increasing water concentration. A plot of difference between half-wave potentials of potassium and hydrogen ions ($\Delta E_{1/2}$) *vs.* water concentration was extrapolated to zero water concentration. This value 1.55 v., represented the $\Delta E_{1/2}$ in anhydrous acetonitrile. In practice, in the solution of lowest water content, 0.05%, Vlcek found that the hydrogen ion reduction wave did not show a knee, but the current rose sharply from zero applied voltage (*vs.* mercury pool). At slightly higher water concentrations, 0.2%, the wave was normally formed.

The present work in 0.1 M perchlorate media shows a $\Delta E_{1/2}$ (as defined above) of 1.46 v. with the wave normally formed. Similarly, addition of 1% water shifted the half-wave potential 0.68 v. to more negative potentials. It has been suggested[3] that reduction waves observed for copper, cadmium and zinc perchlorates might actually be due to hydrogen ion reduction. Table I includes data for the shift of these reduction waves upon addition of 0.5% water. It is seen that these shifts are extremely small compared to the shift observed with addition of water to perchloric acid solution. This seems to offer conclusive proof

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

that the reduction waves observed for the metallic cations are due to that cation and not a hydrogen ion reduction.

Stannous perchlorate shows only a single reduction wave and no oxidation to stannic ion in the potential range studied (limited by anodic dissolution of mercury).

A curious current phenomenon was encountered in the case of mercuric, cupric (first step) and ferric (first step) ion reductions. Polarograms were scanned both from the most positive potential possible (limited by anodic dissolution of mercury) toward more negative potentials and *vice versa*. In the case of the ions mentioned, at the higher concentrations (approximately 1×10^{-3} *M*) the current rose sharply at the most positive potentials and then broke abruptly several hundred millivolts more negative to a limiting current plateau. The behavior of copper as shown in Fig. 1 is typical. This behavior is

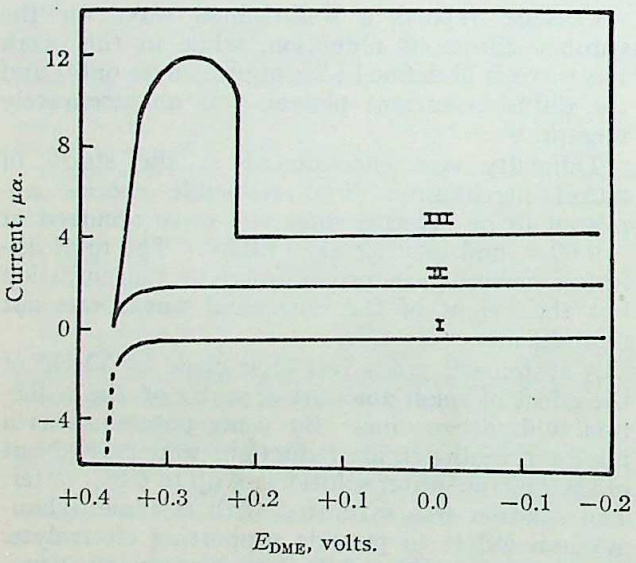

Fig. 1.—Polarograms, current *vs.* applied voltage: I, residual current, 0.1 *M* tetra-*n*-butylammonium perchlorate; II, cupric perchlorate, 0.55×10^{-3} *M*; III, cupric perchlorate, 1.10×10^{-3} *M*.

somewhat similar to that described by Bachman and Astle,[28] who suggest that the discontinuity is due to adsorption processes. A more likely explanation is that there is interaction of the oxidants with the mercury drop causing a "mercury" maxima. Adsorption reactions would not account for the current in excess of the diffusion current. No studies were made in the present work to differentiate between diffusion and kinetic control of the limiting currents. At concentrations of less than approximately 5×10^{-4} *M* the discontinuous current rise was absent and the wave appeared to be normal. However, subtraction of residual current obtained from polarogram of the supporting electrolyte showed that the apparent wave was caused by the beginning of the mercury dissolution. From this it is concluded that actual half-wave potentials of cupric and ferric ions occur at more positive potentials than +0.36 v.

Discussion

The half-wave potentials observed in acetonitrile are generally in the same order as in aqueous solution (non-complexing supporting electrolyte). Two important exceptions are copper and silver. While the reduction of silver in water occurs at such positive potentials that mercury oxidation occurs first, the reduction is observed easily in acetonitrile. An indication of the solvated nature of silver ion in acetonitrile is seen in the fact that dipyridinesilver(I) perchlorate shows the same half-wave potential as silver perchlorate (the coordinated pyridines are undoubtedly largely displaced by acetonitrile).

Stabilization of the cuprous state in acetonitrile, as indicated by the two-step reduction of cupric ion, is shown by other observations. Morgan[29] isolated cuprous nitrate tetra-acetonitrile, $CuNO_3 \cdot 4CH_3CN$, from reaction between an acetonitrile solution of silver nitrate and metallic copper.

It is of interest to compare observed half-wave potentials with calculated values. Where measurements are made with solid metal electrodes, the half-wave potential is given by the expression[14]

$$E_{1/2} \backsimeq E^0_M + E_S + \frac{0.059}{n} \log C_{satd} f_{satd}$$

The normal electrode potential is given by E^0_M, E_S is the potential of the cell, $M(s)/M^{n+}/M\text{-}(Hg)_{satd}$, and C_{satd} and f_{satd} are the concentration and activity coefficient, respectively, of the metal in the saturated amalgam. Since these last three terms are independent of solvent, calculation of half-wave potentials only requires evaluation of E^0_M.

Values of E^0_M were obtained by assuming the Nernst equation to hold, and then calculating E^0_M from e.m.f. data for the lowest concentration of solute as given in the publication by Pleskov.[11] This estimate of E^0_M should be reasonably accurate since the activity coefficient approaches unity at zero concentration.

Using Pleskov's[11] data for 5×10^{-4} *N* CdI_2 with $E = -0.7327$ v. (*vs.* $AgNO_3$ reference), E^0 is −0.626 v. For cadmium $E_S = 0.051$ v.,[30] $C_{satd} = 6.40$ moles/l.,[31] $f_{satd} = 1.15$[32] giving a calculated half-wave potential of −0.550 v. which compares favorably to the observed −0.553 v. Similar calculations can be made for zinc and lead but are not presented here since the polarographic waves are irreversible.

Calculation of half-wave potentials of some metal ions in acetonitrile from Pleskov's amalgam electrodes has been done.[7] Employing the expression developed by von Stackelberg[33] and using Pleskov's[11] potentiometric data, the half-wave potential of cesium is found to be −2.20 v., which compares well with the recalculated value, −2.23 v., given in Table II as obtained by Wawzonek and Runner.[3]

Vlcek[34] has suggested that the half-wave potential of potassium is the same in all solvents. Un-

der this assumption, comparison of reduction of cations in differing solvents can be made by noting the difference, $\Delta E_{1/2}$, between the potassium half-wave potential and the half-wave potential of the particular metal. This is at least a reasonable approach to absolute comparison of half-wave potentials. Tabulation of these data for acetonitrile and aqueous solutions (non-complexing supporting electrolyte) shows several interesting points. Of the ions studied (outside of the alkali metals) the $\Delta E_{1/2}$ values are most similar for thallium, 1.70 v. in acetonitrile and 1.66 v. in water. This is reasonable when one considers that thallous ion does not form complex ions and presumably is not highly solvated, or at least the degree of solvation is the same in water as in acetonitrile.

The Neutral and Acid Hydrolysis of Ethyl Dibromoacetate in Acetone–Water Solvents[1]

BY FREDERICK N. HORNYAK AND EDWARD S. AMIS

RECEIVED DECEMBER 1, 1956

The neutral and acid hydrolysis of ethyl dibromoacetate was carried out at three temperatures and in water–acetone solvents containing various percentages of acetone. In the neutral hydrolysis the acid formed produced a departure from the first-order law at greater than 8% reaction. The acid-catalyzed runs followed the pseudo first-order law strictly for at least 85% of completion of reaction. The parameters of the Arrhenius equation are presented and discussed. The dependence of the rates on the dielectric constant of the media is compared with that of the acid hydrolysis of ethyl dichloroacetate in acetone–water solvent.

Introduction

As part of the general problem of the effect of solvent and molecular substituent changes upon reaction rate in solution, a study of the neutral and acid-catalyzed hydrolysis of ethyl dibromoacetate was carried out.

Experimental

Materials.—All water was twice distilled; the last distillation employed alkaline potassium permanganate. The water was then boiled to ensure carbon dioxide removal and was stored and delivered from vessels protected with ascarite tubes.

A. C. S. reagent grade acetone was purified according to the procedure of Åkerlöf.[2]

Ethyl dibromoacetate (product of Sapon Laboratories, Inc.) was washed briefly with concentrated sodium bicarbonate and then with calcium chloride solution. After drying over drierite, distillation at 14.5 mm. gave the ester with b.p. 81–82.5° (reported[3] 66–70° at 7 mm.); d^{22} 1.9081; $n^{22}D$ 1.4973; $n^{12.5}D$ 1.5018 (reported[4] d^{20}_{20} 1.9025; $n^{12.5}D$ 1.50167). Observed molar refraction and neutralization equivalent were 37.72 and 244 ± 2, respectively (calculated 37.86 and 246).

Barium hydroxide solutions, 0.002500 and 0.02500 *N*, were made up periodically from concentrated stock solution and were checked frequently against aliquots of standard potassium acid phthalate solutions. The hydrochloric acid solution was 0.3700 *N*. C.P. chemicals were used and all normalities were determined to four significant figures.

Methods and Apparatus.—Reaction temperatures were kept constant to ±0.03° and were determined with a NBS thermometer.

All pipets and burets were calibrated.

Hydrolysis were carried out in glass-stoppered 100-ml. volumetric flasks. By lightly greasing the stoppers (Fisher Rubber Compound Stopcock Lubricant) and fastening them down with rubber bands evaporation of solvent was made negligible. The grease was insoluble and had no apparent effect.

The reaction solution for a kinetic study was prepared as follows. Appropriate amounts of acetone, water and hydrochloric acid (if any) were weighed into a tared volumetric flask. The flask was then stoppered and placed in the constant temperature bath for several hours to reach thermal equilibrium. Weighings were made to 0.02 g. and the weight of hydrogen chloride (if any) was taken into account when calculating the weight of water present. The reaction was started by adding 10.00 ml. of a standard acetone–ester solution and adjusting to the mark with water at the temperature of the experiment. The flask was then shaken and the time noted. At convenient intervals 10.00-ml. samples were withdrawn, run into 25 ml. of ice-cold water and titrated with standard base. Sufficient accuracy in the times of starting and of sample withdrawal was easily attained because of the slowness of the reaction. The actual sample volume delivered by the pipetting procedure was checked by weight and also by titration and allowance was made in subsequent calculations.

The concentration of ester in all runs was 0.0500 molar and the concentration of hydrochloric acid in the acid runs was 0.0500 molar. The acetone percentages employed are shown in the tables of results.

In this work it was found that the standard base, during the titration of an ice-cold reaction sample, reacted in part with unhydrolyzed ester giving an acid value that was too high. It was found that identical samples of reaction mixture gave widely different acid values depending on the strength of the base used; the stronger base gave the highest value. In the titration of standard acid with standard base the addition of pure ester and acetone vitiated the results even under ice-cold conditions. An ester solution alone, without the presence of acid showed a zero acid value on titration with standard base (immediate end-point).

Because of these facts it was necessary to standardize the titration procedure and determine the errors involved. The titrating base solution was run in always at approximately the same rate and the reaction sample was stirred constantly in an ice-bath.

A series of mixtures of standard acid phthalate, acetone, water and ester were made up to correspond to compositions which would be obtained for titration at various stages of reaction. These mixtures were freshly made up and titrated ice-cold in the same manner as the actual run samples. The errors obtained were reproducible and found for acid hydrolyses to be a linear function of the amount of unhydrolyzed ester present. These corrections were applied to the actual run titrations to determine the true amount of acid present.

The acid runs employed the stronger 0.02500 *N* base and the titration error was about 5% in the early stages of reaction where the amount of unhydrolyzed ester is large.

	77.6	28.2	24.9	4.95
51.29	31.0	54.2	170	31.0
	38.6	49.0	112	20.8
	48.05	43.5	84.0	16.1
	57.9	38.1	62.3	21.1
	77.6	27.2	45.2	9.00

The neutral runs employed the 0.00250 N base and the titration error was found to be less than 1%.

The pseudo first-order rate constants k_m and k^1 for neutral and acid-catalyzed runs, respectively, were obtained from plots of log $(M_\infty - M)$ against t where M and M_∞ are the corrected milliliters of standard base required for neutralization of formed acid at time t and time infinity, respectively. M_∞ was calculated.

The second-order rate constants k_H and k_a for the neutral and acid hydrolysis, respectively, were calculated employing the relationship

$$k^1 = k_a(0.0500) + k_H(H_2O)$$

activation parameters were obtained from plots of log k_H and log k_a *versus* $1/T$.

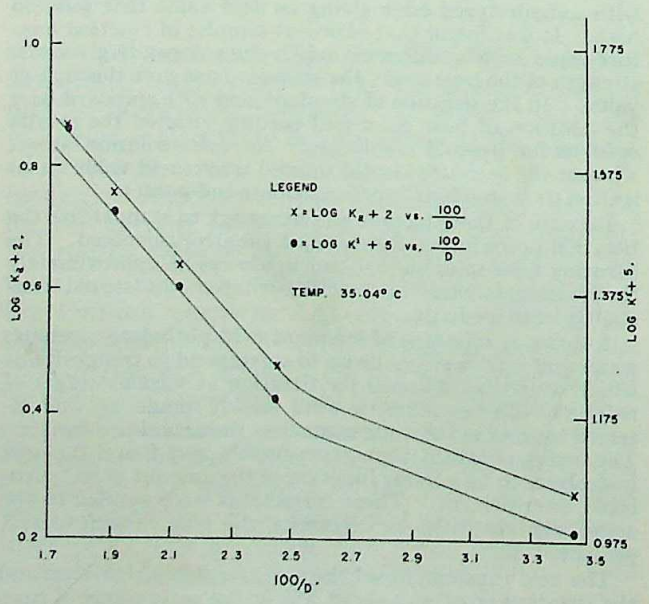

Fig. 1.

Discussion

The neutral hydrolyses proceeded very slowly so that 0.00250 N base was used to measure the production of small amounts of acid. The normality of this base could not be as accurately determined as that of the stronger base and the sensitivity of the indicator was decreased but these disadvantages were outweighed by the greatly increased accuracy of buret readings. Readings could be made to 0.1 ml. easily and end-points were easy to observe.

In the neutral hydrolyses the dibromo acid formed produced a departure from the first-order law at greater than 8% of reaction. The weak base enabled the reaction to be followed with accuracy to this small extent so that fairly good first-order constants were obtained. Acid catalysis by the dibromo acid is to be expected because the electronegative substituents make the acid very much stronger than acetic acid. The rate constants obtained varied with solvent composition and temperature in a reasonable way. Duplicate and triplicate rate constants checked to within ±5–12% generally.

TABLE III

ACTIVATION PARAMETERS[a]

Wt. % acetone	Neutral hydrolysis Log$_{10}$ Z	Neutral hydrolysis ΔE, kcal.	Acid hydrolysis Log$_{10}$ Z	Acid hydrolysis ΔE, kcal.
31	7.2	8.25	13.4	17.6
39	8.3	10.3	12.0	15.8
48	8.6	11.0	11.8	15.8
58	8.6	11.5	12.6	17.1
78	9.1	13.1	13.8	19.1

[a] Based on the second-order rate constants k_H and k_a.

The acid-catalyzed runs followed the pseudo first-order law very strictly for at least 85% of completion of reaction. Apparently the ionization of the produced dibromo acid is insignificant in the presence of the very strong hydrochloric acid. Pseudo first-order rate constants were very reproducible and duplicate runs checked within 2–5%. Also ln k_a *versus* $1/T$ plots were very accurately linear.

The activation energies for the neutral runs showed an increase with increasing acetone percentage. The statistical errors for these activation energies range from 0.9 to 2.1 kcal. per mole.

The activation energies for the acid-catalyzed runs show a minimum at about 45% acetone. This observed minimum might not be real since the statistical errors in these activation energies were from 0.3 to 0.9 kcal. per mole.

The activation energies increased as log Z increased.

In Fig. 1, log k_a and log k^1 are plotted *versus* $100/D$ for 35.04°. In this region of higher dielectric constants, these plots are straight lines of negative slope as was found by Nair and Amis[5] for the acid

The Pyrolysis of Lead Oxalate; Isotope Effects and Product Composition

BY PETER E. YANKWICH AND JAMES L. COPELAND

RECEIVED NOVEMBER 14, 1956

The composition and isotopic constitution of the gaseous products of the pyrolysis of lead oxalate have been studied for reaction between 350 and 625°. Variations with temperature of the ratio of carbon dioxide to carbon monoxide in the product gases and of carbon isotope distribution are considered in terms of simple models in which: (a) it is assumed that the primary products are modified by a secondary reaction among themselves which competes with escape of the gaseous products from the decomposing mass, or (b) oxygen abstraction and C–C bond rupturing processes are presumed to compete. Models in group (a) are shown to correspond to temperature dependences of the molar yield ratio of gaseous products which are not in accord with observation. Consideration of models in group (b) is based primarily on the Bigeleisen–Wolfsberg treatment of three center reactions; satisfactory agreement with experiment is obtained for a model of the activated complex which includes a lead atom.

Introduction

Several investigations have been made of the products obtained when crystalline lead oxalate is decomposed thermally. At temperatures of pyrolysis above about 250° all of the carbon can be obtained as carbon dioxide or monoxide, but there is little unanimity concerning the molar ratio, Y, of these gases in the products. Maumene[1] finds $Y = 2$ and records the stoichiometry $3PbC_2O_4 = 2PbO + Pb + 4CO_2 + 2CO$, while mentioning that previous workers observed Y to be 3. Maumene reported that at higher temperatures some reduction of lead oxide to metal may occur; Sveda[2] studied the pyrolysis in an initially evacuated vessel and found that the extent of this reduction was proportional to the time of contact between solid and gaseous products of the primary reaction.

Denham[3] found that there was no reaction between the solid product (which he and Pascal and Minne[4] believed to be a lead suboxide) and the carbon monoxide produced if the total pressure was below 5 cm. at 270°; he reported $Y = 3$.

Bircumshaw and Harris[5] studied the products of the decomposition at temperatures in the range 310–470°. They found a dioxide/monoxide ratio of 2, established by X-ray and electrical conductivity measurements that the solid was a mixture of metallic lead and red tetragonal lead oxide, and observed that removal of the gaseous products by continuous pumping had only a slight effect on their composition. In a second paper[6] the kinetics of the pyrolysis was studied at temperatures between 309 and 350°. The rate data conformed to predictions based on a model in which decomposition starts at nuclei and spreads through branching chains along paths of lateral strain; the strain is relieved by the formation of Smekal cracks along which the decomposition is favored.

In the present paper we report a study of the composition and isotopic constitution of the gaseous products over the temperature range 350–625°. The study was carried out to elucidate the character of the molecular mechanism of the process, and no kinetics measurements were made.

Experimental

Lead Oxalate.—A slight excess of aqueous reagent oxalic acid was added slowly with constant stirring to a 1 M aqueous solution of reagent grade lead nitrate; after standing in contact with the supernatant for one hour at room temperature, the lead oxalate was removed by filtration, washed with distilled water, then dried in air for 3 hours at 110°.

Apparatus and Procedure.—The pyrolyses were carried out in a stream of dry, oxygen-free helium. The train employed was made up as follows. Sample decomposition took place in a 2 cm. i.d. Vycor tube, the second half of which passed through an electric furnace which maintained a predetermined temperature constant to 2°; the gaseous products passed first through a trap cooled in liquid nitrogen, thence to a combustion tube at 750° filled with copper oxide wire, and finally through another trap cooled in liquid nitrogen. Preliminary tests showed that carbon monoxide and carbon dioxide were separated quantitatively in the first trap at the helium flow rate employed (50 cc. per min.). In a typical experiment 0.45–0.50 g. of lead oxalate was weighed into a shallow platinum boat which was placed in the unheated end of the pyrolysis tube. The train was assembled and the helium flow maintained for one hour to remove traces of oxygen. At the start of most of the runs the pyrolysis tube was tipped, causing the boat to slide into the heated zone. Since the reaction becomes very rapid at the higher temperatures employed, a few runs in that region were made in which the contents of the boat were dumped by an externally operated tipper onto a thick platinum foil in the heated zone to ensure the most rapid possible heating to the run temperature. At 350° the decomposition is complete in 40 minutes[6]; so that no time variable would be introduced, the helium sweep was maintained for 60 minutes in all runs. The two gaseous samples were measured manometrically, then reserved for mass spectrometric analysis.

Isotope Analyses.—The procedures and calculation methods used for the carbon isotope ratio determinations have been detailed in previous publications from this Laboratory.[7,8] The final oxygen isotope ratios were obtained by applying to the observed values of the ratio $(m/q\ 46)/(m/q\ 44 + 45)$ corrections for the magnitude of $(m/q\ 45)/(m/q\ 44)$, and for daily variations in the response of the mass spectrometer; analysis showed that corrections to these ratios for incomplete resolution and the contribution to the peak at m/q 46 of the species $C^{13}O^{16}O^{17}$ (assumed

constant) were so small that considerable uncertainty in them produced no variation in the final corrected ratio.

Results

The corrected carbon and oxygen isotope ratios of the samples of carbon dioxide and carbon monoxide (measured in the form of the dioxide) products are given in Table I. In Table II are collected the calculated values of the ratios $R_r = (R^c_{CO_2}/R^c_{CO})$ and Y = (moles CO_2 product/moles CO product) for each run. The average values of Y and R_r are plotted against each other in Fig. 1; the horizontal

At the helium flow rate of 50 cc. per min. the mean contact time of product gases with the decomposing sample is about 8 seconds; the residence time of the burning carbon monoxide in the combustion tube is 60–65 seconds. Titani, Nakata and Kanome[12] observed the exchange of O^{18} between carbon dioxide and cupric oxide after a contact time of 75 seconds to be 15% complete at 430° and 48% complete at 530°.[13] It is probable then that the carbon dioxide obtained from combustion of the product carbon monoxide is in exchange equilibrium with the copper oxide with respect to O^{18}; if this situation obtains, the differences between R^0_{CO} and the value of $R^0_{CO_2}$ for tank carbon dioxide should be constant. Examination of the data in Table I shows this conclusion to be valid, except for the runs at 350°.

While the oxygen isotope ratio data for carbon monoxide product furnish no useful information about the pyrolysis, those for carbon dioxide may if there is no appreciable exchange between dioxide and monoxide in the pyrolysis tube. The carbon dioxide–carbon monoxide exchange is extremely slow at 800° in quartz vessels[14]; any exchange under the conditions of our experiments presumably would be catalyzed by the decomposing solid.

(10) Includes the uncertainty in the isotope ratios.

(11) Average deviation from the mean.

This point can be tested by comparing the observed values of R_r as a function of temperature with those calculated for exchange equilibrium from the data of Urey[15]; since the mechanism of the exchange involves oxygen atom transfer, carbon and oxygen isotope exchanges must occur simultaneously.[16] It is observed that, at all temperatures, the value of R_r is much smaller than that calculated for complete exchange (at 350°: obsd. 1.0060, calcd. 1.0275; at 625°: obsd. 1.0002, calcd. 1.0160); further, if the exchange were very rapid at the higher temperatures employed, one would expect a plot of ln R_r *versus* $1/T$ to exhibit a positive second derivative since the value of R_r must approach from below that calculated for complete exchange. We conclude that exchange of carbon and oxygen between carbon dioxide and carbon monoxide products is inappreciable under the conditions of the pyrolysis.

Discussion

Variation of Y with Temperature.—While it has been found that the proportions of the product gases are altered if the pressure in the system is maintained at a low value by pumping, the data of Bircumshaw and Harris[5] indicate that the effect is small compared with the variations observed in this research. The kinetics study of the same workers[6] shows that the reaction does not take place in the bulk of the crystals, but in cracks on the surfaces and at imperfections. Consider two situations in which the primary products are modified by a secondary *reaction* among themselves, which competes with *escape* of the gaseous products from the decomposing mass: case I—lead and carbon dioxide primary products, subsequent partial reduction of the carbon dioxide to the monoxide; case II—a simple oxygen abstraction primary process yielding equimolar amounts of lead oxide and the two carbon oxides, subsequent partial oxidation of carbon monoxide to the dioxide. Ignoring the isotope effect, assume that both the *reaction* and *escape* processes may be considered pseudo-first order with respect to carbon; then define the appropriate rate constants as k_r and k_e, respectively, and let $(k_e/k_r) = (1 - \alpha)/\alpha$. For case I, $Y = (1 - \alpha)/\alpha$; for case II, $Y = (1 + \alpha)/(1 - \alpha)$. It seems likely that the activation energy of the forward or reverse of the reaction $Pb(s) + CO_2(g) = PbO(s) + CO(g)$ is of the order of 40–50 kcal. per mole. The escape process may be similar to any of these: simple unactivated diffusion through the interstices of the decomposing powder mass, activated surface diffusion, desorption from an original chemisorbed state, or diffusion through the bulk of individual crystallites from a depth of at least a few tens of ion layers; the maximum apparent activation energy associated with any of these is of the order of 15–20 kcal. per mole, which would require that α increase rapidly with increasing temperature. For case I, Y would decrease with increasing temperature; for case II, Y would increase very rapidly with temperature. Neither situation corresponds to that observed, so we reject those models which require competition between escape and secondary reaction.

It is possible that the mechanism of the decomposition involves an intra-ionic competition between two processes, one which results in conversion of an oxalate ion into two molecules of carbon dioxide and another, with a somewhat lower activation energy, which results in the formation of one molecule each of carbon monoxide and dioxide. In suggesting such a model we presume that no chemical process occurs during the diffusion of the product gases out of the solid mass. If the intra-ionic reactions are assumed to be first order, and the specific rate constants are k and k', respectively, then $Y = (2k + 4k')/(4k')$ and the activation energy difference obtained from the observed temperature dependence of Y is 2.7 ± 0.1 kcal. If the required electron transfer from oxalate ion to lead takes place before gross bond ruptures within the ion, this activation energy difference can be related to the C–C bond energy in the first reaction and the energy of the C–O bond, or of motion of O in a triad such as C–O–Pb, in the second. In the absence of more information we conclude only that the second reaction probably involves something more complex than rupture of a simple C–O linkage since the activation energy difference in that case would be more than a few kcal. per mole.

Calculation of Isotope Effects through Two-center and Three-center Models.—Methods for the calculation of the ratios of isotopic rate constants have been developed by Bigeleisen[17] extending the work of Bigeleisen and Mayer.[18] The usual application, which has been successful in a number of cases,[19] involves the assumption of a two-center model, the effective masses of the activated molecules along the coördinate of decomposition in the transition state being calculated by the method of Slater.[20] As a refinement, Bigeleisen and Wolfsberg[21,22] derived these effective mass ratios, μ, for the three-center system A–B–C, in which a bond between atoms B and C is broken and a bond between atoms A and B is formed. The final corrected formula for these temperature independent factors[22] involves a term whose coefficient is (−cos ABC), and depends on atomic masses and a parameter p which, for this situation, is the square of (amount of bond formation between A and B)/(amount of bond extension between B and C). By analogy, it follows that the original formula[21] which was incorrect for the three-center system formulated above (and in which the sign of the cosine term is positive), applies to the three-center system in which the motion about B is symmetrical rather than asymmetrical, *i.e.*, to the

(15) H. C. Urey, *J. Chem. Soc.*, 562 (1947).

(16) Use of figures for C^{12} and C^{13} is required because the carbon isotope content of the carbon monoxide fraction is unaffected by combustion and the comparison of either carbon or oxygen isotope contents of carbon dioxide and carbon monoxide by direct mass spectrometric measurements is very imprecise due to differences between these two gases of the effect of isotope substitution upon ionization probabilities.

three-center situation in which both A–B and B–C bonds are being made or broken.[23]

In application of the three-center model it is assumed that a single vibration gives rise to the motion in the reaction coördinate, most simply either the symmetric or asymmetric mode in the imaginary triatomic system ABC.

In an earlier publication[24] it was shown that one could obtain, from isotopic rate constant ratio data taken over a sufficiently wide range of temperatures, a value for μ of reasonable precision. Since knowledge of this quantity permits direct computation of the temperature dependent part of such ratios, it is of interest to speculate on the information concerning the differences between the vibrational motions of the reactant and activated states which can be derived from such calculated results.

As detailed by Bigeleisen and Wolfsberg,[21] the vibration lost upon activation generates the quantity μ. Now, it will be possible usually to calculate the temperature dependent part of a ratio of isotopic rate constants in terms of a single frequency, which may have no relation whatsoever to any actual vibrational frequency in the reactant molecule or activated complex, and its isotopic companion, *i.e.*, in terms of an ω and a value for the ratio ω/ω_i (the subscript i denoting the frequency in the molecule labeled with the heavier atom of the isotopic pair).[25] Two simple approaches suggest themselves. First, one could set ω/ω_i equal to μ, then calculate the value of ω required to reproduce the observed temperature dependence; this is what has been done in some two-center cases.[8,19] Second, one could set up a three-center or more complicated model for the reaction, and employing distances, angles and force constants of reasonable magnitudes, compute a set of ω's and ω_i's. An appropriate value of ω/ω_i is estimated by comparison of the various normal modes of the model with the reaction coördinate motion assumed; the estimated ω/ω_i is then used in the calculation of a value for the ω to be lost upon activation which will reproduce the observed temperature dependence. The utility of the calculation lies in the possible similarity of this artificial ω to that for some normal mode in the model or the actual reactant molecule which involves motion like that in the assumed reaction coördinate. Where such similarity is observed one would take some confidence in the choice for reaction coördinate motion; were such correspondence not observed, the calculation would not have yielded a helpful result.

Intra-ionic Competition Models.—The simplest model for the decomposition of oxalate ion into two molecules of carbon dioxide is the two center C–C system; the competing process yielding carbon monoxide and carbon dioxide will be treated as a C–O two-center system in which C–C bond rupture follows the rate-determining oxygen abstraction, as a C–C–O three-center system involving symmetric motion, and as the O–C–O or C–O–Pb triads involving asymmetric motion. The following notation is adopted for the several rate constants

$$\begin{array}{l} C^{12}OO^- \xrightarrow{k_4} C^{12}O + C^{12}O_2 \\ \quad\vdots \\ C^{12}OO^- \xrightarrow{k_1} 2C^{12}O_2 \end{array} \qquad (1)$$

$$\begin{array}{l} C^{12}OO^- \xrightarrow{k_4'} C^{12}O + C^{13}O_2 \\ \quad\vdots \\ \quad\vdots \xrightarrow{k_2} C^{12}O_2 + C^{13}O_2 \\ \quad\vdots \\ C^{13}OO^- \xrightarrow{k_5} C^{13}O + C^{12}O_2 \end{array}$$

It is impossible to obtain the appropriate ratios of these isotopic rate constants from the data available. We choose to assume values for k_1/k_2 and with the average values for R_r at each temperature calculate k_4/k_5, or other related ratio; we then compute the temperature independent part of k_4/k_5, examine its value in terms of some simple models, then carry out a very approximate treatment of the temperature dependent part.

Where a three-center model for the process competing with C–C bond rupture contains only one of the carbon atoms, $k_4/k_4' = 1$; if both of the carbon atoms are involved, as in a C–C–O system, this ratio will depend upon the relative involvement of the C–C and C–O bonds in the reaction coördinate motion, *i.e.*, upon the value of the parameter p. For $p = 0.3$ or less, the values of μ for k_4/k_4' are not very different from unity (Fig. 2, curve C), which suggests that k_4/k_4' is near unity in this range; in the whole range of p from 1 to ∞ the ratio of the μ's for k_4/k_4' and k_4/k_5 (Fig. 2, curves C and B, respectively) deviates from unity less than does that for k_4/k_4' at $p = 0.3$. As a matter of convenience, then, we make the following approximations: for p small compared with unity, $k_4/k_4' = 1$ and $k_4/k_5 \neq 1$; from $p = 1$ to ∞, $k_4/k_4' = k_4/k_5 \neq 1$.

In performing the integrations and in the equations below for R_r we employ the approximation $Y = 1 + (k_1/2k_4)$; this generates an error in R_r smaller than that due to imprecisions in the mass spectrometric measurements. For situations where one carbon atom is involved in the three-center model, where a C–O two-center model is considered, or where p is small for the C–C–O three-center model

$$R_r = \frac{C\left[\frac{M}{D}+2\right]\left[2A_0\left(\frac{M}{D}+\frac{2}{C}+2\right)+B_0(M+4)\right]}{\left[2A_0(M+2)\left(\frac{M}{D}+\frac{2}{C}+2\right)+B_0(M+4)\left(\frac{M}{D}+\frac{2}{C}\right)\right]} \qquad (3)$$

where $M = k_1/k_4 = 2(Y-1)$, $D = k_1/k_2$, $C = k_4/k_5 = k_4'/k_5$, A_0 = mole fraction of C^{12}–C^{12} oxalate in the original material, and B_0 = the corresponding mole fraction for C^{12}–C^{13} oxalate.[26] For the three center C–C–O model with p between 1 and ∞

(23) J. Bigeleisen, *Can. J. Chem.*, **30**, 443 (1952).

(24) P. E. Yankwich and H. S. Weber, THIS JOURNAL, **78**, 564 (1956).

(25) This statement is a generalization to complicated models of a practice already found to be successful in two-center systems[19]: there a stretching frequency of the bond ruptured is presumed lost and, following the diatomic molecule argument,[20] ω/ω_i is taken as the ratio of the reduced masses of the imaginary triatomic.

(26) Neglect of the oxalate species C^{13}–C^{13} introduces imperceptible error.

$$R_r = \frac{\left[\frac{M}{D}+\frac{2}{C}\right]\left[2A_0\,C\left(\frac{M}{D}+\frac{4}{C}\right)+B_0(M+4)\right]}{\left[2A_0(M+2)\left(\frac{M}{D}+\frac{4}{C}\right)+B_0\left(\frac{M}{D}+\frac{2}{C}\right)(M+4)\right]} \quad (4)$$

where $C = k_4/k_5 = k_4/k_4'$, but the other symbols have the same meaning as in equation 3.

In Fig. 3 are plotted as functions of temperature values of k_4/k_5 derived from the experimental data by application of equations 3 and 4; curves C and C′ show the relative insensitivity of the k_4/k_5 values to that assumed for the frequency of the C–C stretching vibration. The temperature dependence of k_4/k_5 as graphed in curve A is very large for an isotope effect of that magnitude; further, the values of μ obtained from the curve range smoothly from 1.009 at $(1000/T) = 1.5$ to 1.018 at $(1000/T) = 1.1$. The temperature dependent part of k_4/k_5 calculated by equation 4 exhibits a similar anomalous dependence upon temperature. For these reasons we reject the C–C–O three-center model involving asymmetric motion and large values of p.

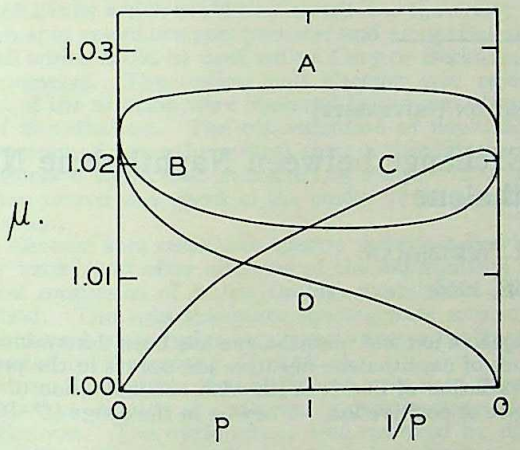

Fig. 2.—Temperature-independent factor, μ, in isotopic rate constant ratio as a function of p.[21] For asymmetric motion about B, curves A and D:

$$\mu = \left[\frac{(m_B^{-1}+m_C^{-1})+p(m_B^{-1}+m_A^{-1})-2p^{1/2}m_B^{-1}(\cos ABC)}{(m_{B_i}^{-1}+m_{C_i}^{-1})+p(m_{B_i}^{-1}+m_{A_i}^{-1})-2p^{1/2}m_{B_i}^{-1}\times(\cos A_iB_iC_i)}\right]$$

for symmetric motion, curves B and C, the minus sign to the cos term is replaced with +. Curve A, O–C–O system: $ABC = A_iB_iC_i = 120°$; $m_A = m_{A_i} = m_O = m_{C_i} = 16$; $m_B = 12$, $m_{B_i} = 13$. Curve B, C–C–O system: $ABC = A_iB_iC_i = 120°$; $m_A = m_{A_i} = m_B = 12$; $m_{B_i} = 13$; $m_C = m_{C_i} = 16$. Curve C, C–C–O system: $ABC = A_iB_iC_i = 120°$; $m_A = m_B = m_{B_i} = 12$; $m_{A_i} = 13$; $m_C = m_{C_i} = 16$. Curve D, Pb–O–C system: $ABC = A_iB_iC_i = 180°$; $m_A = m_{A_i} = 207$; $m_B = m_{B_i} = 16$; $m_C = 12$, $m_{C_i} = 13$.

We consider seriatim the four models described above for the oxygen atom abstraction process competing with simple C–C bond rupture. The values of μ obtained for k_4/k_5 from curves C and C' are 1.0138 and 1.0134, respectively; if these values are assumed for ω/ω_i, the artificial frequency ω is calculated to be 1220 cm.$^{-1}$ for curve C and 1230 cm.$^{-1}$ for curve C′. Each of these groups of μ, ω/ω_i and ω values reproduces the plot of calculated k_4/k_5 within ± 0.0005 over the temperature range covered by the experiments. The C–C stretching

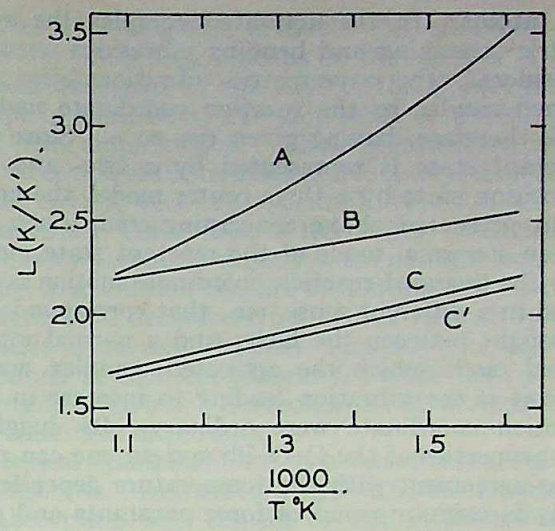

Fig. 3.—Calculated isotopic rate constant ratios; $L(k/k')$ *versus* $1000/T$°K., $L = 100\ ln$. Curve A, k_4/k_5 by equation 4; values for k_1/k_2 taken from curve B. Curve B, k_1/k_2, two-center model; $\mu = \omega/\omega = 1.0198$, $\omega_{C-C} = 850$ cm.$^{-1}$. Curve C, k_4/k_5 by equation 3; values for k_1/k_2 assume $\omega_{C-C} = 850$ cm.$^{-1}$. Curve C′, k_4/k_5 by equation 3; values for k_1/k_2 assume $\omega_{C-C} = 750$ cm.$^{-1}$.

force constant in oxalate ion[27] leads to a calculated stretching frequency near 700 cm.$^{-1}$, and we adopt a value of 1.014, for the μ of k_4/k_5. The values of μ for the C–O two-center system and for asymmetric motion in the O–C–O system with bond angle (120°) near that observed for crystalline oxalates (Fig. 2, curve A) are equal to or greater than 1.0227, leading to rejection of these models. The calculated μ for symmetric motion in the C–C–O system (Fig. 2, curve B) is close to 1.014 for values of p in the vicinity of unity; however, the original approximations leading to equations 3 and 4 require that p be less than 0.2–0.3 in the present instance, so this model is unsatisfactory. Consideration of the vibrations of C–C–O would lead us to the same end, for with force constants of reasonable magnitude chosen for this fragment of the oxalate ion a temperature dependent part of k_4/k_5 is predicted which is much larger at all temperatures than that "observed" (*i.e.*, than that calculated on the basis that k_1/k_2 is appropriately estimated in terms of the C–C two-center model).

We consider finally the linear C–O–Pb triad, for which values have been plotted in Fig. 2, curve D, the motion assumed being asymmetric. In this case we are not limited by the kinetics analysis to p values in any particular range, and the calculated value of μ for the system becomes 1.014 near $p = 0.3$, which implies that the amount of bond extension between C and O is about twice the amount of bond formation between O and Pb. This bond involvement situation seems reasonable for such an oxygen atom transfer. Less clarity is evident when we consider the temperature dependent part of k_4/k_5 which one calculates for this model. The *reactant* state requires consideration only of the stretching vibration between the carbon and oxy-

gen atoms. In the activated complex the symmetric stretching and bending vibrations must be considered, the asymmetric vibration being assumed similar to the reaction coördinate motion and, therefore, having given rise to μ. Since the reactant state is represented by a two- and the transition state by a three-center model, the argument presented above concerning comparison between a normal mode of the reactant state model and the assumed reaction coördinate motion is applied in a different sense, *viz.*, that correspondence is sought between the latter and a normal vibrational mode which the activated complex would exhibit *if* the vibration leading to increase in the reaction coördinate were ordinary. By juggling the properties of the C–O–Pb system one can produce agreement with the temperature dependence of k_4/k_5 using a group of force constants and distances having reasonable magnitudes, provided that the asymmetric normal mode is selected as the reaction coördinate motion.

An alternate choice for the process leading to C–C bond rupture is asymmetric motion in the three-center system C–C–O, bond extension taking place between C and C, and bond formation between C and O. In effect this adds still another parameter to the over-all picture, *i.e.*, p for this triad, and does not further illuminate the situation.

In Table I the total change in $R^0_{CO_2}$ is only $(11 \pm 5) \times 10^{-6}$; for none of the models considered above is the change predicted in O^{18} content of product carbon dioxide outside the limits defined by this figure. Thus the O^{18} isotope effect is not a useful adjunct to evaluation of these models.

Acknowledgment.—We are indebted to Mrs. Beverly Thomas for the mass spectrometric determinations, and to Professor H. S. Gutowsky and Dr. Martin Karplus for stimulating discussion. Dr. James Y. Tong and the staff of the University of Illinois Digital Computer Laboratory have performed calculations which permitted checking of several ideas. This research was sponsored by the U. S. Atomic Energy Commission.

Electron Spin Resonance Study of the Electron Exchange between Naphthalene Negative Ion and Naphthalene[1]

BY R. L. WARD[2] AND S. I. WEISSMAN

RECEIVED DECEMBER 28, 1956

The rate of the electron exchange reaction between naphthalene negative ion and naphthalene has been determined by a spectroscopic method. Broadening of the electron spin resonance lines of naphthalene negative ion occurs in the presence of naphthalene. Bimolecular rate constants are deduced from the variation of line breadth with concentration of added naphthalene. The rate constants vary with solvent and with the choice of positive ion. They lie in the range 10^7–10^9 liter mole^{-1} sec.$^{-1}$.

Introduction

The rate of a chemical reaction is usually determined by a sequence of measurements in time of properties which vary as the reaction proceeds. Such measurements yield directly the net changes in the quantities of reactants and products. Individual rates of production and consumption are inferred from the net rates and these inferred rates are sometimes subject to considerable uncertainties. Direct determination of rates of production and consumption of participants in a reaction has become possible in certain cases by the recent development of radiofrequency and microwave spectroscopic techniques of high resolving power.

The measurements depend on the fact that the shape of a spectroscopic line associated with a transition between a pair of states is affected by the mean life of the states. The essential ideas involved in the relations between lifetimes and line breadths were worked out by Lorentz in his treatments of the effects of collisions on the breadth of spectral lines.[3] Many authors have further developed the subject.[4–11] The theoretical treatment of P. W. Anderson[8a] appears to be the most readily applicable to the interpretation of the kinds of experiments which we shall describe here.

These experiments consist of observations of the electron spin resonance spectra of naphthalene negative ion (to be referred to as naphthalenide) in the presence of naphthalene.

In the concentration range 10^{-4}–10^{-3} M in tetrahydrofuran (THF) or 1,2-dimethoxyethane (DME), the spectrum of naphthalenide consists of a set of seventeen hyperfine components extending over a field interval of 27.2 oersteds. The breadth of each line is about 0.9 oersteds between points of extreme slope. This description applies to the spectrum of lithium, potassium, rubidium or cesium naphthalenide. Sodium naphthalenide, on the other hand, behaves differently. In DME its spectrum is

similar except for a markedly greater line breadth to that of the other salts, while in THF it is completely different in structure.[12] At concentrations lower than 10^{-5} M the normal spectrum of seventeen lines is further resolved into one of twenty-three lines. The contribution of each of the protons in naphthalenide to the hyperfine splitting has been determined.[12]

As naphthalene is added to a solution of naphthalenide, a broadening of the hyperfine components of the ion occurs.[13] As more naphthalene is added, the lines merge into a single broad band which in some cases continues to broaden with further addition of naphthalene and in others becomes narrower. From the broadening at the lower concentration of added naphthalene a rate constant for the electron exchange reaction between naphthalene and naphthalene negative ion may be obtained.

Experimental Methods

Solutions of naphthalenide salts were prepared in high vacuum by methods already described.[14] The apparatus included a tube which could be inserted into the cavity of the electron spin resonance spectrometer and an optical absorption cell which could be used with a Cary or Beckman spectrophotometer. The optical and electron spin resonance spectra of the solution were observed before and after addition of naphthalene. The concentration of naphthalenide was determined from the optical spectra through the use of the extinction coefficients measured by Paul.[15] The optical spectrum served as a check of the purity of the naphthalenide solution.

The electron spin resonance spectra were recorded immediately before and after addition of the naphthalene under identical conditions of cavity tuning, modulation and amplification. The spin resonance spectra were measured at nine thousand megacycles in a spectrometer designed and constructed by Professor J. Townsend.

When small amounts of naphthalene were used they were introduced as aliquots of a solution in cyclohexane of known concentration. The cyclohexane was removed by distillation. When large amounts of naphthalene were required, they were purified and introduced into the apparatus by the methods described by Paul. The naphthalene was contained in an evacuated side arm separated from the rest of the apparatus by a break seal. The concentration of naphthalene, when it could not be added in known amount at the beginning of the experiment, was determined by analysis after completion of the spectroscopic measurements.

Results and Discussion

The small broadenings of the hyperfine components which occur at low naphthalene concentrations are not easily determined by direct measurement of line width. They are better determined indirectly from the intensities of the lines. The spin resonance spectra were recorded as derivative of absorption X'' with respect to magnetic field H against the field. It may be shown that the intensity of a single peak as measured by the difference in values of dX''/dH at maximum and minimum varies inversely as the square of the line breadth, provided the shape of the line remains unchanged, *i.e.*, that the absorption may be represented by a single function of field $X''[(H - H_0)/\delta H]$ where H_0 is the field at the center of the line and δH is a line breadth. In addition, the intensity of the line depends on the number of free radical molecules in the cavity, the Q and filling factor of the cavity, the amplitude of modulation and the amplification. These parameters, with the exception of the number of free radical molecules in the cavity, were kept constant in each of our experiments. The number of free radical molecules in the cavity decreased slightly when naphthalene was added to a solution because of dilution and because of occasional decomposition of free radical by impurities in the naphthalene. This decrease was determined in each experiment from the optical absorption spectrum. Correction for it was made in the treatment of the data.

Typical examples of the observed effects are given in Figs. 1–3. In each case, dX''/dH, the derivative of absorption with respect to field is plotted as a function of field H. In Fig. 1 is shown the effect of addition of naphthalene at 0.103 M to a solution of potassium naphthalenide 1.36×10^{-3} M in THF. A small broadening results. It is observed in two ways. The intensities of the individual peaks are reduced and the resolution of adjacent peaks is diminished. While the derivative changes signs between all pairs of adjacent peaks in the unbroadened spectrum, it does not do so in the broadened spectrum.

In Fig. 2 is shown the effect of addition of naphthalene at 0.218 M to a solution of potassium naphthalenide at 1.4×10^{-3} M in DME. An example of exchange narrowing is shown in Fig. 3.

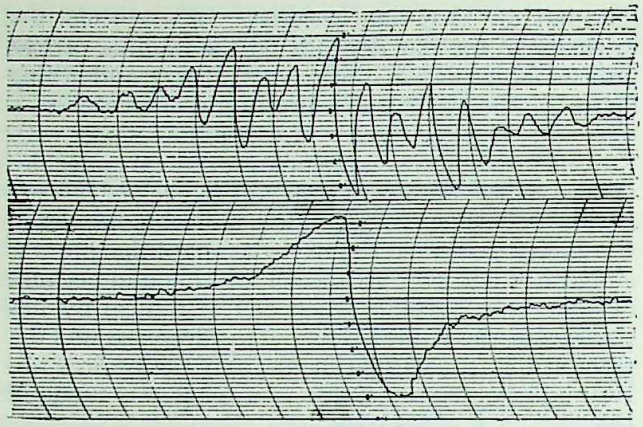

Fig. 3.—Spin resonance of 1.0×10^{-3} M lithium naphthalenide in THF: above, no added naphthalene; below, naphthalene added at 0.405 M.

Here naphthalene at 0.405 M was added to a solution of lithium naphthalenide at 1.0×10^{-3} M in THF.

From the spectra, of which those described in the preceding paragraph are typical, we wish to deduce information concerning the electron exchange reaction. We assume that in the region of small line broadenings (broadenings small compared with the separation betweeen lines), the contributions to the line breadth from individual broadening mechanisms are additive. This assumption corresponds to the more familiar one of additivity of rates.

We write, then, for the breadth of a line $\delta H = \delta H_0 + \delta H_N$ where δH_0 is the breadth in the absence of added naphthalene and δH_N is the contribution to the breadth from the electron exchange reaction with the added naphthalene. The ratio of intensity $I(N)$ at concentration of added naphthalene N to the corresponding intensity $I(0)$ before naphthalene has been added is given by

$$\frac{I(N)}{I(0)} = \frac{(\delta H_0)^2}{(\delta H_0 + \delta H_N)^2} \qquad (1)$$

A convenient form of this relation for our purposes is

$$\sqrt{\frac{I(0)}{I(N)}} = 1 + \frac{\delta H_N}{\delta H_0} \qquad (2)$$

For further analysis we assume that the lines are Lorentzian. The work of Lloyd and Pake[16] has shown that in dilute solutions of the free radical peroxylamine disulfonate the lines are close to Lorentzian and that their breadth is accounted for by thermal relaxation processes. Anderson's[8a] work has shown that in the region of small broadening, exchange reactions also produce Lorentzian lines.

For a Lorentzian line the field dependence of absorption is given by

$$X'' = \frac{X''_{max}\delta H^2}{\delta H^2 + (H - H_0)^2}$$

where X''_{max} is the intensity at the maximum, H_0 the field at the center of the line and δH the half width of the line at half maximum absorption. H in oersteds is related, for a pure electron spin resonance of the type studied here to the frequency V by

$$V = \frac{g\mu_0 H}{h} = 2.83 \times 10^{4} H$$

g is the spectroscopic splitting factor for an electron spin, μ_0 is the Bohr magneton, h Planck's constant.

Anderson's theory which is based on a frequency modulation model (as well as the theories based on the Bloch equations) indicate that in the region of line broadenings small compared with the separation between lines, the contribution to the line breadth δV of the exchange process is given by

$$\frac{1}{\tau} = 2\pi\delta V \qquad (3)$$

where τ is the mean time between electron exchanges, and δV is the half width at half maximum. In Anderson's theory the assumption is made that the exchange process is Markoffian.[17] This assumption seems to be a reasonable one. We should emphasize Anderson's result that the lines are Lorentzian with contributions to the breadth δV given by the last equation only when the mean frequency of exchange $1/\tau$ is small compared with $V_i - V_j$ where V_i and V_j are the frequencies of adjacent lines. When $1/\tau > V_i - V_j$ exchange narrowing may occur.

In naphthalene negative ion each line in the spectrum arises from an electron spin transition in a molecule of specified proton spin quantum numbers. Although there are eight protons, because of symmetry only two proton quantum numbers—M_α, the sum of the projections on the field of the spins of the α protons, and M_β, a similar sum for the β protons—fix the position of the electron spin resonance line. When the electron jumps from one naphthalene to another, it usually finds different values M_α, M_β in the second site from the first.

The central peak in the hyperfine pattern of naphthalene negative ion arises from electron spin transitions in molecules with $M_\alpha = M_\beta = 0$. This peak is the most intense one in the spectrum and it is single. The data to be presented in the following paragraphs are obtained almost exclusively from this peak.

If τ_{N^-} is the mean time between exchanges for a naphthalene negative ion, and τ_N the corresponding time for naphthalene, for a bimolecular exchange where k is the rate constant and (N) and (N^-) are concentrations of naphthalene and naphthalene negative ion

$$\frac{(N^-)}{\tau_{N^-}} = \frac{(N)}{\tau_N} = k(N)(N^-)$$

Hence

$$\frac{1}{\tau_{N^-}} = k(N); \quad \frac{1}{\tau_N} = k(N^-)$$

If ΔH_N is the line breadth as measured between points of extreme slope

$$\frac{1}{\tau_{N^-}} = (2\pi)(2.83 \times 10^{6}) \frac{\sqrt{3}}{2} \Delta H_N = k(N)$$

($\sqrt{3}/2$ is the proportionality factor between half width at half maximum and width between points of extreme slope.) We then find a relationship between the line breadth (between points of extreme

(16) J. P. Lloyd and G. E. Pake, *Phys. Rev.*, 94, 579 (1954).

(17) An essential feature of a Markoffian process is that the probabilities of transition at a given time do not depend on past history.

slope) produced by exchange, ΔH_N, and the second-order rate constant

$$k = \sqrt{3}\,\pi\, 2.83 \times 10^6 \frac{\Delta H_N}{(N)} \qquad (4)$$

From (2) and (4) we find

$$\sqrt{\frac{I(0)}{I(N)}} = 1 + \frac{k(N)}{\sqrt{3}\pi\, 2.83 \times 10^6 \Delta H_0}$$

In the curves given in Figs. 4–8 we plot the measured values of $\sqrt{I(0)/I(N)}$ against $(N)/\Delta H_0$. ΔH_0 in each case was found from direct measurement of the central line before naphthalene was added. Each point represents a separate preparation of naphthalenide and addition of naphthalene to it.

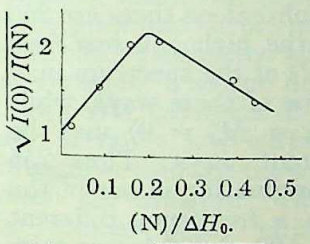

Fig. 5.—$\sqrt{I(0)/I(N)}$ *vs.* $(N)/\Delta H_0$ for potassium naphthalenide in DME.

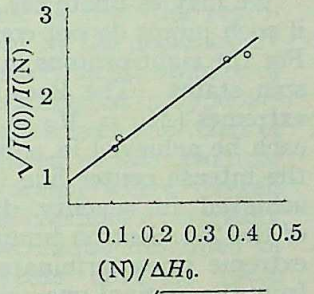

Fig. 6.—$\sqrt{I(0)/I(N)}$ *vs.* $(N)/\Delta H_0$ for potassium naphthalenide in THF.

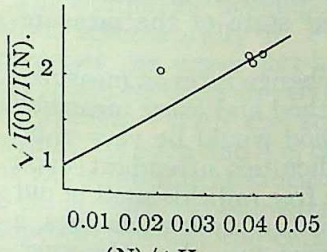

Fig. 7.—$\sqrt{I(0)/I(N)}$ *vs.* $(N)/\Delta H_0$ for lithium naphthalenide in THF.

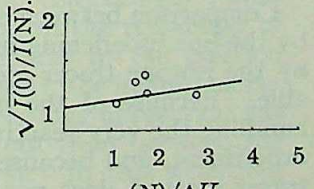

Fig. 8.—$\sqrt{I(0)/I(N)}$ *vs.* $(N)/\Delta H_0$ for sodium naphthalenide in DME.

A second-order rate constant is determined from the slope of the curve at low concentration of added naphthalene.

A summary of the rate constants for the exchange for the various combinations of cation and solvent used in these experiments is given in Table I.

All the experiments summarized in Table I were at temperatures between 30 and 35°. Several experiments were performed with the lithium and potassium salts in tetrahydrofuran at −70° and one was performed with the sodium salt in THF at 60°. All showed no observable effects of temperature. Because our apparatus was not well suited for reliable measurements at these temperatures, a rough upper limit of 2600 cal. mole^{-1} was established for the activation energy.

The reasons for the dependence of rate on the nature of the cation are not clear to us. It will be noticed that the rate constant for the sodium salt in dimethoxyethane is much higher than for the potassium salt. The following experiments were performed in connection with this point. To a solution of potassium naphthalenide in 1,2-dimethoxyethane was added naphthalene at 1.3×10^{-2} *M*. This concentration produces little broadening for the potassium salt. To the solution containing potassium naphthalenide and naphthalene, a large excess (0.22 *M*) of sodium iodide was added. A barely perceptible broadening occurred. In another experiment naphthalene at 1.8×10^{-2} *M* was added to sodium naphthalenide at 0.96×10^{-3} *M* in DME to produce an easily observed broadening. To this solution 1.8×10^{-3} *M* potassium iodide was added. The spectrum reverted to the unbroadened spectrum of the potassium salt. This set of spectra is shown in Fig. 9.

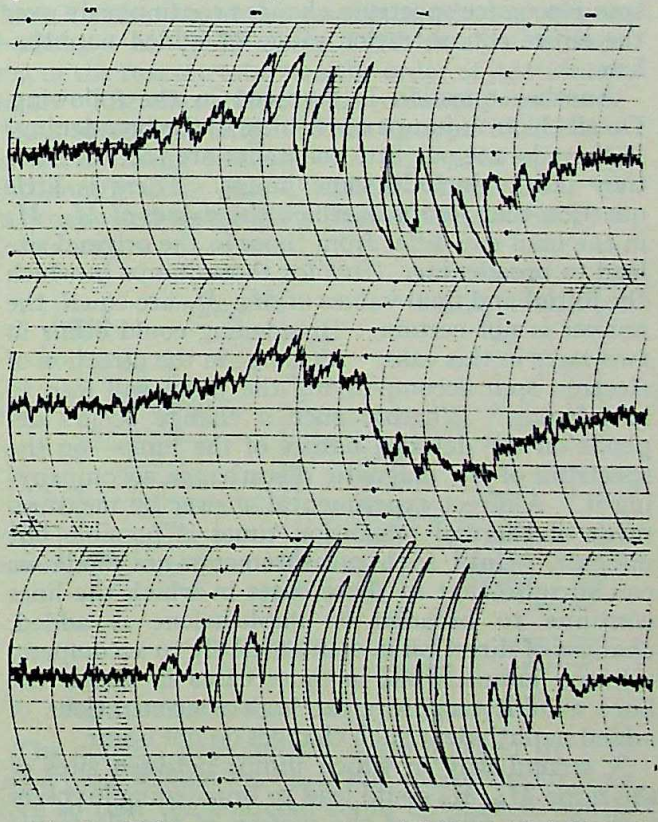

Fig. 9.—Spin resonance spectra of 0.96×10^{-3} *M* naphthalenide in DME: above, pure sodium salt; center, naphthalene added at 1.8×10^{-2} *M*; below, potassium iodide at 1.8×10^{-3} *M* added to solution which had given center spectrum.

The two experiments show that the state of the solution is independent of the order of adding of reagents. While other interpretations are possible, the experiments are consistent with the statement that the rapid exchange of the sodium salt proceeds through ion pairs and that the equilibrium constant for the reaction

$$Na^+C_{10}H_8^- + KI = Na^+I^- + K^+C_{10}H_8^-$$

is at least 10^4

TABLE I

RATE CONSTANTS FOR ELECTRON TRANSFER BETWEEN NAPHTHALENIDE ION AND NAPHTHALENE

Positive ion	Solvent	k (l. mole^{-1} sec.$^{-1}$)
K^+	DME	$(7.6 \pm 3) \times 10^7$
K^+	THF	$(5.7 \pm 1) \times 10^7$
Na^+	DME	$(1 +3 -0.7) \times 10^9$
Na^+	THF	$(1 +3 -0.6) \times 10^7$
Li^+	THF	$(4.6 \pm 3) \times 10^8$

There are a few points concerning interpretation of the results which may be further discussed. One involves the possibility that the formation of stable complexes between naphthalene negative ion and naphthalene is responsible for the observed phenomena. Such a possibility is contradicted by several observations. First, no observable change in the optical spectrum of naphthalenide occurs even in the presence of a thousand-fold excess of naphthalene. Second, if a stable complex were formed, a superposition of the electron spin resonance spectra of the complex and the uncomplexed species would be expected. No sign of such superposition is observed. Third is the fact that the electron spin resonance spectrum changes continuously over the entire concentration range of added naphthalene.

Another question is involved in the following. Do all electron jumps contribute to the broadening? If they do not our rate constants are too low since they fail to include some jumps. There is little question that jumps in which the values of M_α, M_β in the final site differ from those in the original site lead to broadening. But for those jumps in which the initial and final values of M_α, M_β are equal, the answer is not certain. Broadening could occur in two ways in this case. A change in the direction of electron spin accompanying the jump will lead to broadening. Whether such a change occurs depends on the detailed nature of the jump—on the spectrum of the magnetic disturbance accompanying it. A direct experimental answer by measurement of thermal relaxation times is possible but difficult. Until such measurements are made we can surmise that in those cases in which the lines continue to broaden as naphthalene is added, changes of direction in spin are likely to accompany electron jumps, while in those cases in which the lines exhibit narrowing at high concentrations of added naphthalene such changes do not occur.

A second way in which jumps between sites of the same M_α, M_β could lead to broadening involves a change in phase of the motion of the electronic moment without change in direction of spin. A classical description of the problem similar to one given by McConnell and Weaver[11] is the following. If the phase of the Larmor precession of the electron spin at some instant after the jump differs by an appreciable fraction of a radian from the value it would have had at that instant if the jump had not occurred, broadening results. If V_0 is the frequency in the site between which the jumps occur, V^* the average frequency in transit, and τ the time spent in transit, the condition for broadening is

$$\tau > \left| \frac{1}{V_0 - V^*} \right|$$

In the cases studied by us it is unlikely that $V^* - V_0$ would be greater than 10^8 or 10^9 cycles per second (50–500 oersteds). (A value of 10^9 cycles would correspond to a very severe magnetic perturbation during the transition.) Hence transit times of order of 10^{-9} to 10^{-8} second would be required for broadening. If such long times were spent in transit, an appreciable fraction of the electrons would always be in transit at the higher concentrations of added naphthalene. No sign of such behavior is found in the optical spectra of the solutions. Hence it appears that broadening associated with changes in phase of the motion of the electron spin during jumps between sites of the same M_α, M_β are not significant.

We may estimate the error in our rate constants if such jumps do not contribute to the broadening. For the eight protons in naphthalene there are 256 spin states. The lines at the high and low field extremes ($M_\alpha = M_\beta = \pm 2$) of the spectrum may each be achieved in only one of these ways, while the intense center line ($M_\alpha = M_\beta = 0$) may be achieved in seventy different ways. Thus 255 of the 256 electron jumps originating in one of the extreme lines terminate in a frequency different from the original one, while 196 of 256 jumps originating in the central line terminate in a different frequency. Use of the central line may underestimate the exchange rate by about 27%—not a very serious error in the present state of the measurements.

Comparison between exchange rates as measured by the line broadening method and those measured by the isotope tracer method would be very valuable. Because of the difficulties attendant upon handling the very reactive free radicals used in our experiment, and because of the rapid exchanges, a tracer method does not seem feasible. However, in certain other rapid exchanges, especially those studied by Wahl and his collaborators, it may be possible to study the reactions by both methods.

An Improved Microcatalytic Technique

BY W. KEITH HALL AND P. H. EMMETT*

RECEIVED OCTOBER 10, 1956

An improved new microcatalytic technique, capable of yielding reproducible catalyst testing data, is outlined. Data describing the utility of the method in a kinetic study of the catalytic hydrogenation of ethylene are presented, and advantages of the technique over conventional methods are discussed.

In a recent communication from this Laboratory,[1] a new microcatalytic technique was outlined. This technique involved the injection of gaseous or liquid hydrocarbon reactants into a carrying gas stream which was passing over a catalyst and then directly through a chromatographic column. The products of the reaction were measured by the usual chromatographic technique, by attaching a thermal conductivity apparatus to the exit of the column and recording the peaks corresponding to the reaction products on a recording potentiometer. In this previous work, modified and unmodified hypodermic syringes were used for the hydrocarbon injection. The hypodermic needles were inserted into the carrying gas stream by pushing them through rubber serum caps. While this technique is probably adequate for many studies, it has two serious drawbacks: the first of these is that the reproducibility obtainable is limited by the accuracy by which gases and/or the extremely small samples of liquid can be measured and transferred in hypodermic syringes; a second limitation is encountered in studies over catalysts of reduced metals (particularly of fairly low surface areas) where oxygen diffusing in through the serum cap may irreversibly poison the catalyst. The technique described in the present paper circumvents both of these difficulties and in addition provides a means of preparing synthetic blends that may be used either in calibration or in the actual catalytic studies.

The equipment developed in the present work is shown schematically in Fig. 1; the doser device comprises the upper left-hand (blocked-in) corner and is shown there in relation to the remainder of the system. With the stopcocks in the position shown (3 is open and 4 is closed), the helium carrying gas is pushing the measured slug of reactant gas (8 cc. in these experiments) out from between the stopcocks toward the catalyst. In this situation, the by-pass stopcock for the carrying gas (4) is in the closed position. By reversing the doser stopcocks (1 and 2) by 180°, the by-passed stream of reactant gas could be run through the doser (close 3), while in turn, the helium carrying gas would be by-passed (open 4). Thus by proper manipulation, measured volumes of the flowing synthesis gas could be trapped between the doser stopcocks and in turn carried over the catalyst by the stream of carrying gas. The volume between the stopcocks, in which the gas is trapped, was calibrated gravimetrically with mercury before the doser device was sealed into the system. By an obvious modification, the doser volume may be varied by making this part of the assembly interchangeable.

Provision was also made for evacuation of the measured volume and the filling of it with gas blends of known composition from a gas buret attached to a manometric system as shown in Fig. 1. This feature was especially convenient in calibration.

As an example of the utility and reproducibility of this equipment, data will be presented below for an experiment in which a mixture of 60% hydrogen–40% ethylene was passed over a copper–nickel alloy catalyst. These data comprise part of a study which will be reported in more detail elsewhere.[2] The slug of the gas mixture had a volume of about 8 cc. (NTP); the total catalyst surface area in the reactor tube was the order of one square meter. The chromatographic column was made from a seven foot length of one quarter inch stainless steel tubing packed with high area charcoal (Pittsburgh Coke and Chemical "Type B"). It was connected to the glass part of the system by a Kovar seal.

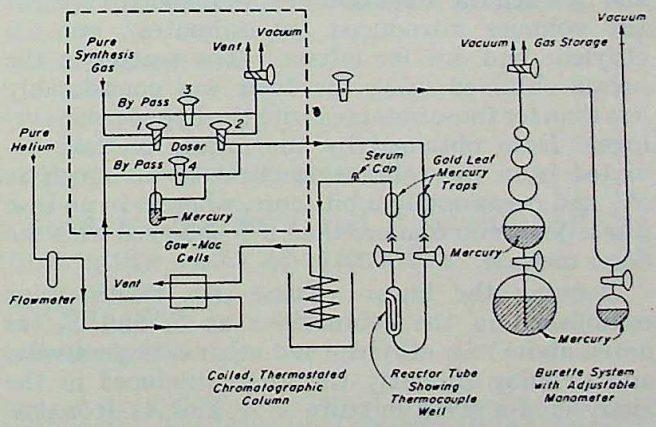

Fig. 1.—Flow sheet of microcatalytic system.

The column packing was accomplished by putting a plug of glass wool into one end of the straight piece so that the charcoal could be packed tightly into the column a little at a time while the tube was vigorously vibrated with an electric Vibra-tool. When the packing was completed, the upper end of the column was plugged with another piece of glass wool. The column was then formed into a coil which fit into a large Dewar flask where it was thermostated at 136°, using a conventional relay circuit. The exit end of the column was connected directly into the Gow–Mac thermal conductivity cell. It should be noted that the metered carrying gas passed through the other side of the Gow–Mac cell before reaching the doser.

An a.c. bridge circuit, developed and supplied by the Department of Instrumentation of the Mellon Institute, was used to link the output of the Gow–Mac cell to the unmodified Speedomax recording potentiometer. It proved to be both flexible and highly stable.

With reference to Fig. 1, the reactant gas was carried from the doser through the gold leaf mercury traps and over the catalyst. As the slug containing the reactant gases emerged from the catalyst, it passed directly over the charcoal chromatographic column and then through the Gow–Mac thermal conductivity cell.

The record obtained was, in effect, a plot of the concentration of hydrogen, ethylene and ethane passing out of the chromatographic column as a function of time. Quantitative measurements of the volume of the various components were obtained by integration of the peak areas using a planimeter. Calibrations to establish the area–volume relationships were made in several ways. First, ethylene and ethane were measured out separately or together in a hypodermic syringe and injected through the serum cap indicated in Fig. 1; the areas obtained from integration of the peaks obtained on the Speedomax record were plotted as abscissas against the volumes of gas injected as ordinates. Second, various gases of known compositions were used to fill the doser and the data obtained when these slugs were carried through the column were plotted on the same graph. The data obtained by both methods served to define two straight lines characterized by the slopes S_1 and S_2 when the areas obtained were plotted against the volumes introduced (as ordinates), one for ethylene and one for ethane. The scatter in the points obtained using the doser was considerably less than for those obtained with the hypodermic syringe. Data obtained by the former method deviated from the calibration curve by as much as 5% and occasionally a bit more, whereas in no case was a deviation of more than 2% observed with the doser method.

Defining the linear volume–area relationships established in the calibrations as S_1 and S_2 (as noted above) for ethylene and ethane, respectively, and defining similarly the areas produced in the analysis of a given mixture as A_1 and A_2, it is possible to write for the fraction ethane, r, in the mixture

$$r = S_2A_2/(S_1A_1 + S_2A_2) = A_2/[(S_1/S_2)A_1 + A_2] \quad (1)$$

When the doser is filled with a mixture of hydrogen and ethylene, and this slug is passed over the catalyst and partially converted, the percentage of ethane in the ethylene plus ethane mixture is a measure of the reaction rate. Thus equation 1 defines the reaction rate, r, which is sought. The ratio of the slopes of the volume–area calibration curves, S_1 to S_2, was found to be 1.012. It should be noted that this ratio would be expected to be less sensitive to uncontrolled external variables such as room temperature, atmospheric pressure, etc., than either S_1 or S_2 separately. It was found, however, that the calibrations were moderately sensitive to the flow rate of the gas, so that it was more convenient to design a series of experiments with a constant flow rate of approximately 40 cc. per minute.

The data in Fig. 2 exemplify the reproducibility of the data obtained in actual catalyst testing. In this expt., the catalyst was contained in the all-glass reactor tube shown in Fig. 1. The catalyst was reduced *in situ* with carefully purified hydrogen; the stopcocks for this are not shown in this schematic drawing. The catalyst was cooled from the reduction temperature of 250° in hydrogen, and then was flushed out with the purified helium carrying gas at the reaction temperature of −69.3°. The data shown in Fig. 2 were then obtained by passing 15 successive slugs of synthesis gas over the catalyst and permanent chromatographic tracings from the Speedomax were obtained. The temperature of the thermostatting cryostat was changed between successive slugs according to a schedule reflected in Fig. 2, where lines connect points taken at the same temperature. The cumulative errors in these data are due not only to the errors in the calibration data, but also to those in reproducing the temperatures and to those in the inherent reproducibility of the catalyst. When this is taken into account, the data shown are gratifying.

If points are picked off the curves shown in Fig. 2 at any given slug number and plotted against the reciprocals of the absolute temperatures, a conventional activation energy curve is obtained. Figure 3 was constructed in this manner from the data for the twelfth slug.

In the course of the experimental work[2] over an entire series of catalysts similar to that outlined above, some additional advantages were discovered. These are listed separately below.

(1) When this technique was employed, the glass reaction vessels became nearly isothermal reactors. With the 8-cc. slugs which were passed over the catalyst, even at complete conversion no more than two calories of heat could be liberated. In attempts at steady-state reaction, it was found that at even moderate conversions it was difficult to control the reaction, but in these same tubes, using the microcatalytic technique, there was no evidence of local overheating of the catalyst.

(2) Semi-quantitative estimates of the results obtained by passing a single slug over the catalyst could be made before the next slug was sent over the catalyst. Experimentally this was found to be a great advantage because in a single experiment the information obtained on the first slug could be used immediately to establish conditions for the second, and so on.

(3) The technique was found useful for determining the effects of small amounts of poisons. In this case, data such as shown in Fig. 2 would not be independent of slug number but would constitute a family of curves, falling with slug number.

(4) Similarly, the technique was quite useful, for studies involving changes in activity occurring as catalysts are lined out (brought into a steady state).

(5) With obvious modifications, the same equipment could be used to study steady-state reaction

conditions. In this case, a stream of synthesis gas would be passed over the catalyst and the doser would be used to collect measured volumes of the tail gas. This in turn would be carried through the chromatographic column as before, so that most of the advantages listed above would be applicable.

(6) In the present work, adsorption chromatography[3-6] was used because it was most convenient in dealing with the low molecular weight gases of interest. Vapor phase chromatography[5-11] would be preferable for studies involving molecules of higher molecular weight.

Capacity of the Electrical Double Layer between Mercury and Aqueous Sodium Fluoride. II. Effect of Temperature and Concentration

BY DAVID C. GRAHAME

RECEIVED NOVEMBER 12, 1956

The differential capacity of the electrical double layer between mercury and aqueous solutions of sodium fluoride has been measured at five different temperatures and four different concentrations. The results are in agreement with a theory previously proposed. The results also provide several clues to the anomalous behavior of the electrical double layer and suggest a new theory according to which the rise in the capacity on the *anodic* side of the potential of the electrocapillary maximum is attributed to electrostriction. The "hump" is attributed to the formation of a pseudo-crystalline semi-rigid layer through which anions pass only with difficulty, but without activation energy. The solvent next to the metal never achieves a state of free rotation comparable to that which it enjoys in the bulk of the liquid, which is offered as a partial explanation for the fact that the dielectric coefficient of the substance making up the inner layer is so much lower than that of pure water.

Introduction

The fluoride ion is unique among the univalent anions so far investigated in that it exhibits little or no specific adsorption on mercury even when the latter is positively charged.[1-3] This makes it particularly useful as a tool for studying the properties of the electrical double layer on mercury, since it eliminates the most complicating factor.

The choice of a positive ion is dictated largely by convenience, since monatomic cations are never observed to be chemisorbed on mercury. The sodium ion has several advantages for this investigation as follows: (1) its mobility in water is nearly the same as that of the fluoride ion,[4] which tends to reduce or eliminate liquid junction potentials between two concentrations of aqueous sodium fluoride, or between sodium fluoride and potassium chloride in solution. (2) Unlike KF and NH_4F, so-

dium fluoride solutions in water do not attack Pyrex glass rapidly. (3) Sodium fluoride is much easier to purify than either KF or NH_4F. It can be handled in Pyrex vessels, as just indicated, and its solubility in water is about right for efficient recrystallization. Because it has nearly zero temperature coefficient of solubility, it has been necessary to evaporate the water solutions in a vacuum desiccator, an operation which usually produced large clear crystals which could then be dried and weighed prior to making up the desired solutions.

General Considerations.—It has been shown previously[2] that the capacity of mercury in contact with aqueous solutions of sodium fluoride at 25° can be adequately represented by a combination of the Gouy–Chapman theory and an assumption to the effect that the differential capacity of the inner region of the electrical double layer (the region between the metal and the plane of closest approach of the non-adsorbed ions, called by Overbeek the Gouy plane) is a function of the electronic charge on the metal but not of the concentration of the ions in the solution. The capacity of the inner region of the double layer will be denoted C^0. It is well known that the nature of the cation has only a small effect upon electrocapillary properties, so long as the cation is monatomic. The effect upon C^0 of a change of temperature is dealt with in the present paper. The effect of changing the solvent (from water to methanol) has been reported elsewhere.[3] It is found that in methanol the above-mentioned theory of the electrical double layer works very well, and that the capacity C^0 changes with potential in a manner which is qualitatively similar to that found for water solutions at elevated temperatures. In all cases C^0 goes through a pronounced minimum when plotted as a function of the potential or of the surface charge density q, and in methanol solutions there is no trace of the "hump" which is so characteristic a feature of differential capacity curves of mercury in contact with aqueous solutions at room temperature.

Experimental Details

The experimental procedure was the same as that described in part I.[2] For measurements at elevated temperatures, the solution was jacketed by a stirred water-bath of the desired temperature. For measurements at 0°, the jacket of the cell was packed in ice, covered with a minimum of water, and stirred gently with a stream of air bubbling up through the mixture.

The reference electrode was a normal calomel electrode held at 25°. This is better practice than changing the temperature of the reference electrode. The uncertainty in the absolute value of the potential is of no consequence, since no use is made of the *absolute* value of the recorded potential.

The mode of purification of the sodium fluoride has been mentioned above. Solutions were made up in conductivity water of specific conductance 1.0×10^{-6} or better. Special care was taken to prevent the contamination of the fluoride solutions by chloride ions from the calomel electrode. This is of particular importance in the present work because the chloride ion is chemisorbed on positively charged mercury.

The potential of the electrocapillary maximum (e.c. max.) was found by the drop weight method described earlier (method III of ref. 5) or from the potential of the capacity minimum in rather dilute ($\sim$0.01 N) solutions.[6] The latter method is somewhat more reliable in practice.

(5) D. C. Grahame, R. P. Larsen and M. A. Poth, This Journal, 71, 2978 (1949).

(6) To be precise about this matter, it was not the capacity minimum which was used but the minimum in the C^0–E curve, part of the double layer, C^d, as determined from an analysis of the capacity curves for 0.01 N solutions. C^d goes through a minimum when dC/dE is the same as dC^0/dE. The latter is known from measurements in more concentrated solutions, as described in the text.

(7) Tables of values corresponding to these figures, and also tables of values of q, the surface charge density, will be printed up separately and will then be available on request.

Results and Discussion

The differential capacity of the electrical double layer between mercury and aqueous solutions of sodium fluoride is shown as a function of potential, temperature and concentration in Figs. 1–5.[7] From differential capacity measurements made on 0.795 N NaF (data not shown), values of C^0 as a function of the surface charge density, q, have been computed. The method of computation is described in paper I.[2] In brief, q is found by integrating C (the observed differential capacity) against E (the observed potential), the constant of integration being fixed by noting that $q = 0$ at the potential of the e.c. max. The capacity of the diffuse part of the double layer C^d is known from Gouy–Chapman theory (see ref. 3 for the explicit equation most readily applicable), and the capacity of the inner region, C^0, is found by regarding the observed capacity C as the series capacitance of C^d and C^0. That is to say

$$1/C = 1/C^d + 1/C^0 \qquad (1)$$

This equation may be regarded as a definition of C^0. It is derived from more theoretical considerations in another place which in point of logic, therefore, give physical meaning to the C^0 defined by the equation.

The results of the computation are shown in Fig. 6. The first point to be noted in Fig. 6 is the convergence of the curves at the capacity minimum. This observation suggests and probably requires the assumption of complete dielectric saturation of the inner region at the point of convergence. To the right of the point of convergence (*i.e.*, on stronger cathodic polarization), the curves remain sensibly coincident in spite of the very considerable increase in the capacity. There is hardly room for doubt that this coincidence results from dielectric saturation of the inner region over this whole range of potentials in question.

To the left of the point of convergence the separation of the curves is also consistent with this interpretation. The capacity is lower at the higher temperature, as expected, and the ratios of the capacities at, say, $q = -4$ μcoul./cm.^{2} are about equal to the ratios of the dielectric constants of water at the various temperatures. No precise agreement is to be expected.

The folding over of the low temperature curves is manifestly related to the "hump" which forms so conspicuous a part of the differential capacity curves of most electrolytes in water. The results show that it is not a consequence of the specific adsorption of the anion, as was previously informally supposed, since the beginning of the hump is clearly observed at 25°, where specific adsorption of fluoride ions is surely absent.

Further evidence to the effect that specific adsorption is not responsible for the hump comes from the observation that the hump in solutions of

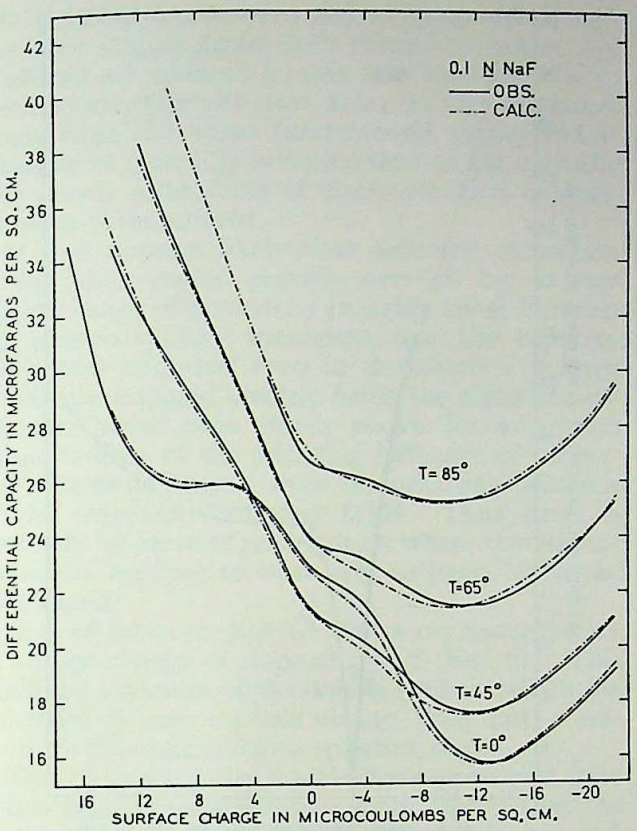

Fig. 1.—Observed and calculated values of the capacity of the electrical double layer between mercury and 0.1 *N* solutions of sodium fluoride at various temperatures. Calculated values depend upon measurements made with 0.8 *N* NaF solutions at same temperature.

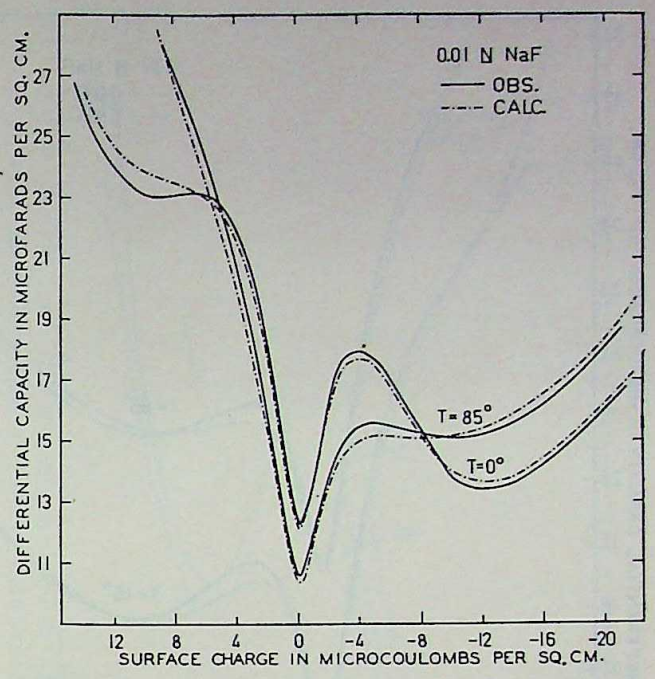

Fig. 2.—Observed and calculated values of the capacity of the electrical double layer between mercury and 0.01 *N* solutions of sodium fluoride at two temperatures.

chlorides vanishes above about 85°[8] although the specific adsorption of the ion is still strong, as evidenced by comparison of the capacity curves with those of fluorides.

A clue to the cause of the "hump" is furnished by the observation that at values of q more positive than about 6 μcoulombs/cm.^{2} the capacity of the inner region is larger at high temperatures than at low (Fig. 6). This means that comparatively weak forces (sufficient to be influenced by the *average* kinetic energies of the ions or molecules) are involved. In the absence of specific adsorption, the only two ways of increasing the capacity per unit area of the inner region are (1) increasing the dielectric coefficient of the region and (2) decreasing its thickness.

It is difficult to assess the dielectric coefficient of the inner region without knowing either its field strength or its thickness, but an increase with temperature of dielectric coefficient is seemingly unknown in any other context. Moreover, the comparatively normal variation with temperature of the dielectric coefficient to the right of the hump makes it unlikely that the dielectric coefficient behaves so very abnormally elsewhere.

A much more plausible explanation of the phenomena observed is found by exploring the second possibility, namely, that the thickness of the inner region may increase with decreasing temperature, a statement which immediately brings to mind the possibility that the surface may be covered with what the author has called[9] a "pseudo-crystalline ice-like" layer of solvent. The expression "ice-like" is not to be interpreted literally, since there is no assurance that the layer is hydrogen bonded. The significant property of the layer, and the only one for which we have any experimental evidence, is its ability to exclude anions, some more than others. With all these restrictions in mind, it is still convenient to speak of an ice-like layer and to refer to the theory as the ice-layer theory. A more accurate description would be to speak of the anion-excluding-layer theory.

The "ice-like" layer must have the property of "melting," not abruptly, like ice, but gradually, like tar. This property is indicated by the *gradual* disappearance of the hump as the temperature is raised (Fig. 6). The layer must also have the property of excluding certain anions, such as nitrate, more easily than it excludes others, such as fluoride. This is evident from the curves shown in Fig. 7, where even at 89° the "hump" has not completely disappeared.

It is natural to assume that the "ice-like" layer is composed of water molecules oriented with their oxygen atoms weakly chemisorbed to the positively charged mercury. This is a form of dielectric saturation, of course, and suggests that the rise of C^0 on strong anodic polarization may have the same cause as the rise of C^0 on strong cathodic polarization. The latter can be explained as the result of electrostriction compressing the solvent and making the inner region thinner.[10]

(8) D. C. Grahame, unpublished results.

(9) D. C. Grahame, *J. Chem. Phys.*, **25**, 364 (1956).

(10) In ref. 3 the author attributed this effect to the increase in the dipole moment of the solvent molecules in the high field. This now seems to be a concurrent but less important effect than the simple compression of the dielectric by the field. The compressed dielectric allows the ions to move closer, thereby increasing the capacity of the inner layer. Macdonald (*J. Chem. Phys.*, **25**, 364 (1956)) takes the position that the ions themselves compress the solvent.

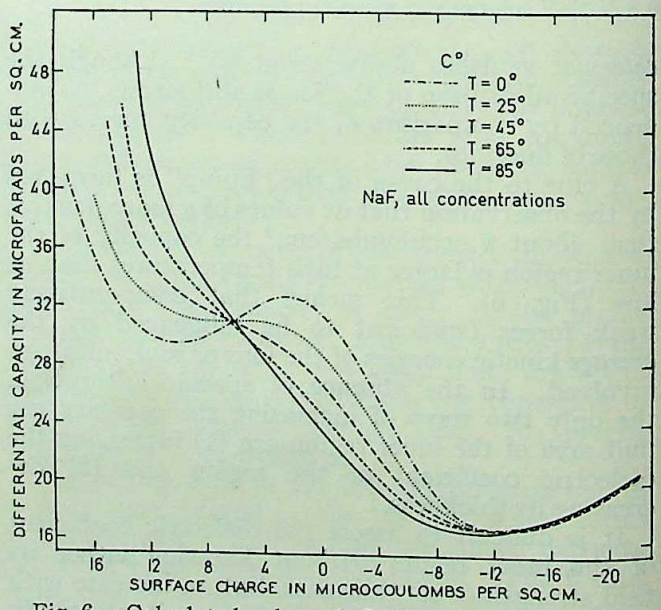

Fig. 6.—Calculated values of C^0, the differential capacity of the inner part of the electrical double layer, between mercury and aqueous solutions of sodium fluoride at several temperatures. Calculations made from data obtained with 0.8 *N* solutions.

Considerable support for the view that electrostriction is largely responsible for the capacity rise on *both* branches of the curve (and in the absence of specific adsorption, which overwhelms the effect in question on the anodic branch) is found in data already presented on the capacity of the double layer in methanol.[3] Here the "ice-layer" is absent and the compressibility of the solvent is large (a point already made by Macdonald[11]), with the re-

sult that the curves are nearly symmetrical and rise very steeply from their minimum values. It is almost self-evident in this case that the rise in the capacity on the two sides of the minimum stems from the same fundamental cause, and it seems to be generally accepted that on the cathodic side this is some form of electrostriction or compression of the solvent.

It now appears likely that dielectric saturation of the inner region prevails over all but a very limited range of potentials (roughly those between the electrocapillary maximum and the capacity minimum) and that even in the absence of large externally imposed electric fields the dielectric coefficient never rises much above its saturation value because of the orienting influence of "chemical" forces as distinct from the orienting influence of the externally imposed fields. Thus there is probably no state of polarization where the solvent molecules are free to turn over as freely as in the bulk liquid.

It is of interest that C^0 shows no discontinuity or abrupt change of slope at $q = 0$ (Fig. 6). This again fits a picture of the double layer in which the potential of zero surface charge does not correspond to a condition of no orienting forces.

The concept of the double layer presented here differs from that published a year ago[3] in that the "natural" field of the metal is no longer called upon to account for the lack of a maximum in the plot of C^0 *vs.* q. The role of the "natural" field is now left unspecified; it may well turn out to be of no particular importance. The change in the potential of the electrocapillary maximum when the solvent is changed may now be attributed, as formerly,[12] to changes in the amount of dielectric orientation and to changes in the dipole moment of the solvent molecules.

What emerges from the above considerations is a qualitative but reasonably self-consistent picture of the electrical double layer. The "ice-layer" turns out to be a layer of oriented solvent molecules (not hydrogen bonded to one another) which excludes large anions at room temperature and even small anions (F^-) at lower temperatures. The "hump" in the capacity curves marks the formation of the layer, and its disappearance at elevated temperatures marks the "melting" of the layer. Electrostriction is responsible for the rise in the capacity both on the anodic and cathodic ends of the curve, although relaxation of dielectric saturation also makes a contribution to this rise over a limited range of potentials, as mentioned above.

The Effect of Concentration.—It has already been stated that at 25° C^0 was found to be a function of the surface charge density, q, and not of the concentration. It was of interest to see to what extent this result holds at higher and lower temperatures and also how the potential of the electrocapillary maximum varies with temperature.

The most satisfactory method of testing the constancy of C^0 is to calculate the capacity of the whole double layer, using eq. 1 and diffuse double layer theory in the classical manner, and then to compare the calculated and observed results.

(12) A. Frumkin, *Colloid Symp. Ann.*, **7**, 89 (1930).

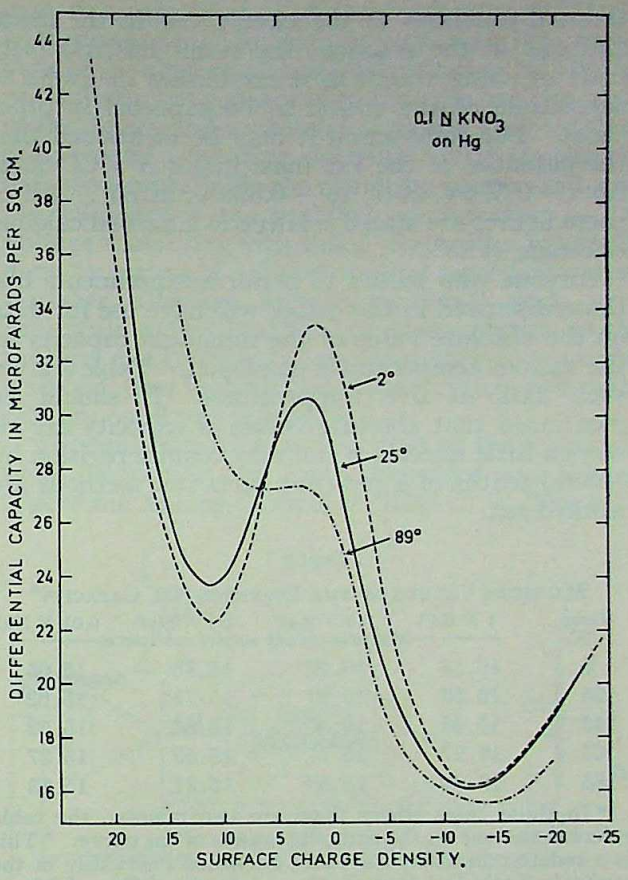

Fig. 7.—Observed values of the differential capacity of the electrical double layer between mercury and aqueous 0.1 N solutions of potassium nitrate at three temperatures.

This procedure has the advantage that it does not magnify errors in the observations or errors in the theory of the diffuse double layer in such a way as to produce uninterpretable results. The results of the calculations are shown in Figs. 1–5. The agreement is as good as one could expect, bearing in mind that the accuracy of the measurements falls off as one goes away from room temperature. Where the disagreement is systematic, this is attributable to small errors in the measurement at the highest concentration, which affects all the other results at that temperature.

The relatively good agreement between theory and experiment at 0° provides the first evidence that the fluoride ion is not adsorbed (strongly) on positively charged mercury at that temperature. It was self-evident that the adsorption at temperatures above 25° would not exceed that at 25°, a fact which these observations tend to confirm.

There is always some disagreement between theory and experiment on the anodic end of the curves. This disagreement is no worse at low temperatures than at high temperatures, a result which indicates that specific adsorption of the fluoride ion is not responsible for the disagreement.[13]

The potential of the e.c. max. varied from −0.48 v. at 0° to −0.44 v. at 85°.[14] Since there are two

(13) If fluoride ion were specifically adsorbed on positively charged mercury, the adsorption would certainly be expected to diminish at elevated temperatures.

(14) This result is independent of concentration within the limits of error of the measurements. At 45° the value is −0.46 v. and at 65° it is −0.455 v.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized By Arya Samaj Foundation Chennai and eGangotri

thermal junctions in the circuit, one in the metal and one in the solution, the result has relatively little meaning except as it establishes the order of magnitude of the effects to be expected in other cases. For comparison it may be mentioned that the potential of the e.c. max. in 1.0 *N* KCl varies from −0.574 v. at 0° to −0.522 v. at 85°. All of these figures are stated relative to a normal calomel electrode at 25°.

Anyone who wishes to perform experiments like those discussed in this paper will have use for data on the absolute value of the minimum capacity at the various temperatures employed. Table I gives such data at five temperatures. It should be mentioned that absolute values of capacity are always a little uncertain and may require revision by several tenths of a per cent. as better methods are worked out.

TABLE I

MINIMUM VALUES OF THE DIFFERENTIAL CAPACITY[a]

Temp., °C.	1 *N* KCl	0.8 *N* NaF	0.1 *N* NaF	0.01 *N* NaF
	Microfarads per square centimeter			
0	16.58	16.00	15.76	15.65
25	16.50	15.97	15.74[b]	15.62[b]
45	16.43	15.90	15.66	15.52
65	16.27	15.77	15.52	15.37
85	16.08	15.56	15.31	15.13

[a] In those cases where there are two minima, the table refers to the one on the cathodic branch of the curve. [b] This is a redetermination of a value published previously in the author's Technical Report No. 14 to the Office of Naval Research, dated February 18, 1954.

It is a great convenience in this work to have values of the surface charge density, q, at some sufficiently cathodic potential that the effect of the anion is virtually eliminated. For this purpose Table II gives values of q at a potential of −1.205 v. This potential is sufficiently cathodic for all but the most strongly adsorbed anions (I^-, SCN^-, $S^=$) and is convenient for the integration of capacity data by the trapezoidal rule using potential intervals of 0.01 v. These data, like those in Table I, are a little uncertain in absolute value but give correct results for the potential of the e.c. max. when used together.

TABLE II

SURFACE CHARGE DENSITY, q, AT POTENTIAL AT −1.205 VOLTS[a]

Temp., °C.	1 *N* KCl	0.8 *N* NaF	0.1 *N* NaF	0.01 *N* NaF
	Microcoulombs per square centimeter			
0	14.60	14.20	13.58	12.73
25	14.22	13.73	13.03	12.14
45	13.86	13.49	12.79	11.83

85	13.28	12.86	12.10	11.14

[a] All potentials measured relative to a normal calomel electrode at 25°.

Conclusion

The investigation of the capacity of the electrical double layer in aqueous solutions of sodium fluoride in contact with mercury at several temperatures has provided a clue to the behavior and structure of the double layer. This has permitted the formulation of a theory which is at least qualitatively understandable and for which the next step will be to provide a quantitative expression. The author wishes to make it clear that he is merely *proposing* a theory and is not yet prepared to underwrite it.

Acknowledgments.—The author is grateful to Professor Earle S. Scott for stimulating discussions leading to the formulation of the theory proposed in this paper. He is indebted to Miss Vera Brewus for making many of the measurements and to the Office of Naval Research for the support of the project of which this work forms a part.

Primary Quantum Yield for the Dissociation of Iodine Molecules in Carbon Tetrachloride Solution and the Rate Constant for the Recombination Reaction[1]

BY R. L. STRONG AND J. E. WILLARD

RECEIVED NOVEMBER 24, 1956

The quantum yield for the dissociation of iodine molecules in carbon tetrachloride solution at room temperature by a continuous spectrum of visible light has been found to be 0.13 ± 0.04. The determination has been made by the flash photolysis technique with a d.c. analog computer used to aid in correcting for the fact that the duration of the flash is appreciable relative to the time of recombination of I atoms. The recombination rate constant obtained is $k = 5.7 \pm 0.5 \times 10^9$ liters mole^{-1} sec.$^{-1}$ where $d[I_2]/dt = k[I]^2$. The relative extinction coefficients of iodine in the gas phase and in carbon tetrachloride solution and the visible spectrum of the xenon flash lamp have been determined.

Introduction

When a gaseous iodine molecule in the presence of a foreign gas absorbs a quantum of visible light, it always dissociates.[2] If, however, it is surrounded by a "cage" of solvent molecules, the atoms may lose their energy to the cage walls and immediately recombine[3] or they may recombine by diffusion after having escaped only a molecular diameter or so from each other.[4]

Knowledge of the quantum yield for the escape of such atoms from each other is relevant in interpretations of the over-all quantum yields of photochemical reactions, in reasoning about caging ef-

fects which may occur in the tracks of ionizing radiations[5a] and atoms activated by nuclear processes,[5] and in considerations of diffusion controlled kinetics[6] in general.

In principle this quantum yield can be determined by flash photolysis experiments in which the rate of recombination of iodine atoms in a solution is measured by the change in transmittance of an analyzing beam immediately after the iodine has absorbed a known number of quanta from an intense short-duration flash. Extrapolation of the recombination curve (on the straight line plot of $1/[I]$ *vs.* time) to zero time would give the concentration of iodine atoms initially produced (and escaping parent recombination) if the flash were instantaneous. In practice the rates of recombination in solution are so fast, and minimum flash times so long, that appreciable recombination occurs before the flash is over, thus invalidating a simple extrapolation and making it necessary to solve for the quantum yield ϕ in the equation

$$-d[I_2]/dt = (1/2)(d[I]/dt) = \phi(I_a) - k[I]^2 \quad (1)$$

where I_a is the rate of light absorption, which varies with time. We have done this with the aid of an analog computer.

The method employed here is more quantitative than that employed for similar determinations by Marshall and Davidson[7] and differs radically in approach from that used by Lampe and Noyes.[8]

Methods and Results

Equipment and Materials.—The flash photolysis equipment used in the present work has been described elsewhere.[9]

The carbon tetrachloride solvent was Mallinckrodt AR low sulfur grade further purified by degassing and distilling through a phosphorus pentoxide train on the vacuum system used for filling the reaction cell. Mallinckrodt AR grade iodine was further purified by grinding with reagent grade potassium iodide followed by sublimation from the mixture through phosphorus pentoxide on the vacuum system.

Solution of the Differential Equation.—The value of ϕ in eq. 1 can be determined with the aid of a d. c. analog computer if I_a (the rate of light absorption in quanta cc.$^{-1}$ sec.$^{-1}$) is known as a function of time, if k has been determined, and if the iodine atom concentration is known at time t (these determinations will be described below).

In a d. c. analog computer, voltages are made to behave in a manner analogous to that prescribed by the variables and coefficients in the given differential equation.[10] To accomplish this, several computing elements, each consisting of a very high gain d. c. amplifier modified by input and feed back components in such a way that its output voltage is some mathematical function of the input voltage, are connected so that the various parts of the differential equation are represented by operations in the computing elements. With time as the independent variable the computer is operated, and the solutions of the problem are recorded as the voltage variations with time. Recording is usually done by means of a direct-writing recording potentiometer, although some computers[11] work on a time scale so fast that the complete solution to the problem can be repeated automatically many times a second, thus making visual observation on a cathode-ray oscilloscope possible.

The computer setup represented by the schematic block diagram in Fig. 1 was assembled on a Reeves Electronic Analog Computer (REAC).[12] The voltage corresponding to $d[I]/dt$ was treated as if it were known and was fed into the integrator computing element. Its output, $-[I]$ (each electronic integration results in a change of sign), was applied to a squaring unit that consisted of a servodriven potentiometer. The voltage corresponding to $-[I]^2$ was finally multiplied by the constant $2k$ by means of a potentiometer and amplifier, giving $-2k[I]^2$. This was fed into the integrator input along with the light intensity function (I_a) multiplied by 2ϕ. As defined by the differential equation, the sum of these two quantities ($2\phi I_a - 2k[I]^2$) is equal to $d[I]/dt$, which has been assumed to be the input to the integrator. Thus the voltage corresponding to $[I]$ must vary as prescribed by the differential equation. The value for ϕ was obtained by recording the voltage representing $[I]$ as a function of time (output 1) and adjusting the potentiometer (2ϕ) until

the voltage corresponded to the experimentally determined value of the iodine atom concentration at 150 microseconds.

The change in the relative light intensity of the flash as a function of time is shown in Fig. 2. This curve was adequately generated by a cathode-ray function generator, or photoformer,[13] in which an opaque mask shaped like the function is placed over the lower portion of a cathode-ray screen. As the electron beam sweeps across the tube face, an applied bias voltage on the vertical plates of the CRT tends to force the spot upward away from the mask. As soon as it emerges from behind the mask, however, a photocell mounted in front of the screen applies a voltage on the vertical plates phased so the beam is forced downward toward the mask. The net effect of the two voltages is that the beam will tend to travel just below the edge of the mask. Assuming that the voltages on the CRT plates are proportional to the deflections, the voltage on the vertical plates is forced to vary as a function of the voltage on the horizontal plates, the function being determined by the shape of the mask boundary. This voltage was fed into the computer as representative of I_a, and observed at output 2 (Fig. 1).

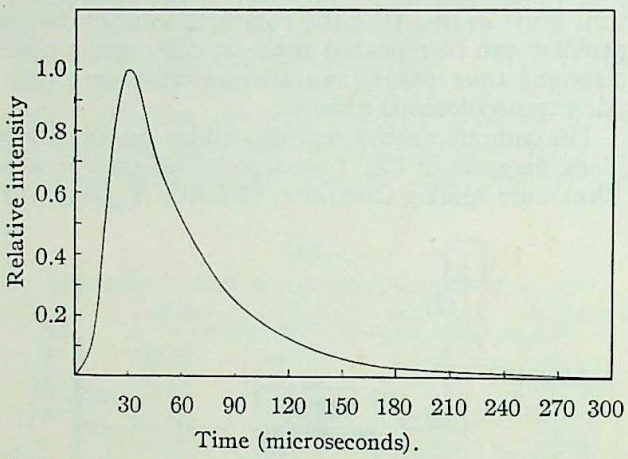

Fig. 2.—Relative light intensity from the flash lamp as a function of time.

The independently variable quantity in a machine such as the REAC is time (τ). The dependently variable quantities are voltages and potentiometer settings, designated below as capital letters. By convention, 100 volts = 1 computer unit. The following transformation equations were used to transform the variables in eq. 1 to machine variables: $\tau = \alpha t$; $Y = a_y[I]$; and $Z = a_z I_a$, where α, a_y and a_z are scale factors. Equation 1 thus becomes

$$dY/d\tau = 2\phi Z(a_y/\alpha a_z) - 2kY^2/\alpha a_y \qquad (2)$$

in terms of machine variables. The time scale factor (α) is numerically equal to the number of seconds representing the unit of the independent variable under consideration. In this case it was desirable to let the machine operate for 15 seconds corresponding to 150 microseconds problem time, so that $\alpha = 10^5$. A maximum rate of light absorption by the iodine in carbon tetrachloride was found to be 1.2×10^{20} quanta cc.$^{-1}$ sec.$^{-1}$ (as discussed below); the function generator was adjusted so that its output at the maximum of the curve was 0.75 computer unit (75 v.), giving $a_z = 6.25 \times 10^{-21}$ (computer units) (quanta cc.$^{-1}$ sec.$^{-1}$)$^{-1}$. Assuming a maximum iodine atom concentration of less than 10^{15} atoms cc.$^{-1}$, a value for a_y of 10^{-15} (computer units) (atoms cc.$^{-1}$)$^{-1}$ was chosen so that $Y = 1$ computer unit when $[I] = 10^{15}$ atoms cc.$^{-1}$.

Experimentally, it had been found (see Table II) that $k = 5.7 \times 10^9$ liters mole^{-1} sec.$^{-1}$ $= 9.5 \times 10^{-12}$ cc. molecule^{-1} sec.$^{-1}$, and $[I] = 9.2 \times 10^{-7}$ moles liter^{-1} $= 5.54 \times 10^{14}$ atoms cc.$^{-1}$ at 150 microseconds. Equation 2 then becomes $dY/d\tau = 3.2\phi Z - 0.19Y^2$ and $Y = 0.554$ computer unit (55.4 v.) at 150 microseconds. The scale factor potentiometer corresponding to 3.2ϕ was varied until this voltage was obtained, resulting in a value for ϕ of 0.13. A maximum error of ± 0.04 was determined by feeding into the computer, maximum and minimum experimental values for k and the iodine atom concentration at 150 microseconds, and estimated maximum and minimum values for the light intensity function.

As shown by the recording for Y *vs.* τ, the iodine atom concentration reached a maximum value of *ca.* 1.4×10^{-6} mole per liter at 65 microseconds, although the light intensity from the flash lamp was at a maximum at only 30 microseconds.

Rate of Light Absorption.—The number of quanta absorbed from a flash of the flash lamp by the iodine in a Pyrex cell 10 cm. long and 25 mm. i.d. containing gaseous iodine at 1.07×10^{-5} mole per liter was 3.49×10^{15} per cc. This was determined by assuming a yield of two iodine atoms per photon absorbed and extrapolating a plot of $1/[I]$ back to the time of initiation of the flash,[14] a valid procedure since the time required for atom recombination in the *gas* is long compared to the duration of the flash. On the basis of the fact that this value is the area enclosed by a curve identical in shape to that shown in Fig. 2, it can be shown by graphical methods that the peak rate of light absorption in the gas phase cell was 5.74×10^{19} quanta cc.$^{-1}$ sec.$^{-1}$.

To find the light absorption by a carbon tetrachloride solution of iodine in a cell placed in the same position and flashed with the same intensity as the gas cell, comparison was made of the extinction coefficients of gaseous and dissolved iodine (Table I), and the spectral distribution of the light from the flash lamp (Fig. 3) was determined. The experimental comparison was necessary because there are large inconsistencies in the extinction coefficient

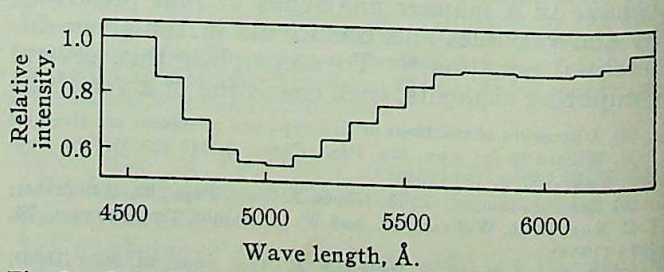

Fig. 3.—Spectral distribution of light from the flash lamp.

values in the literature. Measurements of optical density as a function of wave length on gaseous iodine (using a Beckman DU spectrophotometer) were compared with similar measurements on the same iodine dissolved in a weighed amount of carbon tetrachloride. By assuming a value of 905[8,15] for the extinction coefficient of iodine in carbon tetrachloride at 5200 Å., its wave length of maximum absorption, the concentration in the carbon tetrachloride solution and the extinction coefficients at the other wave lengths were calculated.[14]

At wave lengths greater than 4995 Å. the spectrum of iodine gas consists of bands rather than a continuum[2] even at an argon pressure of 710 mm. Therefore, relatively large fluctuations in the measured values of the extinction coefficients were obtained at the longer wave lengths because of the use of a narrow spectrophotometer effective band width.

The relative intensity of the flash lamps[9] (containing 70 mm. of Xe and flashed at 27 μf. and 9000 v.) for successive 100 Å. bands from 4400 to 6500 Å. shown in Fig. 2 was determined with the aid of an Applied Research Laboratories 150 cm. grating spectrograph and an ARL projector densitometer.[14,16,17]

The rate of radiant energy absorption may be expressed as $I_a' = I_0(1 - 10^{-\epsilon\, cd}) = I_0(1 - e^{-2.3\epsilon\, cd})$ in units of quanta traversing unit area per sec. Expanding the exponential term in a series gives $(1 - e^{-2.3\epsilon\, cd}) = 2.3\epsilon\, cd - (2.3\epsilon\, cd)^2/2! \ldots$; for small absorption ($\epsilon\, cd << 1$) the higher power terms may be neglected, so that $I_a' = I_0(2.3\epsilon\, cd)$. The average number of quanta absorbed per unit volume per second, I_a, is given by $I_a = (A/V)I_0(2.3\epsilon\, cd)$, where A is the area of the cross-section of the radiation beam and V is the volume of the vessel, (A and V will cancel out when the comparison is made between the light absorbed by the gas and solution cells under identical experimental conditions, assuming no differences in incident light at the interface surfaces.) It follows, then, that

$$(I_a)_{gas} \cong (A/V)\, 2.3[I_2]_{gas}\, d\Sigma(I_0)_\lambda\, (\epsilon_{\lambda,\,gas})(\lambda/hc)$$

$$(I_a)_{soln} \cong (A/V)\, 2.3[I_2]_{soln}\, d\Sigma(I_0)_\lambda\, (\epsilon_{\lambda,\,soln})(\lambda/hc)$$

where λ is the average wave length of a 100 Å. band, and λ/hc is the conversion factor from ergs to quanta at each wave length. Therefore

$$(I_a)_{soln} = (I_a)_{gas} \frac{[I_2]_{soln}\, \Sigma(I_0)_\lambda\, (\epsilon_{\lambda,\,soln})\lambda}{[I_2]_{gas}\, \Sigma(I_0)_\lambda\, (\epsilon_{\lambda,\,gas})\lambda}$$

Average values for the extinction coefficients for each 100 Å. band for iodine gas and iodine in carbon tetrachloride solution were calculated from the extinction coefficients measured in this work (Table I) and values of $(I_0)_\lambda$ were determined from Fig. 3. A value of 1.22 was calculated for the ratio: $(\Sigma (I_0)\, (\epsilon_{\lambda,\,soln})\lambda)/(\Sigma(I_0)_\lambda(\epsilon_{\lambda,\,gas})\lambda)$. The concentration of iodine in the carbon tetrachloride cell was 1.84×10^{-5} mole per liter, and the concentration of iodine in the gas phase cell (argon pressure = 532 mm.) was 1.07×10^{-5} mole per liter, so that the maximum rate of light absorption by the iodine in carbon tetrachloride was 1.2×10^{20} quanta cc.$^{-1}$ sec.$^{-1}$.

scattered light trace and the recombination trace is proportional to the iodine atom concentration. The precision of these results was less than for those in the gas phase[9,14] because of the smaller per cent. initial dissociation, resulting from the caging effect, and the faster rate of recombination, resulting from the constant presence of solvent molecules to serve as the "third body." Nevertheless, the best curve through the $1/[I]$ *vs.* time plot clearly showed a second-order dependence of the rate on the iodine atom concentration. Values of k in the relation $d[I_2]/dt = k[I]^2$ were calculated as previously described[9,14] and are given in Table II for 20 determinations. Included in the table are the values obtained for the iodine atom concentration at 150 microseconds, which were used in the calculation of the primary quantum yield.

Discussion

The procedures outlined above gave a value of 0.13 for the fraction of the iodine molecules in carbon tetrachloride solution which, having absorbed a photon, produce iodine atoms which escape recombination to the parent partnership. The light used was the full light of the xenon flash lamp transmitted by a Pyrex cell.

Marshall and Davidson,[7] also using the flash technique, but making no attempt to correct quantitatively for the time dependence of the flash intensity or for the difference in the absorption spectra of iodine in the gas and in solution, and using only light of wave lengths greater than 5000 Å., obtained 0.19 molecule dissociated per quantum. From a determination of the quantum yield for disappearance of iodine in air-saturated solutions of allyl iodide in carbon tetrachloride solution, Lampe and Noyes[8] have obtained a value of 0.14 for the quantum yield of I atom escape from the parent partnership. This determination was made with 4368 Å. light. It is presumed that the allyl iodide reacts with all of the iodine atoms which escape recombination and that the radicals so formed are removed from further chemical activity by reaction with oxygen.

The fact that three laboratories using two widely different techniques obtain values as close together as those cited above is convincing evidence that the true value lies in the region indicated. It, together with the values which have been obtained for iodine in hexane[7,8] (0.41, 0.66) and in hexachlorobutadiene[9] (0.075), offers the most direct experimental evidence yet obtained for the "cage effect."[3] It will be desirable if it is possible for the direct measurements by the flash photolysis technique to be extended to determine the effect of wave length and of a variety of solvents. Use of the analog computer technique described in this paper makes quantitative determinations of this type possible even when the duration of the flash is necessarily appreciable relative to the time required for atom recombination.

The Thermal Decomposition of Methyl *n*-Butyl Ketone[1,2]

BY WILLIAM T. BARRY, JR., AND W. D. WALTERS

RECEIVED DECEMBER 13, 1956

The gas-phase thermal decomposition of methyl *n*-butyl ketone has been studied in the neighborhood of 430–500°. The principal products of the reaction during the early stages are: (a) propylene and acetone, (b) ethane and methyl vinyl ketone and (c) methane, carbon monoxide and 1-butene. A small quantity of ethylene also has been found. Acid-forming constituents, *e.g.*, ketenes, are present in only small amounts. The order of the decomposition is about 1.3 and the variation of the rate with temperature gives an apparent activation energy of approximately 52 ± 3 kcal./mole for 200 mm. experiments. The reaction is predominantly homogeneous although it is inhibited to a slight extent by packing the reaction vessel. The addition of propylene markedly inhibits the decomposition. Small quantities of added biacetyl at 475° or ethylene oxide at 450° accelerate the decomposition.

The thermal decomposition of methyl *n*-butyl ketone over a copper–aluminum oxide catalyst has been reported by Mailhe.[3] The composition of the gaseous products was found to be carbon monoxide (18.9%), hydrogen (8.0%), methane (23.5%), saturated hydrocarbons (16.5%) and

unsaturated hydrocarbons (33%). The unsaturated fraction consisted of ethylene, propylene and 1-butene. A liquid product fraction boiling below 90° was obtained, but not identified. The photolysis of methyl *n*-butyl ketone has been studied rather extensively[4] and the chief products at low temperatures are acetone and propylene. Davis and Noyes[4b] found that the acetone yield is relatively constant under all conditions indicating that acetone and propylene are formed in a single step. It was of interest to investigate the homogeneous thermal decomposition in order to make a comparison with the photochemical studies and with the thermal decompositions of the lower ketones.

Experimental

Materials and Apparatus.—Methyl *n*-butyl ketone was prepared in this Laboratory (a) by the reaction[5] of *n*-butylmagnesium bromide with an excess of acetic anhydride at −70° and (b) by converting *n*-butylmagnesium bromide to the cadmium alkyl with anhydrous cadmium chloride and treating the cadmium alkyl with acetyl chloride.[6] Methyl *n*-butyl ketone (c) which had been prepared by the chromic acid oxidation of 2-hexanol was purchased from Paul C. Kletzke Co.

Materials (a) and (b) were purified by recrystallization of the semicarbazone and the regenerated samples of the ketone (aI and bI) were dried over anhydrous calcium sulfate, filtered and fractionated. In one instance, material (a) was purified by conversion to the bisulfite addition compound and regeneration of the ketone gave sample (aII). Material (c) was shaken with pure mercury for 24 hours to remove peroxides, distilled once, and then fractionated. All of the samples were fractionated (usually twice) in an atmosphere of pure, dry nitrogen. Similar results were obtained with the various samples described above. The indices of refraction of the purified samples were: $n^{24}D$ for sample (aI) 1.3991; $n^{20}D$ for (bI) 1.4006, (aII) 1.4009, and (c) 1.4006. A value of 1.4008 for $n^{20}D$ has been reported previously.[7]

Ethylene oxide was obtained from the Dow Chemical Co. Biacetyl from the Eastman Kodak Co. was purified by fractionation under vacuum. Propylene (99.5%, Ohio) was used without further purification other than thorough degassing at −196°. Nitrogen (99.99%) was supplied by Linde Air Products Co. Nitric oxide (Matheson) was passed through three traps at −160°, and before each use it was frozen at −196°, degassed and distilled from a −78° bath.

The apparatus was almost identical with the one used in an earlier study.[8] The rate of pressure rise was measured usually with a heated mercury manometer, but in some experiments a click gage or a mirror gage was used.

Analysis of the Products.—Infrared measurements, conventional gas analysis involving absorption and combustion techniques and mass spectrometric analyses[9] were used to identify the gaseous products. To establish the identity of butene the more volatile products from a series of static experiments were removed by vaporization at low temperatures; the infrared absorption curve for the less volatile portion of the gases indicated that the main C_4 hydrocarbon is 1-butene. Prior to the quantitative analyses the gaseous products were separated usually into a fraction volatile at −196° and another volatile at −78°.

Tests for formaldehyde[10] and for higher homologs[11] did not reveal the presence of any aldehyde. A solution of the products in water showed a slight acid reaction, indicating the presence of ketene, substituted ketenes or other acidic substances. By titration with standard base it was found that after 10–20% pressure increase at 450° for 250 mm. experiments ketenes are present to the extent of less than 1% of the gaseous products. For an initial pressure of about 120 mm. at 512° with a pressure increase of 58–64% the acidic constituents amounted to 3.4% of the gaseous products.

In order to secure sufficient amounts of the liquid products for identification a series of static experiments (250–300 mm., 525°, 40–75% pressure increase) was performed. The liquid portion of the reaction mixture was fractionated in a semi-micro column. The boiling point and the index of refraction were measured for each fraction. Since the evidence indicated the presence of acetone and methyl vinyl ketone as important products (formed in comparable amounts), the semicarbazones of the appropriate fractions were prepared, recrystallized and compared with the semicarbazones from the pure ketones. The data are summarized in Table I. The infrared curves of fraction I4 and I8 agreed with the curves for acetone and methyl vinyl ketone, respectively. There appeared to be a trace of acetone in I8. Some evidence was obtained for the presence of another substance which came over in the first fraction of the distillation along with 1-butene and acetone. It had a maximum in its ultraviolet absorption at 223 mμ, but due to the minute quantity an infrared identification could not be made.

TABLE I

[a] 744 mm. [b] From reference 12a, b.p. at 760 mm. [c] From reference 12b, refractive index at 22°.

The amount of methyl vinyl ketone in the products was determined by two methods. The products which had not volatilized at −78° were dissolved in a 0.1 *N* potassium chloride solution (90% water–10% methanol). A portion of this solution was used for polarographic measurements[13] carried out with a Fisher Elecdropode. A second portion of the solution was diluted with water and the optical density was determined at 210 mμ with a Beckman DU spectrophotometer. For each method standard solutions of methyl vinyl ketone were used for calibration purposes.

Acetone in the products was estimated by a colorimetric method involving the reaction with vanillin.[14] A wave length of 540 mμ was employed and the contributions resulting from the methyl vinyl ketone and the unreacted methyl *n*-butyl ketone were taken into account. The acetone analyses seemed to be satisfactory for a comparison between experiments on a relative basis, but the absolute values may have been in error by 20–25%.

Results

Products of the Reaction.—The results from the mass spectrometric analyses of the gaseous products formed at 450 and 475° are plotted in Fig. 1. The data from two other series of experiments analyzed by conventional gas analytical procedures were in good agreement with those shown in Fig. 1. In the initial stages of the decomposition propylene and ethane are the most important gaseous products. For comparison a plot of (pressure of methyl vinyl ketone/pressure of gaseous products) for a

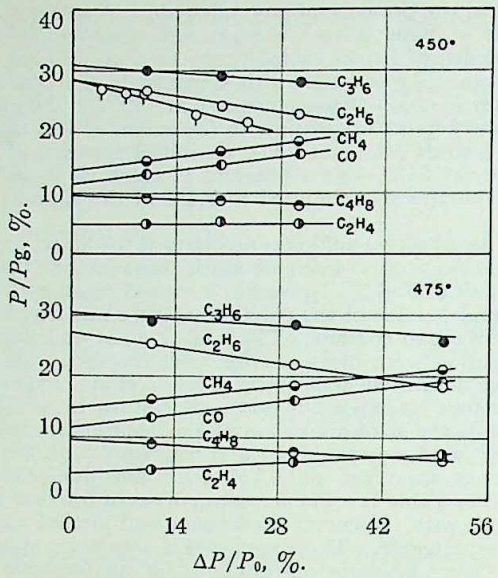

Fig. 1.—Products formed during the decomposition of methyl *n*-butyl ketone, 250 mm. at 450° and 160 mm. at 475°. *P*/*P*g represents the ratio of the amount of each substance to the total amount of gaseous products in % for various percentages of pressure increase ($\Delta P/P_0$, %). ♀ gives the ratio of methyl vinyl ketone to gaseous products for experiments at 200 mm.

series of 200 mm. experiments at 450° is shown also in Fig. 1. The agreement between the ethane and methyl vinyl ketone at the start of the decomposition indicates that one of the reactions is

$$CH_3COC_4H_9 \longrightarrow CH_3COCH{=}CH_2 + C_2H_6 \quad (1)$$

The acetone determined for 200 mm. experiments at 450° by the colorimetric method appeared to be about 80–85% of the percentage of propylene shown in Fig. 1. In view of the difficulties inherent in the colorimetric method in the presence of other ketones the results point toward the occurrence of

$$CH_3COC_4H_9 \longrightarrow CH_2{=}CHCH_3 + CH_3COCH_3 \quad (2)$$

The fact that the lines for methane, carbon monoxide and butene extrapolate to percentages of comparable magnitudes at the beginning of the reaction gives evidence for the reaction

$$CH_3COC_4H_9 \longrightarrow C_4H_8 + CH_4 + CO \quad (3)$$

Since methane and carbon monoxide grow in importance during the decomposition, they are probably formed also by the decomposition of intermediate products. It might be expected that in the presence of undecomposed ketone and liquid products some of the butene may remain in the −78° trap. Two experiments employing a more elaborate procedure of separation by fractional condensation and volatilization indicated that as much as eight parts per hundred of the butene might have been retained, but the loss of other gases was negligible. Thus the amount of butene may be somewhat closer to the carbon monoxide than the data in Fig. 1 show.

The presence of ethylene in the initial portion of the decomposition points toward the occurrence of at least one other reaction of lesser importance, as will be considered in the Discussion. For the experiments at 450 and 475° other products not shown in Fig. 1 were found in the gases by the mass spectrometric analyses: H_2, 0.3–0.8%; C_3H_8, 0.2–1.7%; C_5-C_6 hydrocarbons, 0.1–0.3%; CH_3COCH_3, 0.2–0.4% (most of the acetone is in the condensed fraction).

It was observed that the relative proportions of the products change as the decomposition proceeds, but for a given percentage of pressure increase the composition, particularly in the early stages, does not depend appreciably upon the initial pressure or temperature over the range used in this study. This finding indicated that the pressure increase could be used for the investigation of the kinetics of the reaction.

To study the appearance of methyl vinyl ketone during the decomposition both the spectrophotometric and the polarographic methods were used and the data are summarized in Fig. 2. The pressure of methyl vinyl ketone rises rapidly at first, reaches a maximum and then gradually diminishes in the later stages of the decomposition. In the early portion the points representing the polarographic and spectrophotometric measurements are essentially coincident, but at the higher percentages of pressure increase ($\Delta P/P_0$) where the reaction times are considerably longer, there are differences probably due to the ultraviolet absorptions of secondary products.

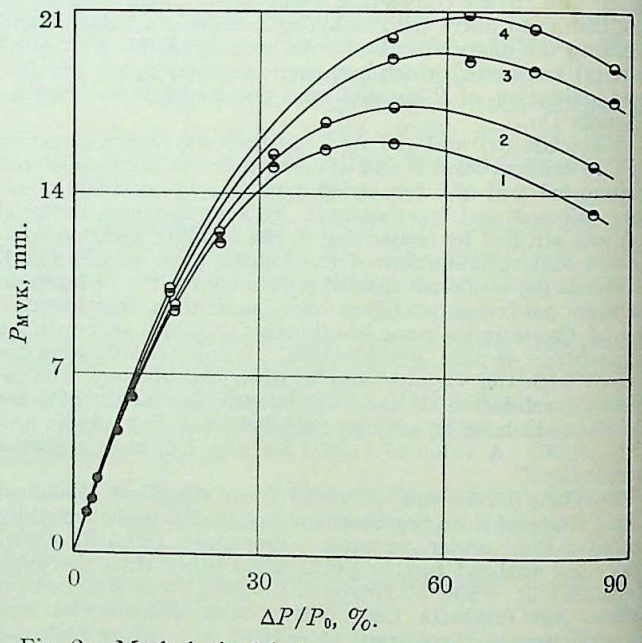

Fig. 2.—Methyl vinyl ketone present during the decomposition of methyl *n*-butyl ketone: Curves 1 and 2, ~200 mm. of $C_6H_{12}O$ at 450°; curves 3 and 4, ~198 mm. of $C_6H_{12}O$ at 495°. Pressure of methyl vinyl ketone based on polarographic measurements, ⊖ ; on the ultraviolet absorption of a solution of the reaction mixture at 210 mμ, ◒ .

Pressure–Time Curve and Homogeneity.—The change of pressure with time at 450° is shown in curve 1, Fig. 3. The slope of the curve decreases more than expected during the first ten minutes and then remains almost constant to about 60% pressure increase. The decrease in the initial stages may be due to the formation of products, such as propylene, which can inhibit the reaction. Later, secondary reactions involving the products initially formed will be occurring.

Curve 2 in Fig. 3 shows that a 22-fold increase in the surface to volume ratio reduces the rate of pressure rise. This decrease may result from the increase in the termination of free radical chains due to packing. Analyses after 40 min. at 450° showed that methyl vinyl ketone in the packed vessel is about 90% of that in the unpacked vessel for similar experiments at 200 mm. In view of the large difference in the total surface between the packed and unpacked vessels it is probable that surface effects play a relatively insignificant role in the unpacked bulb under the conditions used.

Influence of Added Substances.—The effect of the addition of propylene upon the rate of pressure rise is shown in curve 3, Figure 3. It was observed that as little as 4 mm. produces some decrease in the initial rate and the addition of 150 mm. propylene inhibits about 80% or more of the initial rate of pressure increase. Analyses were performed in order to ascertain whether this decrease in the rate of pressure rise is associated with a real inhibition of the decomposition. The amounts of methyl vinyl ketone present at 475° with and without added propylene are shown in Table II.

TABLE II

EFFECT OF PROPYLENE UPON THE APPEARANCE OF METHYL VINYL KETONE AT 475°

Propylene added, mm.	0	150	200	250
Reaction time, min.	Methyl vinyl ketone present, mm.			
2.5	3.2	0.75	0.67	0.49
11.5	9.8	3.9	3.5	3.1

P_0 (methyl *n*-butyl ketone) = 200 ± 4 mm.

A similar inhibiting effect of propylene upon the build-up of methyl vinyl ketone was observed at 450°. The results show that the major portion of the methyl vinyl ketone is formed by a chain process which is markedly inhibited by propylene. It is to be noted that the addition of 100 mm. of nitrogen to 200 mm. of methyl *n*-butyl ketone at 450° produced no appreciable effect upon the pressure–time curve or upon the amounts of methyl vinyl ketone and acetone formed in 40 min.

To find out whether the formation of other products is affected by propylene, gas analyses were made on reaction mixtures from experiments in the presence of propylene and the quantities of products were compared with the quantities from pure methyl *n*-butyl ketone under similar conditions (Table III). It is apparent from these results

TABLE III

AMOUNTS OF PRODUCTS FORMED WITH ADDED PROPYLENE RELATIVE TO THE AMOUNTS FROM PURE METHYL *n*-BUTYL KETONE (200 MM.) AT 450°

Propylene, mm.	$\Delta P_i/\Delta P_n$[a]	CO	CH_4	Higher saturates	Unsaturates
	Reaction time, 40 min.				
80	0.45[a]	0.38	0.45	0.52	0.3
160	.38[a]	.38	.42	.50	.4

[a] Ratio of the pressure increases in the presence and absence of propylene.

that the processes producing carbon monoxide and methane are inhibited by propylene. Since ethane is the principal higher saturated hydrocarbon, the formation of ethane is presumably decreased also.

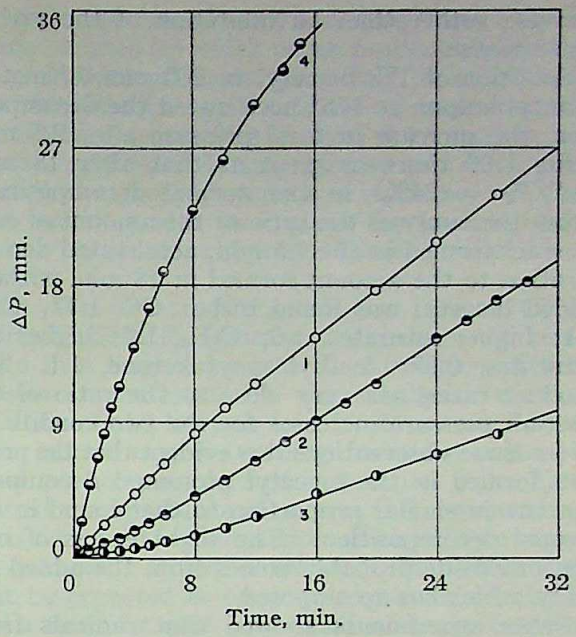

Fig. 3.—Pressure increase during the decomposition of 200 mm. of methyl *n*-butyl ketone at 450°: ○, pure ketone; ◓, packed bulb (other curves from unpacked bulb); ◑, 105 mm. of propylene added; ◒, 1% ethylene oxide and 99% ketone.

The values for the unsaturates are subject to considerable error since they were obtained by subtraction of the amount of added propylene, but the rate of production of olefins seems definitely lower in the presence of propylene.

The effect of propylene upon the formation of acetone was evaluated semi-quantitatively in two ways. The colorimetric method was used for (a) two experiments with 200 mm. of methyl *n*-butyl ketone at 475° for 2.5 min. with 151 and 201 mm. of added propylene and (b) the experiments shown in Table III (greater percentages of decomposition and smaller pressures of propylene). It was estimated that the acetone in the presence of propylene compared to that in the normal decomposition probably does not exceed a value of 15% in the case of the (a) experiments and is not greater than 45% for the experiments shown in Table III. The infrared absorption technique was employed for experiments with 200 mm. of methyl *n*-butyl ketone in the presence and absence of 260 mm. of propylene for reaction times of 40 and 56 min. at 450°. In each case a sample of vapor removed from the liquid portion of the reaction mixture by volatilization was examined in the region of 8.2μ where acetone absorbs quite strongly and the absorptions of methyl vinyl ketone and methyl *n*-butyl ketone are relatively weak. The absorption observed for acetone (after correction for the absorption of methyl *n*-butyl ketone) in the inhibited experiments seemed to be not more than 30–35% of the absorption of samples for the experiments without added propylene. On the basis of these results it can be concluded that the added propylene under the above conditions inhibits at least 60% of the acetone formation.

Experiments with 0.3–7.0 mm. of nitric oxide added to 200 mm. of methyl *n*-butyl ketone at 450° gave a decrease in the time for 10% pressure

increase rather than an inhibition of the rate of pressure rise.

Addition of 1% biacetyl to 200 mm. of methyl *n*-butyl ketone at 475° accelerated the decomposition, the increase in total pressure after 9.5 min. being 1.06 times as great as that after 18 min. ($\Delta P/P_0$ = 24%) in the normal decomposition. From the analyses the ratio of the amount of each product formed in the 9.5 min. accelerated decomposition to the amount formed in 18 min. without added biacetyl was found to be: CO, 1.17; CH_4, 1.1; higher saturates, 1.0; C_2H_4, 1.1; higher unsaturates, 0.97; methyl vinyl ketone, 1.1. The product ratios are very close to the ratio of the over-all pressure increases for the two conditions. From these observations it is evident that the products formed in the biacetyl promoted decomposition are in similar proportion to that found in the normal decomposition. The slight excess of carbon monoxide probably comes from the added biacetyl which has decomposed.

Other experiments showed that radicals from decomposing ethylene oxide can sensitize the decomposition. The influence of added ethylene oxide is shown in curve 4, Fig. 3. For a 200 mm. mixture of methyl *n*-butyl ketone and 1% ethylene oxide the increase in the total pressure at 450° after 15 min. was 1.03 times as large as that observed for 200 mm. pure ketone in 40 min. ($\Delta P/P_0$ = 16.5%). Ratios of the amounts of the products formed in the 15 min. sensitized decomposition to those in the 40 min. normal decomposition were: CO, 1.1; CH_4, 1.16; higher saturates, 1.0; C_2H_4, 1.1; higher unsaturates, 1.1; methyl vinyl ketone, 1.0. The ratio is approximately the same for every product and is close to the value of 1.03 for the ratio of the observed pressure increases. These results also give evidence for the similarity of the products in the normal and sensitized decompositions.

Kinetics.—In experiments at 450° with pressures from 50 to 300 mm. the initial slope of the pressure–time curve $(dP/dt)_0$ and the rate of pressure rise in the region of essentially constant slope (after 6% pressure increase at 450°) were measured and their logarithms were plotted against the logarithm of the initial pressure (Fig. 4). Likewise the average rate of build-up of metal vinyl ketone during the first 8 min. ($\Delta P_{MVK}/\Delta t$) was measured and the data are shown in Fig. 4. The slopes of the three lines are almost the same and all lie within the range 1.30 ± 0.06. Thus an order of about 1.3 is indicated for the over-all reaction and for the build-up of methyl vinyl ketone.

Figure 5 summarizes the data showing the temperature variation of the reaction over the range 430–495° at a constant pressure of 200 ± 2 mm. (or corrected to this value). Each point in Fig. 5 represents two or more experiments. For methyl vinyl ketone in Figs. 4 and 5, each point is the

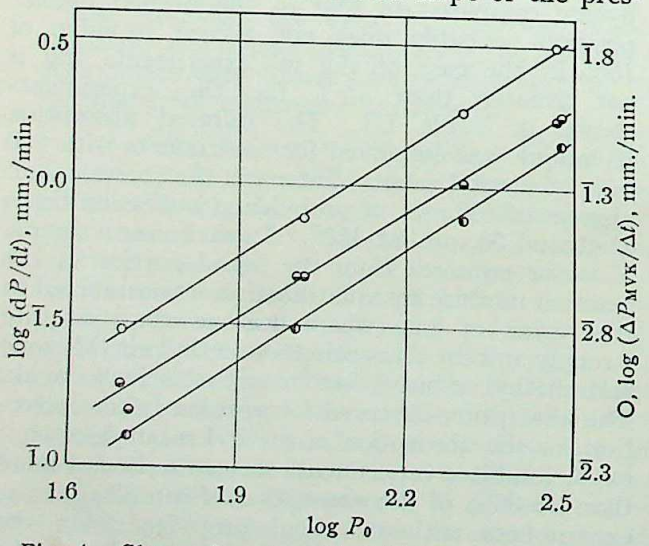

Fig. 4.—Change in rate with initial pressure, P_0: ◒, $(dp/dt)_0$, initial rate of pressure rise; ◐, $(dp/dt)_c$, rate of pressure rise after ~6% pressure increase; O, $(\Delta P_{MVK}/\Delta t)$, average rate of build-up of methyl vinyl ketone during the first 8 min. Each point showing the rate of pressure rise at 200 mm. represents the average of three runs.

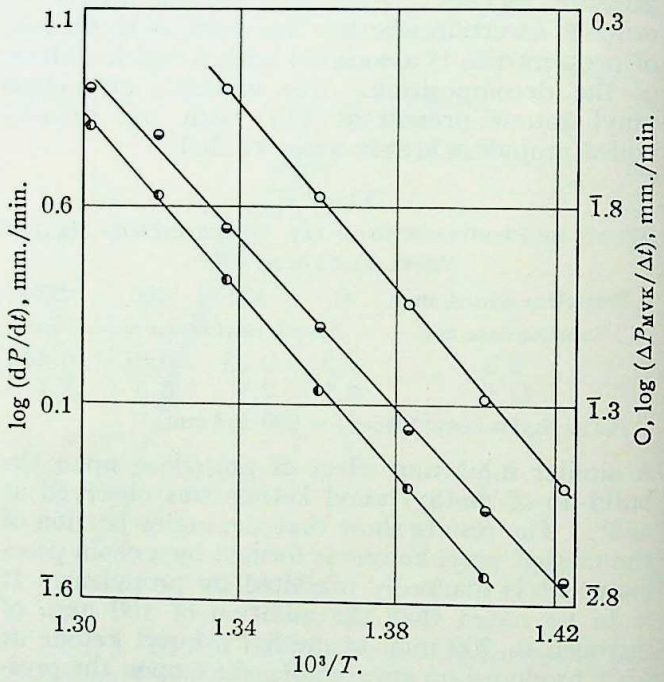

Fig. 5.—Variation of rate with temperature: ◒, $(dP/dt)_0$, initial rate of pressure rise; ◐, $(dP/dt)_c$, rate of pressure rise after ~10% pressure increase; O, $(\Delta P_{MVK}/\Delta t)$ initial rate of appearance of methyl vinyl ketone.

average of the spectrophotometric and polarographic analyses, the former being on the average about 5% higher. If one assumes that for a constant initial pressure each of the rates can be represented by an expression involving a constant multiplied by $e^{-E/RT}$, the values for E obtained from the data shown in Fig. 5 are: 50 ± 2 kcal./mole from $(dP/dt)_0$, 52 ± 1 kcal./mole from $(dP/dt)_c$, and 53.5 ± 1 kcal./mole from $(\Delta P_{MVK}/\Delta t)$. It is to be noted that for the measurement of $(\Delta P_{MVK}/\Delta t)$ the reaction time at each temperature was kept sufficiently short to permit the build-up of only 2.7-3.1 mm. of methyl vinyl ketone. Due to secondary reactions the observed rate of build-up will not be identical with the rate of formation, but the difference should be small. In the evaluation of the temperature variation and the order by the use of $(\Delta P_{MVK}/\Delta t)$ a compensating factor is that approximately similar percentages of methyl vinyl ketone may disappear in the various experiments.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

To estimate the importance of the disappearance of methyl vinyl ketone for the kinetic studies above, two experiments with 11 mm. of this compound plus 200 mm. nitrogen were allowed to proceed for 8 min. at 450°. Analyses did not reveal any significant loss, but the disappearance of about 5% might have escaped detection. Small amounts (12 mm.) of methyl vinyl ketone were added to 200 mm. of methyl *n*-butyl ketone and analyses were made after 8, 24 and 40 min. at 450°. The influence of added methyl vinyl ketone upon its own formation is not known, but it is estimated that the disappearance of methyl vinyl ketone probably is not in excess of 1% per minute in the initial stages of the reaction.

Discussion.—The experimental results indicate that even in the initial stages the homogeneous thermal decomposition of methyl *n*-butyl ketone is not a simple reaction, but involves three major reactions designated above as (1), (2) and (3). However, the order and the temperature coefficient of the reaction producing methyl vinyl ketone are approximately the same as the order and temperature coefficient obtained from the rate of pressure increase. Furthermore it has been shown that the three reactions given above can be inhibited by propylene and sensitized by free radicals to form the products in nearly the same proportions as in the normal reaction. The rate of pressure rise is also reduced by an increase in the surface to volume ratio of the reaction vessel. To explain the results a free radical chain mechanism of the Rice–Herzfeld type can be used. Although the exact nature of the primary radical producing process is not known, the rupture of any carbon–carbon bond in methyl *n*-butyl ketone can produce free radicals. The abstraction of a hydrogen atom from the ketone by a radical can then lead to a chain reaction

$$R + CH_3COCH_2CH_2CH_2CH_3 \longrightarrow RH + C_6H_{11}O$$

$$C_6H_{11}O \longrightarrow M + R'$$

$$R' \left(\begin{matrix}\text{or smaller}\\ \text{radical}\end{matrix}\right) + C_6H_{12}O \longrightarrow R'H + C_6H_{11}O$$

The formulas for M and R′ will depend upon the particular hydrogen atom abstracted. In some cases R′ will decompose before abstracting a hydrogen atom. The chain products which could be formed by the type of mechanism given above are shown in Table IV.

TABLE IV

Carbon atom from which H is abstracted	M	Products from reaction of R	
3	$CH_3COCH{=}CH_2$	C_2H_6	(A)
4	$CH_2{=}CHCH_2CH_3$	$CH_4 + CO$	(B)
5	$CH_2{=}CHCH_3$	CH_3COCH_3	(C)
1	$CH_2{=}CO$	$C_2H_4 + C_2H_6$	(D)
6	C_2H_4	$C_2H_4 + CH_4 + CO$	(E)

It is apparent that processes (A), (B) and (C) lead to the formation of the major products. Reactions (A), (B) and (C) would be expected to be important on the basis of the fact that they involve the abstraction of secondary hydrogen atoms and in the case of (A) the hydrogen is on a carbon atom adjacent to a carbonyl group.[15] After the abstraction of hydrogen there are in certain cases alternative routes by which other products might be formed instead of those given in Table IV, but from theoretical considerations or experimental evidence they appear less likely. For example, an alternative to methyl vinyl ketone and ethane in (A) might be propyl ketene and methane, but the experimental results have given no positive evidence for the presence of propyl ketene in important amounts.

That the decomposition of the radical $CH_2COCH_2CH_2CH_2CH_3$ (reaction (D)) does not contribute to a large extent to the formation of the products is indicated by the smallness of the quantities of the ketenes found. Moreover, some of the ketene may be coming from the acetonyl radical (or acetone) formed in reaction (C). The apparent unimportance of process (D) is somewhat surprising since the abstraction of a hydrogen atom from carbon 1 which is adjacent to a carbonyl might be expected to occur to a greater extent.[15a] From a spatial model of the radical it can be seen that there is a position in which carbon atom 1 is close to the hydrogens on carbon 5 so that it may be possible for $CH_2COCH_2CH_2CH_2CH_3$ to isomerize by an intramolecular hydrogen abstraction to $CH_3COCH_2CH_2CHCH_3$.[16] Decomposition of the latter radical would lead to an enhancement of reaction (C) at the expense of reaction (D) and would tend to make the products from (C) more important than (B) as is observed experimentally.

Reaction (E) which produces two molecules of ethylene probably can account for the ethylene formed in addition to that from reaction (D). Since the initial percentage of ethylene is not more than 5% (see Fig. 1), reaction (E), which involves the abstraction of a primary hydrogen atom, does not seem to be as important as (A), (B) or (C).

The decomposition of methyl *n*-butyl ketone appears to have considerable similarity to the decompositions of the lower methyl alkyl ketones particularly with respect to the occurrence of chain processes which are inhibited by propylene.[17] However, with methyl *n*-butyl ketone the reactions leading to the formation of ketenes seem to be less important. The activation energies observed in the present case are close to those (51–53 kcal./mole) found for methyl *n*-propyl ketone.[17d] The order of the reaction of methyl *n*-butyl ketone seems to be somewhat higher than the first order behavior found for the lower ketones; this could be due to the existence of several types of chain termination which might lead to an order between 1 and 1.5.[18]

Although propylene and acetone are among the

important pyrolytic products from methyl *n*-butyl ketone, in contrast to the photochemical decomposition at low temperatures there are other products formed in comparable amounts. Moreover, the results from the experiments with added inhibitor show that in the thermal decomposition acetone and propylene are formed mainly by a free radical chain process rather than by a single-step reaction.

A detailed treatment of the kinetics of a free radical mechanism has not been attempted on account of the complexity of the chain decomposition which probably involves the participation of a number of different radicals. The inhibiting effect of propylene indicates that even in the relatively early stages of the decomposition a partial inhibition of the reaction by the products should be taken into account. In the later stages the subsequent reaction of several of the primary products would be expected to introduce additional complicating factors.

Carbonium Ions. V. The Nature of the *t*-Butyl Cation as Indicated by a Study of the Formation of N-*t*-Butylacrylamide[1]

BY N. C. DENO, TOM EDWARDS AND CARL PERIZZOLO

RECEIVED DECEMBER 20, 1956

The kinetics of the acid-catalyzed formation of N-*t*-butylacrylamide from *t*-butyl alcohol and acrylonitrile have been studied from 20–69% sulfuric acid. The rate is proportional to the first powers of the acrylonitrile concentration, the *t*-butyl alcohol concentration and the Hammett h_0 function. The rate constants for the reactions of protonated *t*-butyl alcohol with water, acrylonitrile and propionitrile were found to be identical within a factor of three. The combined results are interpreted in terms of transition states in which the incoming group is so weakly bonded to the transition state that its nature has only a small effect on the rate. The results do not support the concept of a free *t*-butyl cation. The rate of hydrolysis of acrylonitrile was studied from 28–85% sulfuric acid. The rate is proportional to the concentration of acrylonitrile and the h_0 function.

Since Whitmore[2] first introduced the concept of aliphatic cations, considerable controversy has existed as to their exact nature.

On the basis that methanolysis of hydrogen 2,4-dimethylhexyl-4-phthalate proceeded with 55% inversion and 45% racemization, Doering and Zeiss[3] concluded that no free alkyl cation was an intermediate. Their argument was that if the *t*-alkyl cation was not free enough to racemize, it is difficult to conceive of a transition state in which there is no covalent participation by the incoming group. Their conclusion is strongly supported by the failure to observe a mass-law effect in the solvolysis of *t*-alkyl halides.[4]

The strongest arguments proposed in favor of free *t*-alkyl cations are the studies of Winstein, Grunwald and Jones[5] on the variation of rate with solvent. We interpret these studies as showing that there is nearly complete charge separation in the transition state, a situation that can be accommodated by transition states of the type described by Doering and Zeiss.

In our work, a study of the acid-catalyzed reactions of *t*-butyl alcohol was initiated with the expectation that it would provide evidence as to the existence of the *t*-butyl cation as a reaction intermediate. It was first necessary to develop acidity function theory and this was the concern of an earlier paper.[6]

The reaction chosen for study was the formation of N-*t*-butylacrylamide from *t*-butyl alcohol and acrylonitrile. This reaction is of a type extensively studied by Ritter,[7] who demonstrated that it was a remarkably general reaction between alcohols and nitriles.

Experimental

Extinction Coefficients.—In order to determine the concentration of N-*t*-butylacrylamide spectroscopically, it was necessary to know the extinction coefficients for *t*-butyl alcohol and acrylonitrile (the reactants), N-*t*-butylacrylamide (the product), acrylamide (a side product) and acrylic acid (the hydrolysis product of acrylamide or N-*t*-butylacrylamide). The *t*-butyl alcohol and acrylonitrile showed no measurable absorption in the region of wave lengths greater than 220 mμ at the concentrations employed in the kinetic runs. Their absorptions were thus neglected. The absorption spectra of the remaining compounds are summarized in Table I.

Kinetic Measurements.—The kinetics of the reaction between *t*-butyl alcohol and acrylonitrile were studied in 20–69% sulfuric acid. The formation of the product, N-*t*-butylacrylamide, was determined spectroscopically with a Beckman DU spectrophotometer. Measurements were made at 260–280 mμ. The cells of the spectrophotometer were thermostated at 25 ± 0.1° by means of thermospacers. Rapid runs were conducted entirely in the spectrophotometer cells whereas slow runs were held in thermostated volumetric flasks from which a portion was periodically introduced into the cells.

270	27	22				

[a] Under each compound, the values in the first column are for 41% sulfuric acid and those in the second column are for 55% acid.

All runs were conducted as pseudo first-order reactions by using at least tenfold excess of either reactant, acrylonitrile or *t*-butyl alcohol. The fit of the data with first-order kinetics is demonstrated in Table II for two typical runs in which *t*-butyl alcohol was in excess and a run in which acrylonitrile was in excess.

[a] The values are taken from a smooth curve drawn through a plot of optical density against time. Observations at 270 and 280 mμ were converted to the equivalent at 260 mμ. The value at 100% completion was calculated from the extinction coefficient of the product, N-*t*-butylacrylamide, and the initial concentrations of reactants.

The rate constants, which are summarized in Table III, were calculated from integrated forms of the equation $dc_{product}/dt = kc_{RCN}c_{t\text{-BuOH}}$. The added *t*-butyl alcohol significantly lowered the acidity of the reaction mixtures similar to the effect of adding 2-propanol to water–sulfuric acid.[8] It was necessary to make small corrections for this effect in computing the rate constants since varying concentrations of *t*-butyl alcohol were used in different runs. For this purpose the Hammett H_0 function[9] was measured as a function of added *t*-butyl alcohol at several concentrations of sulfuric acid. The data are summarized in Table IV. The method of computing the correction for k was to determine d log k/dH_0 at each % H_2SO_4 from the variation of rate with % H_2SO_4. The change in log k due to the added *t*-butyl alcohol could then be estimated from the data in Table IV.

TABLE III

RATE CONSTANTS FOR THE FORMATION OF N-*t*-BUTYLACRYLAMIDE

Run	% H_2SO_4	Initial molarities $CH_2{=}CHCN$	Initial molarities *t*-BuOH	$(k \times 10^6)$,[a] l. mole^{-1} sec.$^{-1}$	% Completion[b]

22	64.9	.0178	.209	350	20
23	65.8	.0178	.209	488	25
24	68.0	.0178	.209	560	30
25	69.1	.0178	.209	628	40

[a] The values of k were calculated from integrated forms of the equation $dc_{amide}/dt = kc_{RCN}c_{t\text{-BuOH}}$. The concentrations used in this equation were the stoichiometric concentrations. All values of k were corrected for the small change in acidity due to the added *t*-butyl alcohol. [b] The rate constants did not vary by more then 10% out to the % completion listed in this column. The runs at 20 and 25% H_2SO_4 were inconveniently slow to carry to completion. The runs at 40–50% acid were arbitrarily stopped at the % completion listed. For runs at acid concentrations greater than 50%, no observations were made beyond the % completion listed in this column because of the appearance of cloudiness. [c] In this run where the acrylonitrile was in excess, about 17% of the *t*-butyl alcohol disappeared in some reaction other than the formation of N-*t*-butylacrylamide as judged by the final constant optical density reading. When a correction was made based on the assumption that the side reaction involved a bimolecular reaction between two derivatives of *t*-butyl alcohol, the calculated values of k were constant within 10% out to 85% completion. For these reasons this value of k must be considered uncertain.

Evidence for the Validity of the Kinetic Data.—Although Ritter[7] has shown that under certain conditions acryloni-

TABLE IV

VARIATION IN H_0 ON ADDITION OF *t*-BUTYL ALCOHOL TO FOUR DIFFERENT CONCENTRATIONS OF SULFURIC ACID

Ml. of *t*-butyl alcohol per l. of soln.	H_0[a] A	B	C	D
0	1.28	0.31	−0.92	−4.36
10	1.30	.32		
20	1.36	.36	− .86	−4.32
40	1.46	.40	− .78	−4.26
60	1.54	.44		
80	1.58	.46		
100	1.63	.51		

[a] The data in column A refer to addition of *t*-butyl alcohol to a 0.45% solution of sulfuric acid, column B to 4.39% acid, column C to 20.35% acid and column D to 60.3% acid. The indicators used were 2-nitroaniline at 0.45 and 4.39% acid, 4-chloro-4-nitroaniline at 20.35% acid and 2,4-dinitroaniline at 60.3% acid.

trile and *t*-butyl alcohol react to give high yields of N-*t*-butylacrylamide, it was necessary to demonstrate that this was true under the conditions of the kinetic experiments. Related to this problem was the fact that both reactants and the product undergo hydrolysis or dehydration–polymerization in at least some of the regions of acidity studied. Particular emphasis was thus placed on demonstrating that the spectrophotometer data really measured the formation of N-*t*-butylacrylamide and that its formation was nearly quantitative.

The most direct evidence was that crystalline N-*t*-butylacrylamide was isolated in runs at 41 and 55% sulfuric acids in amounts equal to 80% of that calculated from the rate data.

The side reactions, hydrolysis of acrylonitrile and N-*t*-butylacrylamide, were investigated independently. Both of these reactions were found to be sufficiently slow under the conditions employed so that they did not interfere with measurements on the formation of N-*t*-butylacrylamide.

The behavior of *t*-butyl alcohol alone in the various concentrations of sulfuric acid was investigated spectroscopically to be certain that no significant absorption due to isobutene polymers or oxidation products was present during the time that the kinetic data were recorded. The behavior of the *t*-butyl alcohol in the various concentrations of sulfuric acid also was observed visually to see whether any cloudiness developed. No measurements were taken after any cloudiness developed.

The most convincing evidence was the spectrophotometric measurements. Below 45% sulfuric acid where formation and polymerization of isobutene was absent, the final optical density reading was generally at least 95% of that calculated for complete conversion of the reactants to the product, N-*t*-butylacrylamide. The calculated values were based on the extinction coefficient of the product (Table I) and the initial concentrations of reactants. In addition the calculated values of the rate constant, k, were constant until either the reaction was complete or cloudiness prevented further measurements.

Hydrolysis of Acrylonitrile to Acrylamide.—The rate of formation of acrylamide from acrylonitrile was determined from 25–85% H_2SO_4. The concentration of acrylamide was followed by measurements of the optical density at 230–250 mμ. The further hydrolysis of acrylamide to acrylic acid was sufficiently slow so that it did not interfere.

The rate constants, k, were calculated from the integrated form of the equation $-dc_{RCN}/dt = kc_{RCN}$. In all cases values of k were constant to within 5% at all stages of the reaction. The data are summarized in Table V.

Competition Experiments.—The relative rate of reaction of *t*-butyl alcohol with acrylonitrile and propionitrile was determined at 50.3% H_2SO_4. The initial concentrations were made sufficiently large so that the first-order direct hydrolysis of acrylonitrile did not interfere. Although no direct measurements were made on the rate of hydrolysis of propionitrile, this reaction was slow enough so as not to interfere. The evidence for this was that the ratio of rates was constant although the ratio of initial concentrations of the two nitriles was varied from 2.42/1 to 0.58/1. The data are summarized in Table VI.

TABLE V

RATE CONSTANTS AND THEIR VARIATION WITH SULFURIC ACID CONCENTRATION FOR THE HYDRATION OF ACRYLONITRILE TO ACRYLAMIDE

% H_2SO_4	$k \times 10^5$, sec.$^{-1}$	% Completion[a]	$\frac{d \log k}{d\ \%\ H_2SO_4}$	$\frac{-dH_0}{d\ \%\ H_2SO_4}$	$\frac{d \log c_{H_3O^+}}{d\ \%\ H_2SO_4}$
25.5	4.27	0.5	0.04	0.065	0.021
41.3	22.2	5	.061	.087	.013
54.8	188	40	.078	.110	.010
72.0	5960	90	.112	.124	
85.0	82800	90	.112	.134	

[a] The runs were arbitrarily stopped at the % completion listed in this column.

TABLE VI

RELATIVE RATES OF REACTION OF *t*-BUTYL ALCOHOL WITH ACRYLONITRILE AND PROPIONITRILES IN 50.3% H_2SO_4

t-Butyl alcohol	Initial molarities: Acrylonitrile	Propionitrile	Final optical[a] density: Calcd.	Obsd.	$\frac{k_{propionitrile}}{k_{acrylonitrile}}$[b]
0.102	0.184	0.304	16.9	4.43	1.78
.109	.171	.295	18.1	4.87	1.72
.111	.227	.225	18.4	6.92	1.90
.093	.128	.130	15.4	5.67	1.97
.100	.377	.156	16.6	9.00	2.02

[a] The calcd. values were obtained by assuming that the *t*-butyl alcohol was completely converted to N-*t*-butylacrylamide. The observed values were obtained by multiplying the optical density of diluted reaction mixtures by the dilution factor. [b] The calculation of this ratio was made by the equivalent of a graphical integration which took into account that the ratio of the concentrations of the two nitriles changed during the course of the reaction and that the two nitriles disappeared at different rates.

Discussion

Rate Law for the Formation of N-*t*-Butylacrylamide.—At constant concentration of sulfuric acid, the rate law was found to be eq. 1. The majority of reactions were conducted

$$dc_{amide}/dt = kc_{RCN}c_{t\text{-buOH}} \qquad (1)$$

using an 11.7/1 ratio of *t*-butyl alcohol concentration to acrylonitrile concentration. In these runs, the rate constant calculated by eq. 2 was constant (Table II) to within 10% out to the % completions listed in Table III.

$$k = (2.3)(\log c_{RCN}/c'_{RCN})/(c_{t\text{-buOH}})(t) \qquad (2)$$

This demonstrated that the rate was proportional to the first power of the acrylonitrile concentration.

The proportionality of the rate to the first power of the *t*-butyl alcohol concentration was demonstrated in two ways. First, when the concentration of *t*-butyl alcohol was doubled (runs 8 and 13), the value of k was unchanged providing that it was computed by eq. 2. Secondly, in two runs (runs 9 and 17, Table III) the procedure was reversed in that a 14/1 excess of acrylonitrile was employed. In run 9 the plot of log $c_{t\text{-buOH}}$ against time was linear. This was also true for run 17 providing a correction (*cf.* footnote *c*, Table III) was made for the 17% of the *t*-butyl alcohol which disappeared by an uninvestigated side reaction.

In summary, eq. 1 was obeyed over a 330-fold variation in the ratio of *t*-butyl alcohol concentration to acrylonitrile concentration. This range probably could have been extended greatly by using lower acrylonitrile concentrations, but exten-

sion in this direction was not critical to the arguments to be considered.

From 20–40% sulfuric acid, the variation of rate with acid concentration was expressed accurately by eq. 3 as shown by the data in Table VII. In this eq. as with all others that follow in this paper, all derivatives are taken in respect to % H_2SO_4 unless otherwise specified. Thus d log k stands for d log k/d % H_2SO_4.

$$\mathrm{d} \log k = -\mathrm{d}H_0 \qquad (3)$$

TABLE VII

60	.060	.120	.110	.26
65	.060	.170	.116	.26

[a] The calculation of k' differed from that of k in that instead of using the stoichiometric concentration of *t*-butyl alcohol in eq. 2, a concentration of *t*-butyl alcohol was used which was corrected for the equilibrium between alcohol and protonated alcohol. This correction was calculated on the hypothesis that $pK = -3.8$ for *t*-butyl alcohol. It was not felt necessary to tabulate values of k'.

From 40–70% sulfuric acid the variation became more complex. This was anticipated because Bartlett and McCollum have found that ethanol has $pK = -2.2$,[10] which means that it is half-protonated in 40% H_2SO_4. For 2-propanol, $pK = -3.2$,[8] which means that it is half-protonated in 50% H_2SO_4. It was thus expected that *t*-butyl alcohol would be half-protonated near 60% H_2SO_4, and that this protonation of the alcohol would affect the fit of the kinetics with eq. 3.

If a $pK = -3.8$ ($H_0 = -3.8$ at 55% H_2SO_4) is assumed for *t*-butyl alcohol and the concentration of free *t*-butyl alcohol computed on this basis, the kinetic data now fit eq. 2 from 20–65% H_2SO_4 as shown in Table VII. The fit is not sensitive to the value chosen for the pK so that the value -3.8 must be considered at best an estimate precise to perhaps ± 0.4.

The complete rate eq. is thus given by eq. 4 where h_0 is the $-$antilog H_0.

$$\mathrm{d}c_{\mathrm{amide}}/\mathrm{d}t = kc_{\mathrm{RCN}}c_{t\text{-BuOH}}\,h_0 \qquad (4)$$

Significance of Eq. 3.—On the basis of limited work, there appear to be two groups of cations for which d log f in sulfuric acid is dependent only on the sulfuric acid concentration.[6] The first group are cations of a type (type I) exemplified by Ar_3C^+, $(C_6H_5)_4P^+$ and Bu_4N^+ in which the common character is a positive charge well shielded by non-polar groups. The second group are cations of the general formula BH^+ (type II) where the common character is a positive charge on the periphery of a non-polar moiety.

(10) Unpublished results.

By the development previously presented,[6] the fact that the data fit eq. 3 and 4 would be interpreted to mean that the transition state resembles type II, BH^+, close enough so that d log (f_{BH^+}/f^*) is negligible. Generally this would be more likely to happen if the transition state were composed of acrylonitrile and protonated *t*-butyl alcohol rather than some other derivative of *t*-butyl alcohol (such as the *t*-butyl cation) and this is our tentative interpretation.

Relative Rates of Reaction.—In a typical SN1 reaction involving a stable cation intermediate such as the triphenylmethyl cation, the relative rate of formation of triphenylmethyl azide and triphenylmethanol is 2.8×10^5.[11] The wide range of rate constants in SN2 reactions is too well known to merit examples. In contrast, a unique feature of the substitution reactions of *t*-butyl derivatives is that their rate constants are so similar.

Using the data of Ingold, *et al.*, Swain, Scott and Lohmann[11] calculated the relative rate of formation of *t*-butyl azide to the rate of formation of *t*-butyl alcohol (from the solvolysis of *t*-butyl chloride in 10% water–90% acetone at 50°) as being 3.9.

Another example of similar rates is the ratio of *t*-butyl thiocyanate to *t*-butyl isothiocyanate formed in solvolysis of *t*-butyl chloride in the presence of thiocyanate ions. Taft and Cannell[12] found the ratio to be 71/29 at 38°. The same authors found that the ratio of the same products was 65/35 when *t*-butylamine was treated with nitrous acid in the presence of thiocyanate ion.[12]

In our work we found that the relative rates of reaction of propionitrile and acrylonitrile with *t*-butyl alcohol in the acid-catalyzed Ritter reaction was 1.9/1 (Table VI).

A more striking example is a comparison of the rates of oxygen exchange on *t*-butyl alcohol with the rate of reaction of acrylonitrile with *t*-butyl alcohol. Dostrovsky and Klein[13] measured the oxygen exchange rate. Their data at 55 and 75° in 0.45 M H_2SO_4 and one molar *t*-butyl alcohol can be extrapolated to 25° to give a rate constant equal to 2.42×10^{-7} sec.$^{-1}$. If this reaction is assumed to be of the same type as the formation of N-*t*-butylacrylamide, the rate constant must be divided by the molarity of water (about 51 M) to reduce the rate constant to that for unit concentration of water and *t*-butyl alcohol. The rate constant then becomes 4.8×10^{-9} l. mole^{-1} sec.$^{-1}$. This rate constant can be compared with the rate constant, $k = 1.7 \times 10^{-9}$ l. mole^{-1} sec.$^{-1}$, calculated for the formation of N-*t*-butylacrylamide at the same value of H_0 ($H_0 = 1.60$ for 0.45 M H_2SO_4 and 1 M *t*-butyl alcohol). The relative rates are 2.8/1 and this is interpreted to mean that the protonated *t*-butyl alcohol reacts 2.8 times as fast with water as with acrylonitrile. With propionitrile, water reacts about 1.4 times as fast.

The similarity in rates in itself could be interpreted as due to an unstable cation intermediate which is not selective in its reactions or it could

equally well be interpreted as due to weak bonding of the incoming group which thus has a relatively small effect on the free energy of the transition state. The latter interpretation is more in accord with eq. 4 and the experiments of Doering and Zeiss.[3]

These results on *t*-butyl alcohol make it probable that the oxygen exchanges on 2-butanol are simple displacements on the protonated alcohol by water. The result that each exchange proceeds with inversion[14] is thus a most natural result. The author's conclusion that water was not covalently bonded to the transition state was based on the Hammett-Zucker hypothesis which is now suspect.[6]

It is of interest that substitution reactions of even triphenylmethyl derivatives become displacement reactions in non-ionizing media.[15] In these circumstances, the reactions are like those of the *t*-butyl derivatives discussed above in that the rate shows little variation with the nature of the incoming group.[16] It is hard to see how these reactions can proceed in any other way than with inversion of configuration and we are currently studying this problem.

Although we have interpreted the reactions of *t*-butyl derivatives as an extreme type of displacement reaction (SN2), some of the characteristics closely resemble those of an ideal SN1 reaction. Thus the rates depend primarily on the structure of the *t*-alkyl group and may parallel the cation stability as has been shown for solvolysis of diarylmethyl derivatives.[17] Also the large charge separation in the transition state will cause the variation of rate with media to be similar to that found for an ideal SN1 reaction. This intermediate type of nucleophilic displacement reaction as exemplified by the substitution reactions on *t*-butyl alcohol have a unique character of their own and it may be convenient to term them SN(int.) reactions.

Hydrolysis of Acrylonitrile to Acrylamide.—The data in Table V show that to within 10–30% $d \log k = -dH_0$. The transition state contains acrylonitrile and a proton. The presence or absence of water is undecided.

The Binding of Ions to the Muscle Proteins. Measurements on the Binding of Potassium and Sodium Ions to Myosin A, Myosin B and Actin[1,2]

BY M. S. LEWIS AND H. A. SAROFF

RECEIVED JANUARY 2, 1957

The binding of sodium and potassium ions to myosin A, myosin B, actin and bovine and human serum albumin was studied using electrodes made of collodion membranes which were permselective to cations. Data showing *p*H dependence, concentration dependence and temperature dependence were obtained. It was found that myosin A and myosin B bound sodium and potassium, but that the other proteins did not. The imidazol and amino groups appear to control the binding of sodium and potassium to myosin A and B. The values of the equilibrium constants for the interaction of sodium and potassium with the myosins were determined, and values for $\Delta F°$ and $\Delta H°$, were calculated.

Introduction

The interaction of potassium and sodium ions with the proteins of muscle is undoubtedly of considerable importance in the contractile processes in muscle. The extent of these interactions has been studied by several investigators by measuring the amount of the ion adsorbed by threads of myosin.[3–6] Their data present certain difficulties in interpretation because the threads represent a phase different from that of the solution in which they were equilibrated. This study was carried out on the viscous solutions and suspensions of the muscle proteins rather than on the precipitated thread. Other evidence for sodium and potassium ion binding to myosin can be found in Mihalyi's[7] hydrogen ion titration data at different salt concentrations.

When a suitable electrode exists for a certain ion, it is possible to determine the extent of the interaction of that ion with a protein by determining the activity of the ion in the presence of the protein. Hydrogen ion interactions with proteins have been studied using the hydrogen and glass electrodes. Scatchard, Scheinberg and Armstrong[8] studied the binding of chloride to serum albumin using silver–silver chloride electrodes. Carr has used permselective membranes as membrane electrodes to study the binding of cations and anions to a wide variety of proteins.[9]

Because permselective membranes selectively permit the transfer of only a single ion species from one solution to another solution of the same electrolyte, they act as a reversible electrode for that ion species.[10,11] This makes it possible to determine the activities of ions for which no specific reversible electrodes exist or where the use of such conventional electrodes offers considerable difficulty. This method was used in the studies described here to determine the activities of potassium and sodium in the presence of muscle proteins, and thus to determine the extent of their interaction.

Experimental

Myosin A was prepared by a modification of the procedure of Kessler and Spicer.[12] Five hundred grams of chilled, ground rabbit muscle was extracted for 10 minutes with 1500 cc. of ice-cold solution of 0.3 *M* KCl and 0.15 *M* *p*H 6.5 phosphate buffer. After 10 minutes, 6 liters of ice-cold water was added and the suspension was strained through gauze. The residue was used for the preparation of actin. The filtrate then was diluted slowly with 10 liters of cold water and the precipitated myosin allowed to settle. The supernatant was removed by aspiration and the precipitate was centrifuged. The separated precipitate was dissolved in 0.6 *M* KCl. This solution was diluted to 0.12 *M* by the addition of 4 volumes of cold water and clarified by centrifugation. Myosin was precipitated from the supernatant by dilution of the KCl to 0.03 *M* by the addition of 3 volumes of cold water. The myosin was collected by centrifugation and then re-dissolved in 0.6 *M* KCl. The myosin was stored at 0°.

At the time it was used the myosin solution was diluted to 0.12 *M* KCl and clarified by centrifugation. It was noted that the amount of insoluble material increased with the age of the preparation until after about seven days, no myosin would remain in solution. Whether this was essentially denatured myosin or some aggregate of myosin is not known. After centrifugation, the supernatant was diluted with 20 volumes of cold water, the *p*H adjusted to 5.4, and the myosin allowed to settle. The supernatant was removed by aspiration and the myosin concentrated by centrifugation. This procedure gave a protein concentration of 0.8 to 1.0% with a potassium content of about 0.006 *M*. Myosin A prepared in this manner was found to be homogeneous electrophoretically and in the ultracentrifuge. Measurements were made on the myosin within a period of 5 hours after the completion of the preparation.

Myosin B (natural actomyosin) was prepared[13] by extracting the ground muscle for 5 hours with an ice-cold solution of 0.75 *M* KCl, 0.01 *M* Na_2CO_3 and 0.04 *M* $NaHCO_3$. After extraction, the mixture was strained through gauze and then clarified by centrifugation. The binding activity of this protein was found to remain constant for at least three weeks when stored at 0°. The myosin was precipitated by diluting the solution with 30–40 volumes of cold water, and adjusting the *p*H to 6.8. After the myosin settled, the supernatant was removed and the precipitate concentrated by centrifugation. It was then redispersed in 30–40 volumes of cold water, the *p*H adjusted to 5.3, and the myosin allowed to settle again. The supernatant was removed and the precipitate was again concentrated by centrifugation. This gave a myosin concentration of 1.5 to 2.5% and with a potassium ion content of 0.001 *M* or less. This preparation was homogeneous neither electrophoretically nor in the ultracentrifuge.

Actin was prepared by the method of Tsao and Bailey.[14] The G-actin thus prepared was then clarified prior to use by centrifugation for 30 minutes at 75,000 × gravity. The amount of active polymerizable actin in the solutions thus produced was determined by measuring the protein content of the sample, polymerizing the actin, centrifuging down the gel, and determining the protein content of the supernatant which should be free of polymerized actin. Actin solutions prepared by this procedure and tested as described above had a protein concentration of about 2%, of which about one-half was active polymerizable actin.

The bovine serum albumin was the Armour crystalline product. The human serum albumin was fraction V obtained from the American Red Cross. These were dialyzed before use.

Membranes.—The strong acid type (negatively charged) collodion-base membranes used as the membrane electrodes were prepared by the method described by Neihof.[15] The solution used to prepare the membranes contained 0.15% sulfonated polystrene (mol. wt. ~70,000) and 3% collodion in a 50–50 alcohol–ether solution. The membranes were prepared by pouring this solution over 25 × 100 mm. test-tubes rotated in a horizontal position. Three layers were cast with an interval of five minutes between each layer. After the membranes were dried on the forms overnight, they were soaked in water for 30 minutes and water was forced between the membrane and the glass to facilitate removal of the membrane from the form. Glass rings were fitted to the membranes at their open end. After being dried for one hour in an oven at 60–70°, the membranes were stored in 0.1 *N* KCl or NaCl for at least three days before use.

These membranes were clear, colorless and free of wrinkles. They were approximately 50 μ thick and their resistance was approximately 200 ohms/sq. cm. in 0.1 *M* KCl. These membranes gave an average potential of 15.55 mv. (corrected for difference in liquid junction potential) with 0.2 *M* KCl on one side of the membrane and 0.4 *M* KCl on the other. This compares well with the theoretical maximum of 16.00 mv. at 27°, and indicates a high degree of selectivity.

Saturated calomel cells were used as indifferent reference electrodes in the measurement of the potentials. Agar-saturated KCl bridges were used to connect these cells to the solutions on each side of the membrane. Both cells were maintained at the same temperature in a bath to avoid thermal asymmetry potentials. The potentials were measured with a Leeds and Northrup type K potentiometer.

In the determination of the concentration of the potassium or sodium ion in a solution,[10,11] the solution of unknown concentration was placed inside the membrane tube and the membrane was immersed to about two-thirds of its length in 100 ml. of water in a 150-ml. beaker and clamped in position. Various volumes of 1.00 *M* KCl or NaCl were added to the external solution, the external solution stirred thoroughly, and the potential measured. Slight asymmetries in the liquid junction potential were found even when the solution was the same on both sides of the membrane. This difference was measured over a range of concentrations, and used to correct the measured potentials. If the potentials obtained are plotted against the logarithm of the concentration, a straight line will result. At the zero potential obtained from their graph, the activities of the critical ion inside and outside the membrane are the same, and it has been assumed here that their concentrations are the same. In this manner it was possible to determine the concentration of an unbound ion in the presence of a protein, and since the total quantity of that ion present could be readily determined, the amount bound could be calculated.

Twenty cc. ±0.02 cc. samples of the protein solutions were used. These were weighed out because the viscosity of the protein solutions made accurate pipetting difficult. The temperature of the solution was adjusted just before use, the desired amount of 1.00 *N* KCl or NaCl added, and the *p*H adjusted with dilute KOH or NaOH of known concentration. The *p*H was adjusted to within ±0.05 *p*H unit. The salts used to adjust the K^+ or Na^+ content were recrystallized three times to remove traces of impurities which produced erratic results. The protein concentrations were determined by dry weights of samples of known volumes. The residual potassium or sodium content of the protein solutions was determined with the flame photometer.

Experimental Errors.—For myosin B at *p*H 7.7, and at a free concentration of 0.01 *M* K^+, the standard error in $\bar{\nu}_K$ is 1.5%, and at 0.1 *M* K^+ is ±7.5%. For myosin A, which was used at a lower protein concentration, the error at 0.01 *M* K^+ is ±2.5%, and at 0.1 *M* K^+ is ±18%. These errors are somewhat higher at *p*H 6.4 and lower at *p*H 9.0. These

are the errors intrinsic in a single measurement. The errors in the apparent constants n' and k'_K were calculated from the scatter of the experimentally determined values of $\bar{\nu}_K$, after assuming that the data at pH 6.4 and pH 9.0 were essentially representative of the first and second sets of sites, respectively (see below). The errors in the apparent constants were determined by applying the least squares procedure using the equation

$$\frac{1}{\bar{\nu}_K} = \frac{1}{n'k'_K c_K} + \frac{1}{n'}$$

The values of $1/\bar{\nu}_K$ were so weighted that the variance of $1/\bar{\nu}_K$ was proportional to $1/c_K$. This was necessary to give equal weight to each value of $\bar{\nu}_K$. If this is not done, the low values of $\bar{\nu}_K$ have a much greater weight than high values of $\bar{\nu}_K$, and unrealistic variances of n' and k' result. It is shown in eq. 6 below that the apparent constant multiplied by $(1 + k_{H_1}c_H)$ gives the constant k_{K_1} when n and n' are assumed to be equal. Thus, the values of k'_{K_1} and k'_{K_2} multiplied by $(1 + k_{H_1}c_H)$ for the first set of sites (pH 6.4) and by $(1 + k_{H_2}c_H)$ for the second set of sites (pH 9.0) yield the values of k_{K_1} and k_{K_2} with their associated errors. This operation required an additional estimate of the errors in k_{H_1} and k_{H_2} and their inclusion in the calculation. The range in error of k_{H_1} and k_{H_2} was determined to be ± 0.2 pK unit from the curves shown in Fig. 1. (A change in 0.5 pK unit, the dotted curves, shifted the curve of the pH 7.7 binding by 0.3 of a pK unit too far out of a fit.) The errors shown in Tables II and III were thus calculated with the assumption that k'_K was independent of k_H.

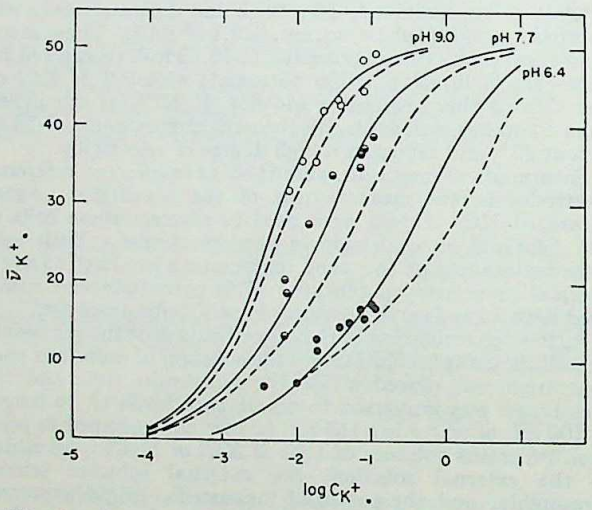

Fig. 1.—Concentration dependence data for the binding of potassium ions to myosin at 5°: ●, pH 6.4; ⊖, pH 7.7; ○, pH 9.0. Solid curves calculated from the constants shown in Table II using eq. 6. Dotted curves calculated from eq. 6 with the same constants except that the value of k_{H_2} has been changed to 10^9.

Myosin A—Results

Binding of potassium and sodium ions to myosin A was measured at 5°. It was important to avoid even brief exposures of myosin A to elevated temperatures. An exposure of a few hours at 27° resulted in a complete loss in binding ability of myosin A for potassium ions. Warming myosin A solutions to room temperature also brings about changes in sedimentation value.[16] The experimental points in Fig. 1 summarize our data on the concentration dependence of K^+ binding to myosin A at the pH values of 6.4, 7.7 and 9.0. Additional experiments were done at a free KCl concentration of 0.100 M at the pH values of 4.7, 5.2, 5.8, 6.4 and 7.0 to complete a pH dependence survey, the data for which are summarized in the experimental points of Fig. 2.

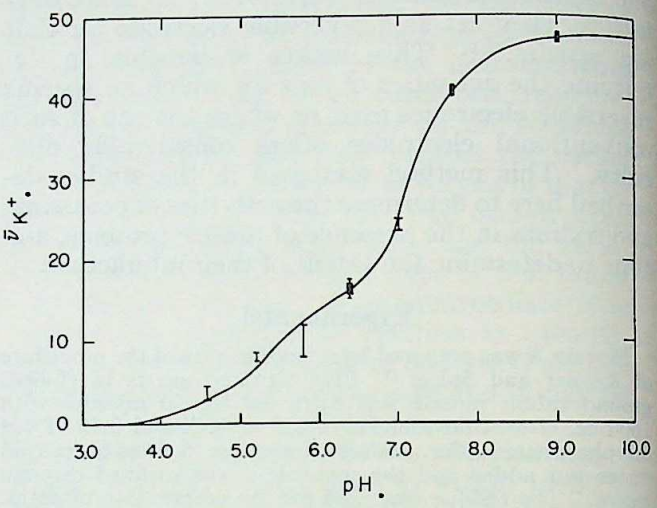

Fig. 2.—pH dependence data for the binding of potassium ions to myosin A at 5°. Concentration of free potassium ion was 0.100 M. Each symbol, I, represents the range of values from 3 to 4 measurements. The symbols, ▮, represent values found by interpolation of the concentration dependence data. The curve is calculated from eq. 6 and the constants in Table II.

Sodium ion binds to myosin A more strongly than does the potassium ion. A study of the concentration dependence of Na^+ binding to myosin A at 5° was made at pH 7.7. The data are represented in the experimental points of Fig. 3.

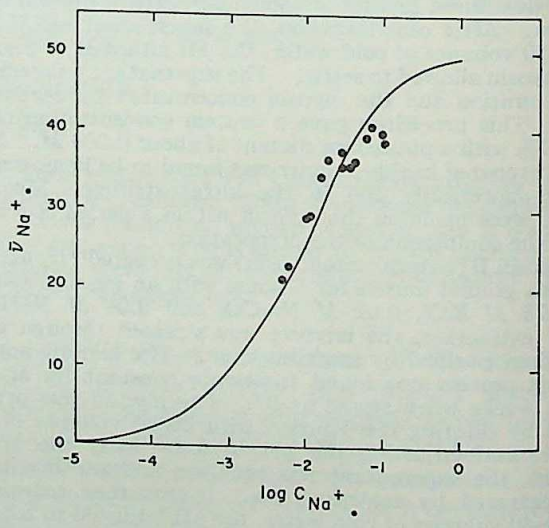

Fig. 3.—Concentration dependence data for the binding of sodium ions to myosin A at 5°, pH 7.7. The curve is that calculated from eq. 6 with the constants in Table II.

Effect of Actin on Binding of Potassium Ions to Myosin A.—To study the effect of actin upon the potassium binding of myosin A, various quantities of G-actin were added to samples of myosin A, the desired quantity of KCl was added, the pH adjusted to the desired value with KOH, and the free K^+ ion measured as previously described. The result of such an experiment is given in Fig. 4. If molecular weights of approximately 70,000 and 420,000 are taken for the actin and myosin A, respectively, then the potassium binding to the resulting actomyosin is at the same level as potas-

sium binding to myosin B (see below) when the molar ratio of actin to myosin A is 0.5:1 or greater. The binding of potassium to actin alone was studied at pH's 7.7 and 9.0 over the concentration range of 0.004 to 0.100 M K^+. Under these conditions, no binding of potassium to actin could be detected.

Interpretation of Myosin A Data

Apparent association constants, k'_K, and apparent maximum number of sites available n', may be evaluated from the concentration dependence data of Fig. 1 and the use of the mass law expression[17]

$$\bar{\nu}_K = \frac{k'_K c_K n'}{1 + k'_K c_K} \qquad (1)$$

where $\bar{\nu}_K$ is the average number of potassium ions found per mole of myosin, c_K is the concentration of the free potassium ions in solution, n' is the apparent maximum number of binding sites, and k'_K is the apparent intrinsic association constant. The usual methods of evaluating these constants are to plot $1/\bar{\nu}$ as a function of $1/c$,[17] or to plot $\bar{\nu}/c$ as a function of $\bar{\nu}$.[18] The values of k'_K and n' are determined from the extrapolated intercepts and slopes. Table I lists the values of k'_K and n' found in this manner from the concentration dependence curves at the three pH values. In Table I are listed, also, the values of k'_K calculated[8] from the k_{K_1} and k_{K_2} values of eq. 6 below. Both the variation of n' and k' with pH and the pH dependence data in Fig. 2 indicate the possibility of competition with hydrogen ion for the site to which the potassium ion is bound.

TABLE I

APPARENT BINDING CONSTANTS FOR MYOSIN A AT 5°

Bound ion	pH	n'	k'_K	$\frac{k_{K_1}}{1 + k_{H_1}c_H}$	$\frac{k_{K_2}}{1 + k_{H_2}c_H}$
K^+	6.4	18 ± 0.8	124 ± 24	89	..
K^+	7.7	43 ± 1.1	98 ± 11	..	..
K^+	9.0	50 ± 1.2	200 ± 33	..	150
Na^+	7.7	42 ± 0.6	225 ± 22	..	..

The following treatment involves the assumption of direct competition between hydrogen and potassium ion for the same site.[19,20]

Equations describing the competition at a single site are

$$\text{Site} + H^+ = (\text{Site } H^+)$$
$$\text{Site} + K^+ = (\text{Site } K^+) \qquad (2)$$

For a group of n sites per mole of protein, neglecting electrostatic corrections, the expression for the number of hydrogen ions bound per mole of protein, $\bar{\nu}_H$, becomes

$$\bar{\nu}_H = \frac{k_H c_H (n - \bar{\nu}_K)}{1 + k_H c_H} \qquad (3)$$

where k_H is the intrinsic association constant of the specific site ($k_H = 10^{pK}$) for hydrogen ion, c_H represents the concentration of the free hydrogen ion in solution, and $\bar{\nu}_K$ represents the number of

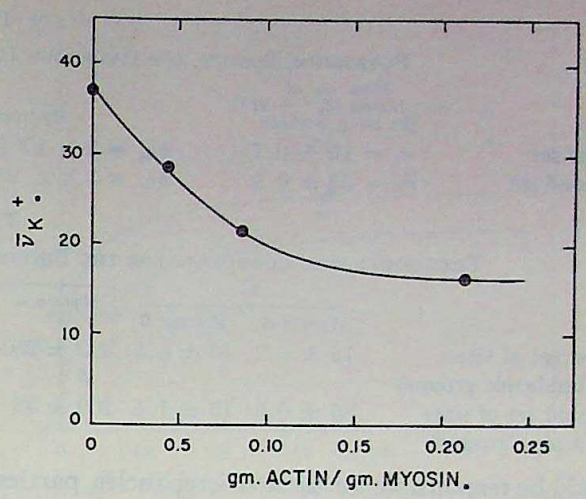

Fig. 4.—The effect of actin on the binding of potassium ions to myosin A at 5°, free K^+ concentration = 0.075 ± 0.002. (The curve is not a calculated one.)

potassium ions bound per mole of protein. The analogous expression for potassium ions is

$$\bar{\nu}_K = \frac{k_K c_K (n - \bar{\nu}_H)}{1 + k_K c_K} \qquad (4)$$

where k_K is the intrinsic association constant for the potassium ion, and c_K is the concentration of the free potassium ion. The solution of eq. 3 and 4 for $\bar{\nu}_K$ gives the expression

$$\bar{\nu}_K = \frac{k_K c_K n}{1 + k_K c_K + k_H c_H} \qquad (5)$$

If more than one set of sites is involved, equation 5 may be written

$$\bar{\nu}_K \text{ (total)} = \sum_i \bar{\nu}_{K_i} = \sum_i \frac{k_{K_i} c_{K_i} n_i}{1 + k_{K_i} c_K + k_{H_i} c_H} \qquad (6)$$

Thus, for this competitive concept, $k_{K_i} = k'_{K_i}(1 + k_{H_i} c_H)$ when n and n' are assumed to be equal.

Examination of the pH dependence data (Fig. 2) reveals that two sets of sites are probably active in potassium ion binding to myosin. When, therefore, two sets of sites, the first with $n = 15$ and the second with $n = 35$, are applied to eq. 6 the solid curves shown in Figs. 1 and 2 are calculated. These curves represent a satisfactory fit to the experimental data. Table II gives the values for n_1, n_2, k_{K_1}, k_{K_2}, k_{H_1} and k_{H_2} required for these calculated curves to fit the data on the assumption that there is competition as described by the eq. 2 and 6.

It is not too difficult to assign reasonable sets of ionizing groups to the pK and n values in Table II. Amino acid analysis[21] indicates that there are 15 histidine residues per 10^5 g. of myosin A. Mihalyi's titration data[7] indicate a pK of approximately 7 for imidazole groups at 25° (7.3 at 5°). Mihalyi's data also indicate approximately 25 amino groups with a pK of about 7.6 at 25° (8.2 at 5°) as well as a larger number at a pK between 10 and 11. The minor discrepancies between these values and the values of $n_2 = 35$ and $k_{H_2} = 3.3 \times 10^8$ (pK 8.5) found here may be at least partly attributable to the differences in the protein preparations used here and in Mihalyi's experiments. Differences of even small amounts of actin in the preparations

TABLE II

POTASSIUM, SODIUM AND HYDROGEN ION BINDING CONSTANTS FOR MYOSIN A AT 5°

	Max. no. of ions bound ($K^+ + H^+$) per 10^5 g. myosin	Association constants: Hydrogen ion	Potassium ion	Sodium ion
First set	$n_1 = 15 \pm 0.7$	$k_{H_1} = 2 \times 10^7$ ($pK_1 = 7.3$)	$k_{K_1} = 800 \pm 250$	$k_{K_1} = 1600 \pm 500$
Second set	$n_2 = 35 \pm 0.9$	$k_{H_2} = 3.3 \times 10^8$ ($pK_2 = 8.52$)	$k_{K_2} = 200 \pm 36$	$k_{K_2} = 400 \pm 72$

TABLE III

THERMODYNAMIC CONSTANTS FOR THE BINDING OF POTASSIUM IONS TO MYOSIN A AND MYOSIN B

	n_K		k_K			$\Delta F°_K$, cal./mole		$\Delta H°_K$, cal./mole av., 16°
	Myosin A	Myosin B	Myosin A 5°	Myosin B 5°	Myosin B 27°	5°	27°	
First set of sites (imidazole groups)	15 ± 0.7	10 ± 0.5	800 ± 250	800 ± 210	800 ± 210	−3690 ± 180	−3980 ± 160	0 ± 3100
Second set of sites (amino groups)	35 ± 0.9	15 ± 1.5	200 ± 36	200 ± 52	50 ± 10	−2930 ± 150	−2330 ± 120	−10,300 ± 2500

could be responsible for these discrepancies, particularly that in the value of n. Studies on myosin B, see below, support this line of reasoning.

Two other competitive mechanisms have been considered, particularly in an attempt to explain the anomalously high association constants for the binding of Na^+ and K^+ to myosin.[22] These mechanisms involve hydrogen bonding and may be described by the reactions

$$—COO^-....H_3^+N- + K^+ = -COOK + H_3^+N- \quad (7)$$

$$—COO^-....H_3^+N- + K^- = -COO^-..K^+..H_2N- + H^+ \quad (8)$$

Equation 7 represents competition between the potassium and ammonium (or imidazolium) ions for the carboxylate ion. Equation 8 represents competition between H^+ and K^+ for the hydrogen bonded and chelated positions, respectively.

Application of the binding expression derived from the idea in equation 7 can result in a satisfactory fit of the experimental data. However, the binding constants required for the fit were such as to result in abandoning the reaction of equation 7 as an explanation for Na^+ and K^+ binding.

The chelation mechanism of equation 8 results in a binding expression which not only fits the data but does so with values of the binding constants approaching those found for the direct competitive reaction of eq. 6. This chelation mechanism, while not changing the binding constants appreciably, makes the values of these constants more acceptable in light of our knowledge of the chelation of small compounds with Li^+, Na^+ and K^+.[23]

Myosin B—Results and Interpretation

The instability of preparations of myosin A at temperatures above 5° makes difficult a study of the temperature dependence of the potassium ion binding. Myosin B may be considered to be a complex of myosin A and actin and was, therefore, chosen as the protein to study for temperature dependence of the binding. Myosin A is the protein of choice for binding studies because this protein appears monodisperse on examination in both centrifugal and electrical force fields. However, myosin B, while stable at room temperature, is polydisperse under the conditions of these potassium ion binding studies. The heterogeneity of myosin B prepared in these studies was found to increase at pH 9.0. Blum[24] has reported a study of the dissociation of myosin B occurring at pH 9 and at relatively high salt concentrations.

Measurements were made at the pH values of 6.4, 7.7 and 9.0, and at the temperatures of 5 and 27°. The experimental points of Figs. 5 and 6 represent these data. Figure 7 summarizes all the experimental data collected at pH 9.0. The data with the free potassium ion concentration above 0.06 M at pH 9.0 were not used in the interpretation of the myosin B binding since we believe that the irregularities noted were caused by the dissociation and heterogeneity phenomena. The solid curves drawn in Figs. 5, 6 and 7 for the data at 5° are calculated curves derived from eq. 6 with the same association constants as those found for myosin A but with $n_1 = 10$ and $n_2 = 15$ for myosin B. (This lower number of binding sites may be attributed to the actin content.) The data fit well the calculated curves at pH 6.4 and 7.7, while there is a discrepancy of one order of magnitude for the value of k_{K_2} at pH 9.0.

The following procedure was used in evaluating the association constants for myosin B at 27°. First, the shifts in pK values for the hydrogen ions from 5 to 27° were calculated using the van't Hoff expression

$$\Delta H°_{ion} = -4.579 \frac{T_1T_2}{T_1 - T_2}(pK_2 - pK_1) \quad (9)$$

The values of $\Delta H°_{ion}$ used were 6,000 cal. for the imidazole groups and 11,000 cal. for the amino groups. This gave association constants at 27° of $k_{H_1} = 1 \times 10^7$ (pK 7.0) and $k_{H_2} = 8.7 \times 10^7$ (pK 7.94). Then, values of n and k_K at 27° were found to fit the experimental data. These were found to be $n_1 = 10$, $k_{K_1} = 800$, and $n_2 = 15$, $k_{K_2} = 50$.

The calculated curves and experimental data show satisfactory agreement except, again, for some of the data at pH 9. With the reservation that the discrepancies at pH 9.0 must be adequately explained, it appears reasonable to assume that similar sites in both myosin A and B bind potassium ions. The difference appears to lie in the number of sites available for binding. With the assumption that eq. 1 and 6 describe the binding reaction of potassium ions to myosin and that the extrapola-

(22) A detailed treatment by H. A. S. of these competitive mechanisms will appear elsewhere.

tion from myosin A to myosin B is legitimate, the values of $\Delta F°$ and $\Delta H°$, for the binding of K^+ to the imidazole and amino groups of myosin A and B were calculated using the relations

$$\Delta F°_K = -RT \ln k_K \qquad (10)$$

$$\Delta H°_K = RT^2 \left(\frac{\partial \ln k}{\partial T}\right)_P \qquad (11)$$

Table III summarizes the values for the binding sites of myosin.

Serum albumin, both human and bovine were studied at 27° in the *p*H range from 5 to 9 and in a concentration range from 0.01 to 0.09 *M* KCl. No binding ($\bar{\nu} = 0 \pm 1$) of potassium ions was found to occur under these conditions.

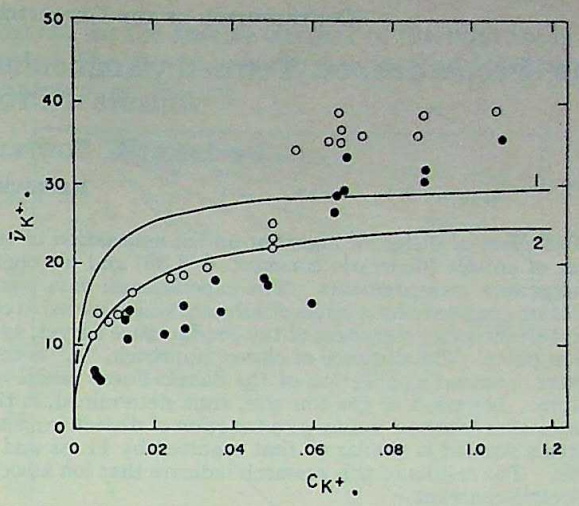

Fig. 7.—The binding of potassium ions to myosin B at *p*H 9.0: ●, 27°; ○, 5°. Curve 1 calculated for 27°, curve 2 calculated for 5° from eq. 6 with the same constants as in Figs. 5 and 6.

Actin was studied at 27° and at *p*H 7.7 and 9.0. No binding of potassium ions was found in the concentration range from 0.005 to 0.09 *M* KCl.

Discussion

The validity of the assumption that the activity coefficients of the free potassium and sodium ions are not affected seriously by the myosin is supported by the following observations: (1) the binding of sodium ions is stronger than that of the potassium ions, and (2) warming the myosin A solutions to room temperature destroys the binding properties of the protein. The second supporting argument requires the qualification that large changes in what constitutes the domain of the molecule (per unit weight) in solution do not occur in the warming process. Additional study of the temperature effect will be required to describe completely the change in myosin, particularly in light of the proposed chelation mechanism.

The temperature dependence data are subject to the limitations already described. The $\Delta H°_K$ for the first set of sites (imidazole groups) is similar to that found for association reactions between ions where it is assumed that oriented water of hydration is lost to give an increase in entropy. It is difficult to speculate on the reasons for the positive $\Delta H°_K$ value for the second set of sites (amino groups) in light of the uncertainties in the *p*H 9.0 data for myosin B. The difficulties in obtaining good temperature dependence data for binding to a protein such as myosin are intrinsic in the nature of this protein.

The Properties of Tetraethylammonium and Tetra-*n*-butylammonium Picrates in Anisole–Nitrobenzene Solutions[1]

BY ARNET L. POWELL[2] AND ARTHUR E. MARTELL

RECEIVED JULY 27, 1956

The effect of dielectric constant on ion association of tetraethylammonium and tetra-*n*-butylammonium picrates in mixtures of anisole (dielectric constant = 4.30) and nitrobenzene (dielectric constant = 34.9) was investigated by electrical conductance measurements. The experimental data were extrapolated to give limiting equivalent conductances and dissociation constants for a series of solvents which varied in composition from pure nitrobenzene to pure anisole. For each electrolyte, increasing steepness of the conductance curves, as anisole was added to nitrobenzene, indicated increasing formation of ion pairs. The distance of closest approach, "*a*," computed from the Bjerrum theory, varied with composition of mixed solvent, whereas application of the Sadek–Fuoss model resulted in an approximately constant value of "*a*" for each electrolyte. Insertion of the ion size, thus determined, in the Sadek–Fuoss equation gave a reaonably good reproduction of dissociation constant values as a function of dielectric constant. Variation of ion association with dielectric constant for the systems studied is similar to that reported by Fuoss and Kraus for tetraisoamylammonium nitrate in dioxane–water mixtures. The results of this research indicate that ion association is influenced by solvation as well as by ion constitution and dielectric constant.

Fuoss and co-workers[3–8] have conducted a series of investigations of electrolye–solvent interactions, using the single electrolyte, tetrabutylammonium bromide, in a variety of solvent mixtures. They found that the Bjerrum model was not satisfactory for all systems investigated, the values of the ion size "*a*" calculated from dissociation constants varying with composition of the solvent mixtures. In a number of cases, changes in ion association, observed for intermediate solvent compositions, were attributed to specific electrolyte–solvent interactions.

In this investigation, two quaternary ammonium salts—tetraethylammonium picrate and tetra-*n*-butylammonium picrate—are studied in mixtures of anisole and nitrobenzene. By variation of the solvent composition over the whole range, a variation of dielectric constant from 34.9 to 4.3 is possible. This combination of solvents offers the additional advantage of providing an opportunity of studying the effect of dielectric constant on solution conductance in a non-aqueous aprotic solvent relatively free of solute–solvent and solvent–solvent interactions. A study of conductance and ion association in such a medium would be of interest for comparison with the results of Fuoss and Kraus[9] for tetraisoamylammonium nitrate in dioxane–water mixtures.

Experimental

Apparatus.—The conductance bridge employed was a modification[10] of the design described by Foy and Martell.[11] A 0–20,000 cycle audio oscillator (General Radio No. 913-G) was used in all measurements. Temperature of the conductance cell was maintained at 25° within ±0.003° by means of a thermostatically-controlled constant-temperature oil-bath. Measurement and bath control were aided by dehumidification and regulation of room temperature in the range of 21–22°. The conductance cell was designed according to the specifications of Kraus and Fuoss,[12] and the cell constant was determined by measurement of the conductances of tetraethylammonium and tetra-*n*-propylammonium picrates in ethylene chloride, taking as standard the measurements of Tucker and Kraus.[13] The value thus determined was 0.03410. A redetermination, made after reconstruction of the cell, yielded the value 0.04163. The latter constant was used for all measurements made with tetra-*n*-butylammonium picrate.

Solvents.—Nitrobenzene and anisole were purified by vacuum distillation, using a modification of the method of Witschonke and Kraus.[14] An all-glass apparatus with ground glass joints was used with a distilling column designed to suppress entrainment. The solvent was refluxed 4–6 hours over activated alumina pellets and distilled slowly. Middle fractions were used for the conductance measurements. The best anisole obtained by this procedure had a specific conductance of about 7×10^{-11} mho, and the best nitrobenzene about 5×10^{-10} mho. Neither solvent was used for conductance measurements unless the specific conductance was less than 1×10^{-9} mho. The ethylene chloride used for cell calibration was purified as described by Healey and Martell[15] for ethylidene chloride. As checks on the purity of the solvents, the refractive indices at 20° were determined for ethylene chloride, anisole and nitrobenzene and the freezing point of the latter was measured. The results are summarized as follows

Solvent	$n^{20}D$ Measured	$n^{20}D$ Lit.	F. p., °C. Measured	F. p., °C. Lit.
Anisole	1.5170	1.5170[16]		
Ethylene chloride	1.4444	1.4443[17]		
Nitrobenzene	1.5524	1.5529[18]	5.82	5.72[19]
				5.50–5.85[20]

Measurements.—Densities of the solvents and solvent mixtures were determined in a 5-ml. pycnometer at 25 ± 0.01°. Doubly distilled water was used as the calibrating liquid. In the case of nitrobenzene, the best literature value of the density, 1.1987 g./ml.,[21] was used in the calculations in place of the measured value, 1.1983 g./ml. For anisole, the measured density, 0.9888 g./ml., was employed; Bien, Kraus and Fuoss[22] reported that the density of anisole at

25° is 0.9890 g./ml. The viscosities of the two solvents and a series of intermediate mixtures were measured in an Ostwald viscosimeter at 25 ± 0.01°, using doubly distilled water as a standard. Dielectric constants of anisole, nitrobenzene and mixtures of intermediate compositions were measured at Brown University through the courtesy of Professor Robert H. Cole. The measured values of the dielectric constant for anisole (4.302) and for nitrobenzene (34.91) agree well with National Bureau of Standards measurements (D of anisole = 4.33, D of nitrobenzene = 34.82).[23] The salts used had been prepared by previous workers.[10,15] Melting points were in good agreement with the literature. The procedure used for the conductance measurements was similar to that described by Healey and Martell.[15]

Results

The results of the density, viscosity and dielectric constant measurements are given in Table I.

TABLE I

PROPERTIES OF ANISOLE–NITROBENZENE MIXTURES AT 25°

Nitrobenzene, wt. %	Nitrobenzene, mole fraction	Density, g./ml.	Viscosity, poise	Dielectric constant
0.00	0.0000	0.9888	0.01008	4.30

100.00	1.0000	1.1987	.01823	34.91

The conductance data are summarized in Table II, where Λ is equivalent conductance and c is concentration in equivalents per liter. The various systems are identified by the weight % nitrobenzene above each set of data. All the solutions were sufficiently dilute so that their densities could be taken as that of the solvent without incurring appreciable error. Corrections for solvent conductance were negligible even in the most dilute solutions.

Discussion

In order to eliminate the effects of changing viscosity from mixture to mixture so that attention could be directed to the effect of variation in dielectric constant, the conductances in Table II were divided by the appropriate values of Λ_0, and Λ/Λ_0 was plotted against the square root of concentration.[6] The results are illustrated in Figs. 1 and 2.

To avoid crowding in these graphs, the curves for the 100% anisole and for the 88.95% nitrobenzene–11.05% anisole mixture in the tetraethylammonium picrate series and the curve for the 93.38% nitrobenzene–6.62% anisole mixture in the tetra-*n*-butylammonium picrate series were omitted. The limiting tangent determined from the Onsager equation is shown on each figure. As anisole is added to nitrobenzene, the dielectric constant of the mixture decreases, and an increase in ion association at a given concentration is observed (Figs. 1 and 2). In nitrobenzene, the curves are approximately straight lines and lie only a little below the limiting tangent. As the anisole content of the mixture is increased, the curves become progressively steeper at a given concentration.

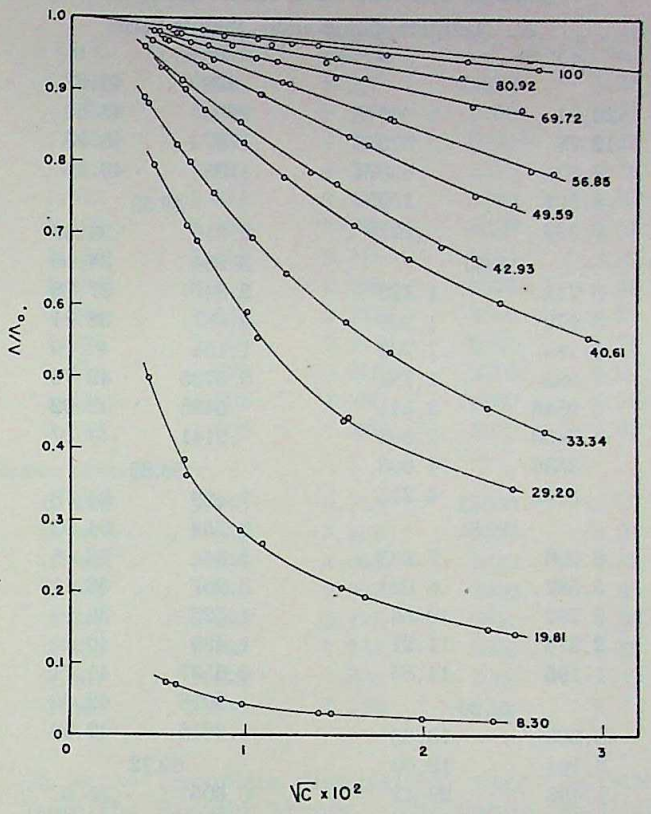

Fig. 1.—Reduced conductance curves: tetraethylammonium picrate in anisole–nitrobenzene mixtures. Figures to right of curves are weight % nitrobenzene.

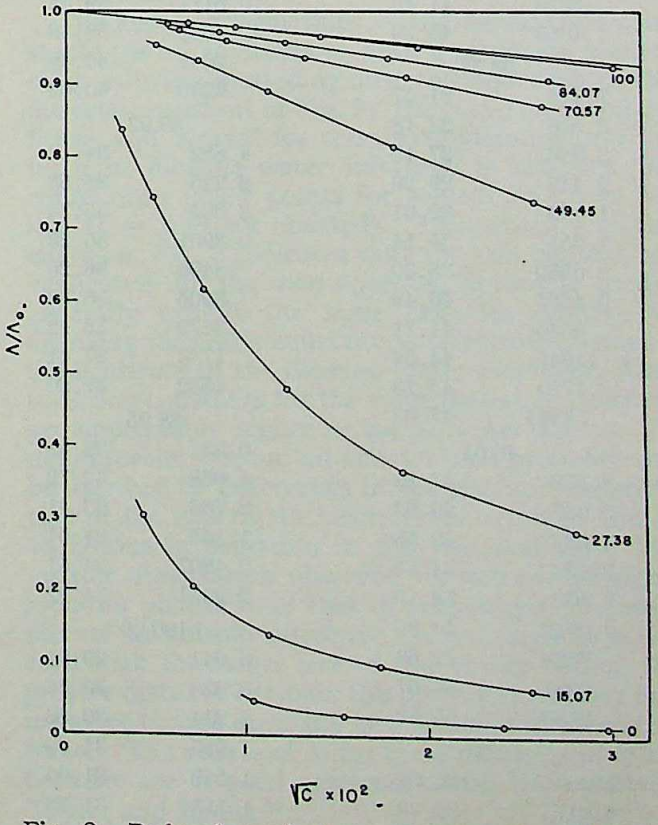

Fig. 2.—Reduced conductance curves: tetra-*n*-butylammonium picrate in anisole–nitrobenzene mixtures. Figures to right of curves are weight % nitrobenzene.

The conductance data for solutions of both picrates in the solvent mixtures with $D \geqq 10$ were extrapolated by use of the Shedlovsky equation[24,25] to obtain limiting conductances and dissociation constants. The values obtained are given in Table III.

The values of Λ for anisole and for the solvent mixtures with $D < 10$ were approximated by use of Walden's rule.[26] The Walden products were computed for each quaternary ammonium picrate for all solvent mixtures with $D > 10$ and plotted *versus* mole fraction nitrobenzene.

Since approximately linear relationships were obtained for each picrate, it was possible to approximate Walden products for mixtures with lower dielectric constants by extrapolation. From these, Λ_0 was calculated for each solution by dividing by the appropriate viscosity. The values of the dissociation constant K were determined by application of the Ostwald dilution law.[9,27] The values of Λ_0 and K determined in this way are included in Table III as are Walden products $\Lambda_0\eta_0$ for all solvents and solvent mixtures investigated.

The free energy of dissociation for each solution of each picrate was computed from

$$\Delta E = 2.303RT \log K$$

The results, which are given in Table III, tend to approach the thermal energy of the solvent molecules ($\Delta E = RT = 596$ cal.) as the dielectric constant increases. The dielectric constant at the point of closest approach represents the critical value, and is in both cases beyond the highest dielec-

[a] Estimated using Walden's rule.

tric constant available from the solvent system (D of nitrobenzene = 34.9).

The ion sizes "a" for each quaternary ammonium picrate were computed from the value of K for each solution by application of the Bjerrum equation.[28] The values of "a" for each salt thus obtained were not constant but varied with the composition of the solvent, as can be seen by referring to Table III. Hence, it was not possible to evaluate the mean ionic diameter by taking an average value, as was done by Fuoss and Kraus,[9] and the modified "sphere-in-continuum" theory of Sadek and Fuoss[8] was employed to obtain constant values of "a" for each solute. The relationship given by Sadek and Fuoss is

$$K = k_D/(1 + k_s)$$

where K is the ion-pair dissociation constant obtained by extrapolating the conductance data, K_D is the solvated ion pair dissociation constant calculated from the Bjerrum equation, and k_s is an empirically-derived "solvation constant" for the expulsion of the intervening solvent from an incipient ion pair. By the use of this method, "a" for tetraethylammonium picrate was found to be 5.8×10^{-8} cm., and for tetra-*n*-butylammonium picrate, 6.0×10^{-8} cm. The computed dissociation constants agree reasonably well with the experimentally-determined values, as can be seen by comparison of the $-\log K$ (exptl.) and $-\log K$ (calcd.) values in Table III. For both picrates, the average difference between the calculated and experimental values of $-\log K$ is 3.4%.

The values of the dielectric constant for each solute–solvent system corresponding to $K = 1$ and $K = \infty$ (complete dissociation) were computed from the Bjerrum theory. The values for tetraethylammonium picrate in anisole–nitrobenzene mixtures were 44 and 48, respectively; for tetra-*n*-butylammonium picrate, the corresponding values were 43 and 47.

The negative logarithms of the dissociation constants for all solutions of both quaternary ammonium salts are plotted against the logarithm of the dielectric constant in Fig. 3; the curve obtained by Fuoss and Kraus[9] for tetraisoamylammonium nitrate in dioxane–water mixtures is included for comparison (their points for solvent mixtures below $D = 3.48$ are omitted). Examination of the curves in Fig. 3 indicates that the two picrates investigated in the non-aqueous, aprotonic media generally exhibit the same behavior relative to changing dielectric constant as tetraisoamylammonium nitrate in the dioxane–water mixtures. Dissociation constants for the same dielectric constant are appreciably higher in the aqueous than in the non-aqueous system, an effect which probably can be ascribed to differences in the size and constitution of the ions of the electrolytes involved and to variations in solvation in the two systems. The greater dissociation observed for tetra-*n*-butylammonium picrate over that of tetraethylammonium picrate in anisole–nitrobenzene mixtures is in accord with the larger size of the former cation, the greater distance between the centers of positive and negative charge resulting in a decrease in attractive force. The values of Λ_0 for these two salts in nitrobenzene are in good agreement with the results of Taylor and Kraus.[29]

The values of the dielectric constant for $K = 1$

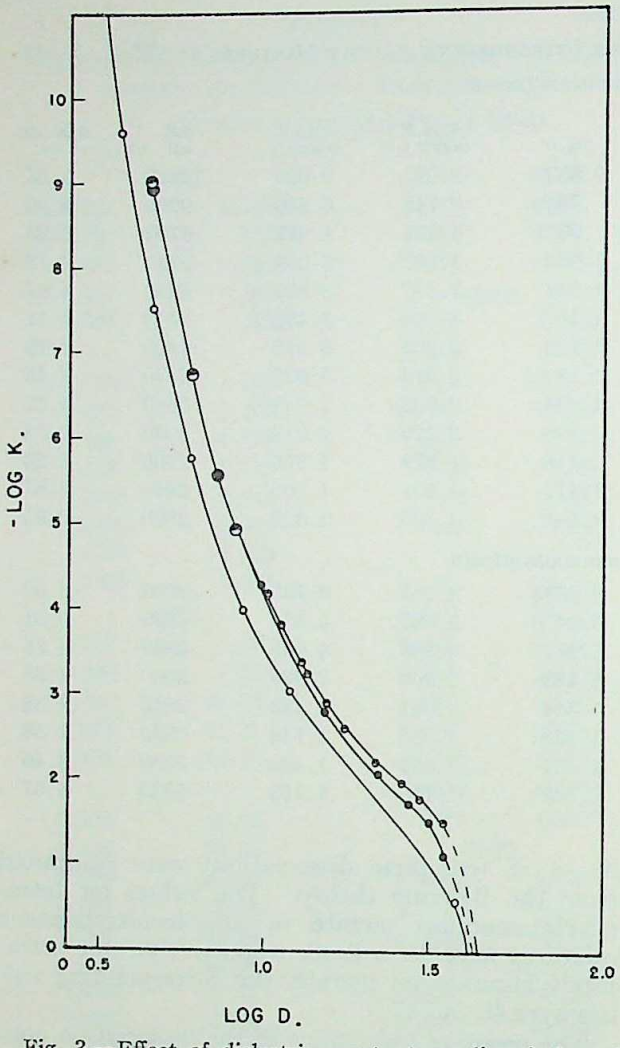

Fig. 3.—Effect of dielectric constant on dissociation of electrolytes in mixed solvents: ⊖, tetraethylammonium picrate in anisole–nitrobenzene mixtures; ●, tetra-*n*-butylammonium picrate in anisole–nitrobenzene mixtures; ○, tetraisoamylammonium nitrate in dioxane–water mixtures.

for each quaternary ammonium picrate in the anisole–nitrobenzene solvent system calculated using the "*a*" values derived from the Sadek–Fuoss model[8] appear to be reasonably close to the results which would be obtained by extrapolating the $-\log K$ *vs.* $\log D$ curves. In any event, these D values and the corresponding critical dielectric constants are only approximate, being limited by the uncertainties in the larger values of K as well as the validity of the assumptions underlying the Sadek–Fuoss model. Fuoss[6,8] and Kraus[30,31] have pointed out that reliable values of dissociation constants from conductance measurements cannot be obtained for $K > 0.01$ because of uncertainties in the magnitudes of the c and $c \log c$ terms in the Onsager equation.

Densities and molar volumes of the solvent mixtures change smoothly from anisole to nitrobenzene, and deviations from volume additivity are small, the maximum being about 0.16%. The values of dielectric constant also vary smoothly with composition of the solvent mixtures. The viscosities of the solvent mixtures change continuously from the less viscous anisole to nitrobenzene and the curve shows little structure. There is no evidence of specific interactions leading to sharp changes in ion association at intermediate solvent composition of the type observed by Fuoss, *et al.*[3–8] and by Kortum and co-workers.[32,33] Since the conductance–viscosity products are approximately constant for both systems investigated (Table III), it could be expected that Stokes' law would hold and that, at least hydrodynamically, the "sphere-in-continuum" model would be a good representation of the physical facts. Constancy of the Walden products requires that the effective ionic volumes should be constant: that is, the ion size "*a*" should not change for that particular system. However, the values of "*a*" calculated from the experimentally determined dissociation constants are not the same but vary continuously, decreasing with increasing nitrobenzene content.

There are two possible explanations which may be advanced to account for this situation. The first of these is that a solvation effect is involved. The observed increase of effective ion size with rising anisole content is consistent with an increase in solvation. Kraus[34] has shown that even large ions, such as quaternary ammonium ions, show specific differences in going from solvent to solvent and that frequently Stokes' law does not apply. Fuoss[8] has raised a possible objection to an explanation on a solvation basis in that this would require that the solvate shall remain intact in the ion pair. Regardless of the validity of this argument, the constancy of the $\Lambda_0\eta_0$ values for the systems investigated indicated that approximately constant ion sizes were to be expected.

The second explanation involves the assumption that the Bjerrum model does not apply to this system. When an anion and a cation are separated by appreciable distances, it seems reasonable to assume that the macroscopic dielectric constant of the medium is a good approximation for calculating the potential energy of the two ions approaching to form a pair. However, upon closer approach of the two ions, it is likely that such an approximation can no longer hold since the solvent molecules will be polarized by the intense electric fields of the ions. The Sadek–Fuoss model is an attempt, on an empirical basis, to solve this problem. It apparently works very well for tetrabutylammonium bromide in nitrobenzene–carbon tetrachloride mixtures[8] and reasonably well in this case for tetraethylammonium picrate and tetra-*n*-butylammonium picrate in anisole–nitrobenzene mixtures.

The results of this research confirm Kraus'[31] conclusion that the variation in ion size with changing dielectric constant cannot be attributed to experimental error. It is much more likely that the mean diameter of the solvated ions cannot be expressed precisely by the Bjerrum theory, and that some additional concept is required for the interpretation of experimentally-derived ion-pair dis-

sociation constants. Indeed, Azzari and Kraus[35] have shown recently that the Bjerrum equation fails completely in solutions of higher dielectric constant.

Acknowledgments.—The authors are indebted to Dr. C. A. Kraus of Brown University for suggesting this research topic and for valuable discussions and advice. Thanks are also due to Professor Robert H. Cole of Brown University for the use of his apparatus to measure dielectric constants of the solvent mixtures. Appreciation is expressed for solvents to The Dow Chemical Company for ethylene chloride, and the Calco Chemical Company for nitrobenzene.

The Association of 4-Methylimidazole with the Ions of Cupric Copper and Zinc; with Some Observations on 2,4-Dimethylimidazole

BY YASUHIKO NOZAKI,[1] FRANK R. N. GURD, RAYMOND F. CHEN AND JOHN T. EDSALL[2,3]

RECEIVED DECEMBER 7, 1956

The 4-methyl and the 2,4-dimethyl derivatives of imidazole have been studied in their interactions with hydrogen, cupric and zinc ions, at different temperatures. The *p*H titrations, in the absence of Cu or Zn ions, gave pK' values which were extrapolated to zero ionic strength. Heats of reaction and standard entropies associated with these pK values were also determined. ($\Delta H°$ is in the range 8.5 ± 0.7 kcal./mole and $\Delta S°$ in the range −6.5 ± 0.8 cal. deg.$^{-1}$ mole^{-1}.) Similar titrations, in the presence of Cu(II) and Zn(II), showed that the number of molecules of both imidazole derivatives, bound to either of these ions, approached an upper limit of 4, at high imidazole concentrations. This number is the same as for unsubstituted imidazole. The intrinsic association constants log $\kappa_i (i = 1,2,3,4)$ at 25° were found for 4-methylimidazole to be 3.53, 3.31, 3.05 and 2.56, respectively, for combination with Cu(II), and 1.84, 2.35, 2.82 and 2.98 for combination with Zn(II). Approximate values for $\Delta H°$ in the combination of 4-methylimidazole with these ions have been estimated. Incomplete studies on the binding of 2,4-dimethylimidazole to copper indicated association constants of the same order of magnitude, but somewhat smaller, than those for 4-methylimidazole. A discussion is given of the stereochemistry of the copper and zinc complexes, and of some of the structural implications of the observed association constants.

The reactivity of the imidazole group of the histidyl residue in proteins has assumed great importance for the understanding of interactions between proteins and several metallic ions.[4-6] A previous report described the application of a method suggested by Scatchard to the interpretation of the equilibria between the parent imidazole and Cu(II) and Zn(II) ions.[7] A similar study has now been made of the corresponding equilibria of the 4-methyl derivative of imidazole, chosen because it is substituted in the same position as the imidazole ring in the histidyl residue, and thus represents a step toward the study of the metal-binding behavior of the histidyl residue in peptide chains. A fragmentary study has also been made of 2,4-dimethylimidazole, in order to determine whether the additional methyl group, attached to the carbon atom between the two nitrogens of the imidazole ring, would significantly alter the binding of the imidazole molecule to the metallic ions.

Materials and Methods

4-Methylimidazole was prepared as the crystalline salt, 4-methylimidazolium nitrate, by a modification of the method of Weidenhagen and Herrmann.[8] The free base was prepared, in the manner described by them, from acetol acetate, aqueous ammonia and formaldehyde in the presence of cupric acetate. The resulting copper complex of 4-methylimidazole was decomposed, and the copper precipitated as sulfide, by treatment with hydrogen sulfide at 50°. After removal of the precipitate, and cooling, dilute nitric acid was added cautiously to the solution, with constant stirring, until a *p*H between 2 and 3 was attained. (Further addition of nitric acid decreases both the yield and the purity of the product.) The solution was concentrated by evaporation to a small volume, *in vacuo* at 45–55°, filtered with charcoal and dried in a desiccator. The resulting crude product was recrystallized two or three times from acetone. The material was colorless and melted at 110.5–111.5°. Dedichen[9] reported a melting point of 110°. The purity of the material obtained by us was confirmed also by the constancy of the value of pK' obtained in the *p*H titrations (see below) for widely varying ratios of the concentration of free base to that of the conjugate imidazolium ion.

2,4-Dimethylimidazole also was prepared by the method of Weidenhagen and Herrmann[8]; the base released on removal of Cu(I) by sulfide was converted directly to the nitrate and the product was obtained by evaporation to dryness at low temperature. Recrystallization was from acetone or acetone–ether mixtures. Thrice recrystallized 2,4-dimethylimidazolium nitrate melted at 133–134°. The purity of the product was confirmed by the *p*H titrations discussed below.

The preparation of mixtures of methylimidazolium nitrates and Cu(II) or Zn(II) nitrates and their titration with NaOH were carried out as previously described.[7] The *p*H of each mixture was determined with a Beckman

Model G pH meter, first at 2.5° in a cold room and again at laboratory temperature. The instrument and solutions were allowed to reach temperature equilibrium for several hours before readings were taken. Measurements were repeated at five-minute intervals and care was taken to maintain the precision of the measurements at ±0.01 pH unit. The buffer described by Bates and Acree[10] containing 0.02M KH_2PO_4, 0.03M Na_2HPO_4 and 0.02M NaCl was used for calibration. The pH values assigned to this buffer at various temperatures were obtained by interpolation in Table II of the publication of Bates and Acree.[10]

Results

Dissociation of Hydrogen Ions.—Table I shows the pK' values for the dissociation of 4-methylimidazole and of 2,4-dimethylimidazole. The values for the former were obtained at 2.5 and 29°, and for the latter at 4 and 22°. Interpolated or extrapolated pK' values are given at 25°. Solutions were made up to 0.02M in total imidazole derivative and the ionic strength adjusted with sodium nitrate. The titration of 4-methylimidazole was carried out, at each ionic strength and temperature, for seven different ratios of imidazolium ion to free base, ranging from 6 to 0.17. The calculated pK' values for the seven solutions agreed within ±0.01, except occasionally at the extreme ends of the curve, where the deviation was sometimes twice as great. The titrations of 2,4-dimethylimidazole are somewhat less accurate, with a probable error of perhaps ±0.025 in the reported pK' values.

The results are given for several different ionic strengths ($\Gamma/2$) and are extrapolated to zero ionic strength according to a simplified version of the Debye–Hückel equation previously employed by Kirby and Neuberger.[11]

$$pK = pK' - 0.5\sqrt{\Gamma/2}/(1 + \sqrt{\Gamma/2})$$

The results of the present study are compared in Table II with their measurements, in which the hydrogen electrode was used. The results agree within experimental error.[12]

TABLE I

APPARENT DISSOCIATION CONSTANTS, pK', AT VARIOUS TEMPERATURES AND IONIC STRENGTHS FOR THE CONJUGATE ACIDS OF TWO IMIDAZOLE BASES

Ionic strength	Temp., °C. 2.5	29	25
	4-Methylimidazolium ion		
0.16	8.20	7.60	7.69
.076	8.17	7.56	7.65
.034	8.15	7.55	7.64
.00	8.06	7.46	7.55
	2,4-Dimethylimidazolium ion		
	4	22	25
0.16	9.05	8.59	8.52
0.00	8.91	8.45	8.38

The values of $\Delta H°$ in Table II range from 7.7 to 9.2 kcal./mole. These values are somewhat larger than those which usually have been assumed as typical for imidazole groups.[13] The standard entropy of ionization is in all cases negative and of the order of −6 cal. deg.$^{-1}$mole^{-1}. In attempting to interpret these values, we note that the process involved is the transfer of a proton from an imidazolium ion to a water molecule to form an H_3O^+ ion. Both the imidazolium ion and the H_3O^+ ion tend to attract and orient water molecules, with an accompanying entropy decrease, around a positively charged center, but the orientation around the positively charged imidazolium nitrogen will be obstructed to some extent by the adjoining atoms of the ring; whereas no such obstruction exists around the H_3O^+ ion. Hence a moderate negative value of $\Delta S°$ is to be expected for a proton transfer of this type.[14]

TABLE II

THERMODYNAMIC VALUES FOR THE HYDROGEN ION EQUILIBRIA OF VARIOUS IMIDAZOLES AT 25°

Conjugate acid of	pK at $\Gamma/2 = 0$	$\Delta F°$, kcal./mole	$\Delta H°$, kcal./mole	$\Delta S°$, cal. deg.$^{-1}$ mole^{-1}
Imidazole	6.95[a]; 6.97[b]	+ 9.5	+7.7[f]	−6.0
1-Methylimidazole	7.06[c]	+ 9.6		
2-Methylimidazole	7.86[a]	+10.7		
4-Methylimidazole	7.52[a]; 7.54[d]	+10.3	+8.6	−5.7
2,4-Dimethylimidazole	8.36[a]; 8.38[d]	+11.4	+9.2	−7.4
2,4,5-Trimethylimidazole	8.92[e]	+12.2		

[a] A. H. M. Kirby and A. Neuberger, *Biochem. J.*, **32**, 1146 (1938). [b] J. T. Edsall, G. Felsenfeld, D. S. Goodman and F. R. N. Gurd, THIS JOURNAL, **76**, 3054 (1954). [c] N. C. Li, J. M. White and E. Doody, *ibid.*, **76**, 6219 (1954). [d] Present investigation. [e] R. W. Cowgill and W. M. Clark, *J. Biol. Chem.*, 198, 33 (1952), give a pK' for this substance of 8.86 in 23.3% ethanol at 30° and ionic strength 0.2. Following their calculation, we have taken the value in water, at 25° and zero ionic strength, as 0.06 greater than this. [f] In reference 6, the value of $\Delta H°$ for imidazole was given incorrectly as 6.0 kcal./mole. The value listed here is based on the data given in that reference, and the calculation has been corrected. Values for $\Delta H°$ and $\Delta S°$ are based on temperature coefficients of pK values determined in the present investigation, or in reference *b* above.

Association of Cu(II) and Zn(II) with 4-Methylimidazole.—The results of the titration of mixtures of 4-methylimidazole with $Cu(NO_3)_2$ and $Zn(NO_3)_2$ are summarized in Tables III and IV. Throughout these measurements the ionic strength was maintained at 0.15–0.16. The first three columns in Table III, and the subhead and first column of Table IV, define the compositions of the mixtures; the next three columns show the results at 2.5°; and the last three show the results at 29 and 27°, respectively. The concentration of the imidazole derivative in the free base form is expressed as its negative logarithm, pA, and the average number of 4-methylimidazole molecules bound per metal ion is denoted by $\bar{\nu}$. The values of pA and $\bar{\nu}$ were obtained from the data by the method previously employed with imidazole.[7]

From the data in Tables III and IV plots of $\bar{\nu}$ against pA (Bjerrum's "formation function") may be constructed. The curves so formed are nearly symmetrical about $\bar{\nu} = 2$, and it appears reasonable to assume that $\bar{\nu}$ approaches a limiting value of 4 at high concentrations of free 4-methylimidazole. The justification for this assumption lies partly in the approximate symmetry about $\bar{\nu} = 2$, referred to above, and partly in the extensive evidence that coördination complexes of Cu(II) and Zn(II) with nitrogenous bases generally approach a $\bar{\nu}$ value of 4. Similar conclusions concerning the Cu(II)–imidazole system[7] have been confirmed by the polarographic technique.[15]

The data in Tables III and IV have been analyzed by the method of Scatchard[7] from plots of log Q *versus* $\bar{\nu}$ where

$$Q = \bar{\nu}/(4 - \bar{\nu})\,(A) \qquad (1)$$

These plots are shown in Figs. 1 and 2, derived from the data of Tables III and IV, respectively. The open circles represent points observed at 29 and 27°, respectively, and the closed circles at 2.5°. The

(15) N. C. Li, J. M. White and E. Doody, THIS JOURNAL, 76, 6219 (1954).

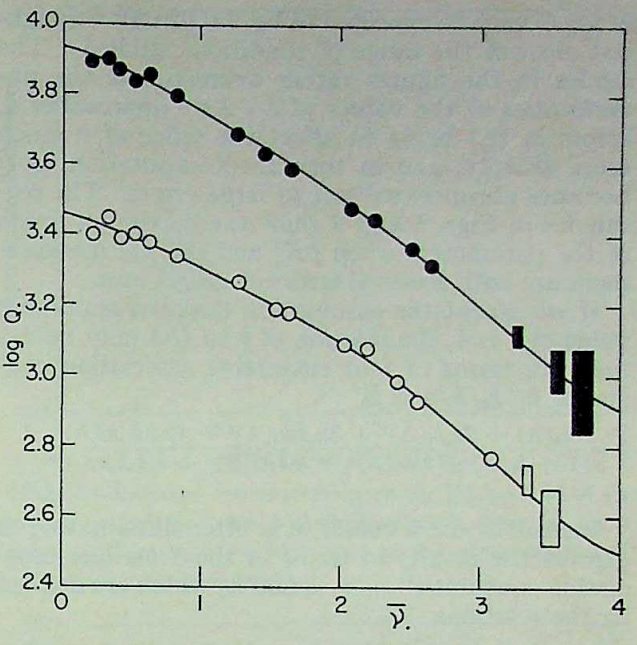

Fig. 1.—Values of the Scatchard function log Q for the binding of Cu(II) to 4-methylimidazole as a function of the mean number ($\bar{\nu}$) of imidazole molecules bound per Cu ion: upper curve data at 2.5°; lower curve data at 29°. Increased probable error of the data at high $\bar{\nu}$ values is indicated by the increased height of the rectangles on the right-hand side of the curves. Circles and rectangles are experimental values; curves are drawn on the basis of the constants listed in Table V.

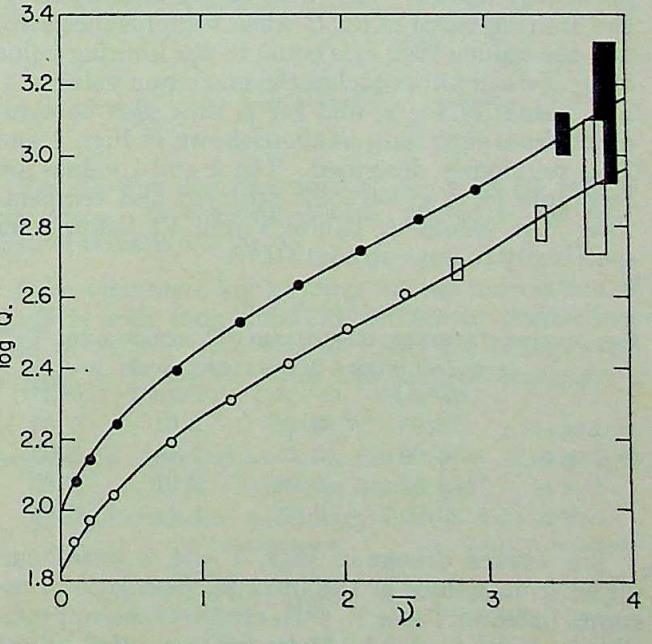

Fig. 2.—Log Q for the binding of Zn(II) to 4-methylimidazole. The data should be compared with those for Cu(II) in Fig. 1: upper curve data at 2.5°; lower curve data at 27°.

circles are drawn to represent the probable accuracy with which log Q is measured. Errors in the pH measurements affect most directly the value of (A) in equation 1. The computed value of (A) depends both on the measurement of the pH in the experimental mixture and on the value of pK' determined separately. Taking the precision of both values as ±0.01 unit, the uncertainty in the value

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

of log Q may be expected to be ± 0.02 unit throughout most of the range of conditions studied. The circles in the figures rather overestimate the uncertainties in the values of $\bar{\nu}$. As $\bar{\nu}$ approaches 4, errors in (A) begin to affect the value of $\bar{\nu}$ much more sharply, and in turn the computation of Q becomes abruptly subject to large errors. The rectangles in Figs. 1 and 2 show the maximum limits of the parameters when pK' and the pH measurement are both ascribed errors of ± 0.01 unit.

If we accept the assumption that the maximum value of $\bar{\nu}$ is 4, the relation of $\bar{\nu}$ to (A) may be defined[7] in terms of four successive association constants, k_1, k_2, k_3 and k_4

$$\bar{\nu} = \frac{k_1(A) + 2k_1k_2(A)^2 + 3k_1k_2k_3(A)^3 + 4k_1k_2k_3k_4(A)^4}{1 + k_1(A) + k_1k_2(A)^2 + k_1k_2k_3(A)^3 + k_1k_2k_3k_4(A)^4} \quad (2)$$

Instead of the k values, it is often illuminating to express the results in terms of the "intrinsic association constants," κ_1, κ_2, κ_3 and κ_4, which are defined by the relations

$$\kappa_1 = k_1/4;\ \kappa_2 = 2k_2/3;\ \kappa_3 = 3k_3/2;\ \kappa_4 = 4k_4 \quad (3)$$

The factors $^1/_4$, $^2/_3$, $^3/_2$ and 4 in (3) are statistical factors. For a system in which all the ligand sites are equivalent and also react independently with the ligand, all the four κ values would be identical. In the systems studied here, this is far from being the case, and the differences in the successive κ values give a measure of the character of the interactions in the binding of the ligand molecules. As previously shown,[7] the value of log κ_1 is equal to the limiting value of log Q when $\bar{\nu}$ approaches zero, and the value of log κ_4 is equal to the limiting value of log Q when $\bar{\nu}$ approaches the maximum value of 4. The values of log κ_2 and log κ_3 may also be computed from such data as those shown in Figs. 1 and 2, as previously described. The k and κ values are constants for a given ionic strength and temperature; the values in Tables V and VI below refer specifically to ionic strength 0.16.

TABLE V

CALCULATED INTRINSIC ASSOCIATION CONSTANTS FOR Cu^{II} AND Zn^{II} WITH 4-METHYLIMIDAZOLE

	Cu^{II}(2.5°)	Cu^{II}(29°)	Zn^{II}(2.5°)	Zn^{II}(27°)
Log κ_1	3.93	3.46	2.01	1.83
Log κ_2	3.69	3.24	2.53	2.33
Log κ_3	3.36	2.99	3.01	2.80
Log κ_4	2.90	2.50	3.15	2.95

The curves drawn in Figs. 1 and 2 were computed from values of the intrinsic association constants listed in Table V. To obtain these, approximate values of κ_1 and κ_4 were first obtained by extrapolation and values of κ_2 and κ_3 were estimated roughly from the values of log Q corresponding to $\bar{\nu} = 1.5$ and $\bar{\nu} = 2.5$, respectively. The values reported in Table V were obtained by successive approximations, to give the best fit between the observed and calculated curves.

In general, a plot of log Q *versus* $\bar{\nu}$ yields most directly the values of κ_1 and κ_4. In the present study, based on pH measurements, κ_1 may be determined with considerable accuracy but, as Figs. 1 and 2 show, the extrapolation to obtain κ_4 is more uncertain. The uncertainty in κ_4 corresponds to about [illegible] of general applicability for estimating temporary values of κ_2 and κ_3 from limiting slopes[7,16] cannot be exploited conveniently. It was found that the value of the product $\kappa_2\kappa_3$ was fixed by the experimental data with considerably less uncertainty than the value of either κ_2 or κ_3 alone. The same point has been emphasized by the very careful studies of Roughton, Otis and Lyster[17] on the combination of sheep hemoglobin with oxygen—a problem mathematically identical with that considered here, if we substitute hemoglobin for Cu(II) or Zn(II), and the concentration of free oxygen in solution, or its partial pressure, for (A).

We estimate the probable range of error of the successive log κ values given in Table V to be ± 0.04, ± 0.10, ± 0.10 and ± 0.20, respectively. The error in the product log $(\kappa_2\kappa_3)$, however, is estimated at ± 0.05–0.06. If anything, we believe that this estimate overstates the probable errors. Standard enthalpy changes, $\Delta H°$, for the first three steps of the complex formation with Cu(II) are computed to be -6.7, -6.4 and -5.3 kcal./mole and with Zn(II) are -2.8, -3.1 and -3.1 kcal./mole. The values for the first step are subject to an uncertainty of about ± 1 kcal./mole, and for the second and third steps they may be as great as ± 3 kcal./mole. No significance can be attached to the apparent trend in the values for the successive steps. The calculation of $\Delta H°$ values for the fourth step scarcely appears justified, in view of the probable errors in the values of κ_4. For imidazole[7] the corresponding value for the first stage of the interaction with Cu is approximately -4.9 kcal./mole, while the value for imidazole and Zn is also negative but decidedly smaller.[18] We note that the combination of a Cu or a Zn ion with an imidazole nitrogen —or rather the displacement of a water molecule and its substitution by an imidazole molecule at one of the coördination positions around the ion— is thus an exothermic process. The heat liberated in the reaction, however, is significantly less than that produced by the combination of a proton with a basic nitrogen of imidazole or one of its methylated derivatives (see Table II). In view of the uncertainty of the data it appears unprofitable to calculate standard entropy changes ($\Delta S°$) for the interactions of 4-methylimidazole with Cu and Zn ions. It may be estimated with some confidence, however, that for the first step of the complex formation with Cu(II) $\Delta S°$ is probably negative.

Association of Cu(II) with 2,4-Dimethylimidazole.—Because of the high pK value of the 2,4-dimethyl derivative (Table II) and the tendency of uncomplexed Cu(II) to hydrolyze at pH values above about 6,[6] only the first step of the association could be determined with assurance. The measurements were made at ionic strength 0.16 and at 26 or 20.5°. Three values of $\bar{\nu}$ between 0.23 and 0.44 were obtained at pH values ranging between 5.37 and 5.72, and the values of log k_1 were

computed to be 3.89, 3.91 and 3.95. Since some contribution from the second step of association was to be expected, judging from analogy with the 4-methylimidazole system (see Fig. 3, below), we estimate that the value of log k_1 at about 25° is 3.8 ± 0.1. This is equivalent to log κ_1 = 3.2 ± 0.1.[7] Very rough estimates from the titration data gave values for log κ_2, log κ_3 and log κ_4 which were of the order of 3.0, 2.6 and 2.4, respectively. These values, however, should not be taken as indicating anything more than the order of magnitude of the constants involved. Values of $\bar{\nu}$ as high as 3.6 were estimated for the solutions containing the highest concentrations of 2,4-dimethylimidazole relative to Cu, but the *p*H in these solutions was as high as 7.8–7.9. Although by working at low total concentrations of cupric ion—of the order of 0.006 *M*—it was possible to attain such high *p*H values without precipitation of cupric oxide, accurate evaluation of the data would require careful correction for the binding of some of the added hydroxyl ion by copper (see the detailed discussion in reference 7). We have therefore refrained from presenting the detailed data for the 2,4-dimethylimidazole system. The available evidence indicates that the association constants involved are all of the same order of magnitude but somewhat lower than those found for imidazole and 4-methylimidazole.[19]

Discussion

The results of the present study with 4-methylimidazole show the same striking contrast in behavior between Cu(II) and Zn(II) as was found in the study with unsubstituted imidazole.[7] In both cases the imidazole compound shows increasing affinity for Zn(II) as the degree of complex formation increases; in other words there are "positive interactions" between the coördinated imidazole groups. With Cu(II) the opposite behavior is seen and the interactions are negative. This contrasting behavior appears to be the rule with all the simple imidazoles that have been tested, including the 1-methyl derivative,[15] and is indeed characteristic of the behavior of other systems in which nitrogen is the donor atom of the ligand molecule.[6]

A consequence of the contrasting behavior with Cu(II) and with Zn(II) is illustrated in Figs. 3 and 4 which show the per cent. of each metal ion in each complex as a function of the concentration of the free base 4-methylimidazole. The curves were computed from the *k* values for 29 and 27° corresponding to the κ values given in Table V. The conversion from κ values to *k* values was made according to equation 3. Noteworthy is the much greater overlapping of the regions of existence of the Zn(II) complexes. Indeed the Zn(II) system moves from 50% in the form of the uncomplexed ion to 50% in the form of the quaternary complex when the concentration of the uncombined base is increased about fivefold. By contrast the corresponding change in the Cu(II) system requires an increase of approximately 200-fold.

(19) Further details concerning the work on 2,4-dimethylimidazole are given in the Honors Thesis of Raymond F. Chen, submitted to the Board of Tutors in Biochemical Sciences, Harvard University, 1955.

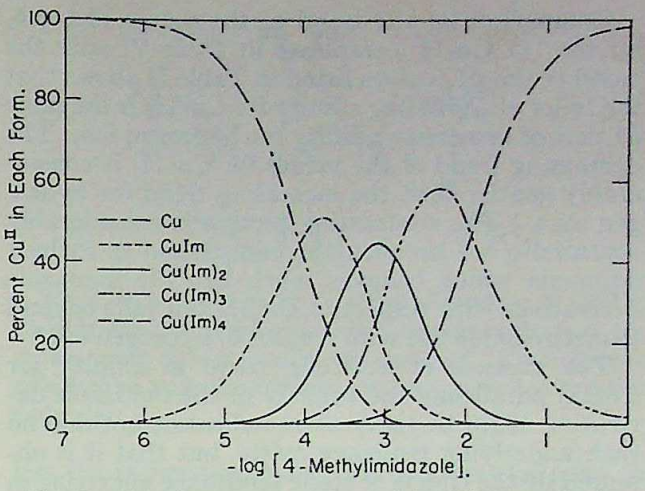

Fig. 3.—Relative concentrations of Cu(II) ion and of its various complexes with 4-methylimidazole, plotted as a function of the negative logarithm of the concentration of free basic 4-methylimidazole.

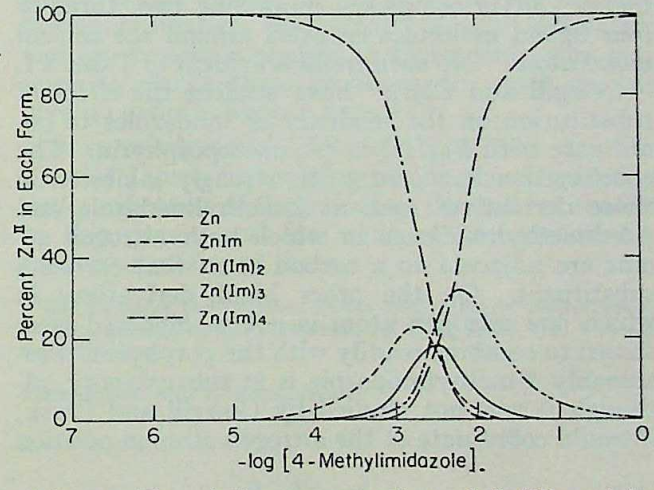

Fig. 4.—The relative concentrations of Zn(II) and its complexes with 4-methylimidazole, plotted in the same manner as the data of Fig. 3.

The successive log *k* values for the association of Cu(II) with four different imidazole derivatives and of Zn(II) with two of them are brought together in Table VI. For the sake of comparison the values are extrapolated or interpolated to correspond with 25° and in each case the ionic strength is 0.15–0.16.

TABLE VI

SUCCESSIVE ASSOCIATION CONSTANTS FOR Cu(II) AND Zn(II) WITH SOME IMIDAZOLES[a]

Log *k* values for ionic strength 0.15–0.16 and 25°

	Cu(II) complexes				Zn(II) complexes	
	Imidazole[b]	1-Methylimidazole[c]	4-Methylimidazole	2,4-Dimethylimidazole	Imidazole[b]	4-Methylimidazole
Log k_1	4.33	4.22	4.13	3.8	2.57	2.44
Log k_2	3.54	3.54	3.49		2.36	2.53
Log k_3	2.82	2.89	2.87		2.22	2.64
Log k_4	2.03	2.21	1.96		2.01	2.38

[a] Note that the values given in this table are log *k* values as defined by equation 2. They are related by equation 3 to the log κ values given in Table V. [b] J. T. Edsall, G. Felsenfeld, D. S. Comparison of the trend of the values of log k_1 for the 1:1 Cu(II) complexes in Table VI with the trend of the pK values listed in Table II shows that the order of *decreasing* affinity for Cu(II) is the same as that of *increasing* affinity for hydrogen ion. The decreasing trend of the values for Cu(II) is considerably gentler than the increasing trend for hydrogen ions. The contrasting picture is considerably accented if we broaden the comparison to include ammonia which behaves much like the imidazole derivatives with respect to Cu(II) but falls beyond trimethylimidazole with respect to hydrogen ion.[6]

The absence of a strong trend in affinity for Cu(II) paralleling the basicity of the imidazole derivative might be taken as an indication not that no such underlying tendency exists, but that it is obscured by the effects of steric hindrance operating in the opposite sense. However, if steric hindrance were such a powerful factor in the formation of the 1:1 complexes we should expect that far larger effects would be evident in the formation of the higher Cu(II) complexes containing two, three or four ligand molecules crowded around the central metal atom. No such trend is evident in Table VI.

Cowgill and Clark[20] have studied the effect of substitution on the tendency of imidazoles to coordinate with Fe(III) in ferrimesoporphyrin. The coördination appeared to be strongly inhibited in those derivatives such as 2-methylimidazole and 4,5-dimethylimidazole in which both nitrogen atoms are adjacent to a carbon atom that carries a substituent. On the other hand, derivatives in which one nitrogen atom is not so hindered were shown to combine readily with the porphyrin. Presumably 4-methylimidazole is in this category, although it was not studied by Cowgill and Clark; it would coördinate at the nitrogen atom in position 1 (in the alternative numbering system these positions would be 5 and 3, respectively), and so on. Possibly there is some tendency for similar preferences in the coördination of imidazole derivatives with free metal ions. The analogy should not be carried far, however, because Cowgill and Clark also showed that among those imidazole derivatives that were effective in forming complexes there was a general tendency for the strength of coördination to increase with increasing pK', an effect opposite to that found in the present study.

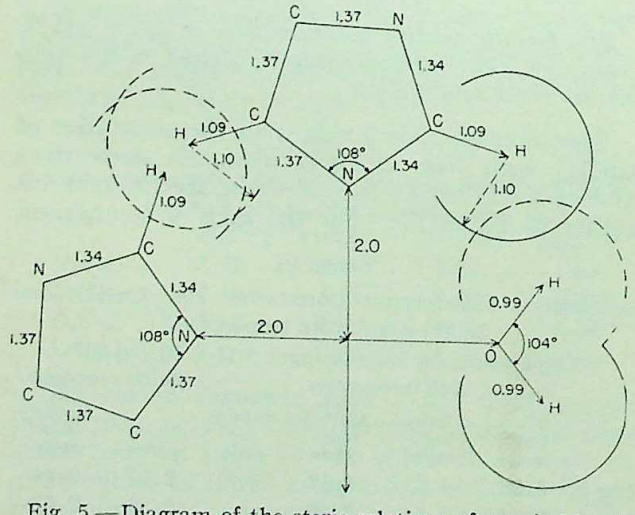

Fig. 5.—Diagram of the steric relations of two imidazole rings and a water molecule, coördinated around a central Cu ion. The Cu–N bonds and the Cu–O bond are assumed to be 2.0 Å. long. In the drawing all these bonds are assumed coplanar. The dotted arcs of circles on the upper left indicate the overlapping van der Waals radii of the hydrogen atoms on two adjoining imidazole rings. A slight overlapping is also shown to exist between the van der Waals radii of the hydrogen atoms of the attached water molecule on the right and the neighboring imidazole ring (see text).

Some further comments on the stereochemistry of these complexes may be offered. In general, tetra-coördinated zinc complexes are tetrahedral, while those of copper are generally planar[6,21] but may sometimes correspond to a more or less distorted tetrahedron. The strongly positive interactions which are apparent in the binding of many organic bases to the Zn(II) ion are present to about the same extent in imidazole and 4-methylimidazole; the extra methyl group apparently produces no added hindrance to the binding of the successive imidazole molecules to the zinc ion. This appears not unreasonable if the methyl groups in the complex are oriented outward, away from the nitrogen which is attached to the copper, which must then be the nitrogen in position 1. On the other hand if the Cu(II) complexes are square and planar, some difficult steric problems arise, in the placing of three or four imidazole rings about a central cupric ion. We take the Cu–N distance as approximately 2.0 Å., which appears reasonable in the light of available data.[22] In constructing a model for the imidazole ring, the detailed X-ray diffraction study by Donohue, Lavine and Rollett[23] of histidine hydrochloride monohydrate gives by far the most definite information available. The imidazole ring in this crystal is in the positively charged (imidazolium) form. The Cu(II) imidazole complexes should be fairly closely similar in electron distribution because of the positive charge on the copper (basic imidazole may well be considerably different in structure, since the removal of the positive charge should have important repercussions on the electron distribution in the ring). We may adopt a simplified model suggested by Donohue, *et al.*, as being compatible with their data within the limits of experimental error. It is illustrated in the two imidazole groups around the Cu atom in Fig. 5. All the internal bond angles are taken as being very close to 108°, and all C and N atoms shown are coplanar within very narrow limits (within 0.017 Å. in the case of histidine hydrochloride monohydrate). An attached carbon in the 4-position, as in histidine and 4-methylimidazole, is also coplanar with the atoms of the ring. Allowing for the usual C–H bond distances and van der Waals radii for the hydrogen atoms, it proves to be impossible to place four imidazole rings, even without substituent

methyl groups, around the central Cu(II) ion, if it is assumed that all the rings are coplanar, and lie in the plane defined by the C–N bonds. The nature of the steric hindrance involved is shown in Fig. 5, in which the C–H distance is taken as 1.09 Å., and the van der Waals radius of the hydrogen atoms as 1.10 Å. The marked overlapping shown between the van der Waals radii of the adjacent imidazole rings in Fig. 5 obviously cannot be obviated by any reasonable change in the assumed dimensions. Presumably some or all of the imidazole rings must be rotated out of the plane of the figure, around the Cu–N bonds, so as to make mutual accommodation easier. Probably there is also some distortion of the orientation of the Cu–N bonds, so that they do not all lie in a single plane.[24]

The insertion of a methyl group in the 4-position on the ring gives rise to new stereochemical problems and also to new possibilities of isomerism, as illustrated in Fig. 6. To minimize steric hindrance it seems probable that the binding will occur chiefly with the 1-nitrogen, as for the imidazole ring shown on the right hand side of Fig. 6. This places the methyl group as far away as possible from the central copper ion. In the binding of 2,4-dimethylimidazole, however, it is inevitable that one of the methyl groups must be on a nitrogen atom immediately adjacent to the copper ion. Nevertheless the rather incomplete studies reported here on 2,4-dimethylimidazole indicate only a slight decrease in its tendency to coördinate with copper as compared with imidazole or 4-methylimidazole. These findings reinforce the conclusion that the Cu–N bonds cannot be coplanar in the tri- and tetra-coördinated complexes. X-ray diffraction and spectroscopic studies on these complexes may serve to clarify these problems, to which we can give no definite answer here.[25]

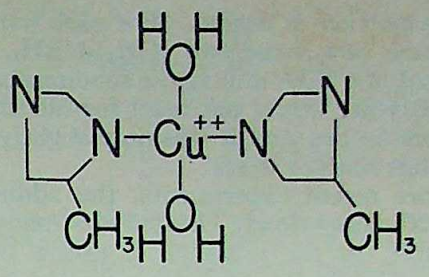

Fig. 6.—Combination of 4-methylimidazole with Cu(II), showing the two possible isomeric arrangements; the one shown on the right is presumably preferred. The other two coördination positions are shown as being occupied by water molecules.

Acknowledgment.—We are indebted to Mr. Charles Lipson for much work on the preparation and purification of the imidazole derivatives studied in this paper, and for some of the preliminary measurements upon them.

(24) Bjerrum, *et al.*,[22] conclude that the $Cu(NH_3)_4^{++}$ complex, and other analogous complexes, are distorted octahedral structures, with attached water molecules above and below the plane defined by the 4 Cu–N bonds. If this is true for the imidazole complexes, the stereochemical problem is not very much changed from that outlined in the text here. The two attached water molecules, however, may make the attachment of 4 imidazole molecules involve an even tighter fit than we have suggested.

Amine Chemistry of the Pentaborane B_5H_9

BY ANTON B. BURG

RECEIVED NOVEMBER 13, 1956

The structure of B_5H_9 suggests certain modes of reaction which its amine chemistry appears to confirm. It adds trimethylamine at −78° to form $B_5H_9 \cdot 2Me_3N$, which on heating *in vacuo* is partly dissociated into the original components and partly converted to Me_3NBH_3 and $(BH)_x$. On heating with excess Me_3N, the adduct yields $2Me_3NBH_3$ and BH polymers incorporating Me_3N, which lends thermoplastic character. Either Me_2NH or aminoboron hydrides such as Me_2NBH_2 or $(Me_2N)_2BH$ remove BH_3 from B_5H_9 on heating, and much of the new $(Me_2N)_3B_3H_4$ (m.p. 95°; b.p. est. 220°) is formed. Small yields of the new liquid $(Me_2N)_2B_4H_6$, of similar volatility, also are obtained. Both compounds, which seem to represent a large new class, are presumed to have cross-ring structures wherein all B and N atoms are four-coördinate. The $(Me_2N)_2B_3H_4$ is especially unreactive and thermally stable but can be converted by heat to still more inert new materials.

The structure of the pentaborane B_5H_9[1,2] is such that the removal of two BH_3 groups from the molecule—as by the use of a tertiary amine to form $2R_3NBH_3$—could occur by breaking only bonds of order less than one, and without shifting any hydrogen atoms from one boron atom to another. The remainder of the molecule then would be a B_3H_3 unit which could not persist as a simple B–B–B chain hydride, but would convert immediately to a high-polymer form. These ideas correlate with some experimental results obtained by the author in the year 1937, during a period of collaboration with Professor H. I. Schlesinger at the University of Chicago. It was found that the adduct $B_5H_9 \cdot 2(CH_3)_3N$ would form slowly at −79° and upon warming *in vacuo* it would decompose in two ways: dissociation into the original components and the formation of $(CH_3)_3NBH_3$ and a yellow residue. The two ways of decomposition, occurring simultaneously, suggested the possibility that the adduct had two forms with different types and strengths of bonding. On heating with more trimethylamine, the yellow solid became almost colorless, with slight production of $(CH_3)_3NBH_3$, and approached the composition $(BH)_x$, containing only a very

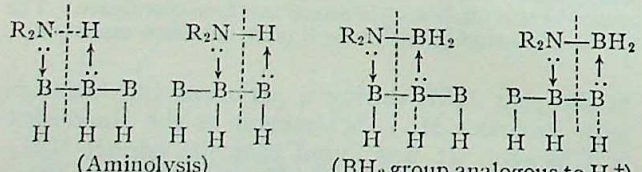
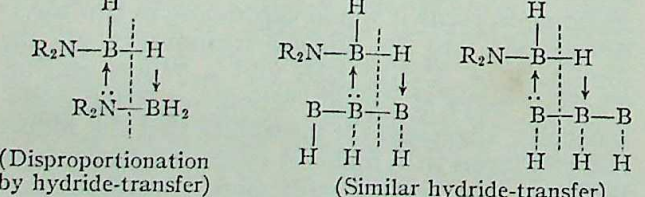
small proportion of amine. For each unrecovered B_5H_9 there now were two $(CH_3)_3NBH_3$, and the equivalent of a B_3H_3 unit in the solid residue. This $(BH)_x$ polymer would not react further on heating with more amine, and it was only slightly affected by aqueous acids or bases.

In more recent experiments, the adduct $B_5H_9 \cdot 2(CH_3)_3N$ was slowly heated to temperatures above 100° in the presence of excess trimethylamine, again always producing $2(CH_3)_3NBH_3$ per B_5H_9. In such experiments some of the excess amine became incorporated in the polymer, which exhibited thermoplastic behavior above 100°. This effect can be understood by assuming that a $(BH)_x$ polymer has a highly cross-linked chain structure of icosahedral or possibly octahedral boron hydride clumps, the interlinking of which can be decreased by amine-complex bonding to boron. Thus it would be possible to have a rubber-like chain instead of a stiff network. Polymers of similar composition were obtained earlier from the reaction of tetraborane with trimethylamine,[3] although their physical character was not closely observed.

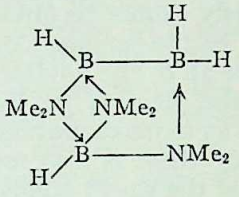
Such aminated boron hydride polymers, ranging from three to five BH units per amine molecule, can neither absorb nor lose amine on heating; indeed one sample was heated *in vacuo* to 400°, losing methane rather than trimethylamine, and forming a very difficultly volatile sublimate. This product would seem to be a dimethylaminopolyborane, a member of a new class of compounds whose prototype was obtained by experiments using dimethylamine.

The reaction of pentaborane with dimethylamine present in excess led only to the previously known aminoboron hydrides,[4] but the reaction with a carefully limited proportion of this amine produced new volatile products wherein direct B–B bonding can be recognized. The yields of such products were improved by the use of the compounds $(CH_3)_2NBH_2$ and $[(CH_3)_2N]_2BH$ with pentaborane, for these pick up the BH_3 group to form $(CH_3)_2NB_2H_5$ and $(CH_3)_2NBH_2$, respectively[4]; and they can react with the B_3H_3 remainder with no net destruction of B–B bonding. The latter aspect can be recognized by comparing with aminolysis or hydride-transfer reactions the attack by an aminoborine upon the B_3H_3 remainder, thus

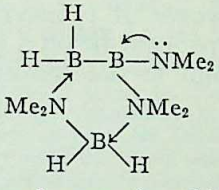




A major product of such reactions was shown by analyses and a molecular weight determination to have the molecular formula $[(CH_3)_2N]_3B_3H_4$. It is a slightly volatile white solid, reasonably stable in the open air, and on heating to 300°, both thermally stable and unreactive toward hydrogen. The only molecular structure which seems both appropriate and sterically possible would be



wherein the two nitrogen atoms in the B_2N_2 ring would be in a line perpendicular to the plane of the B_3N chain. However, it seems necessary to find some explanation for the failure of the substance to react with diborane at 90°, as happens when the B^N_NB ring dimer of $(CH_3)_2NBH_2$ is converted to $(CH_3)_2NB_2H_5$. But this difficulty would seem greater if one considered the conceivable alternative pattern



In any case a formal name for this new compound would be cumbersome; hence in this paper it will be called simply the triaminotriborane, the -ane ending being adopted in view of the probable analogy to a hydrocarbon somewhat like pinane.

Another product of the aminoborine–pentaborane reaction is a somewhat less stable and more reactive liquid, slightly more volatile than the solid triaminotriborane. Its molecular formula was determined as $[(CH_3)_2N]_2B_4H_6$. If it be assumed that B and N always are four-coördinate in such compounds, the following five structural patterns might be considered.

The last three of these structures are sterically not favored, and the second would be less stable than the first, by analogy to the reaction of $[(CH_3)_2NBH_2]_2$ with B_2H_6 to form $(CH_3)_2NB_2H_5$. However, the first pattern might well be less stable than still another form wherein the B–B bonds are along opposite edges of a B_4-tetrahedron. A second pair of opposite edges would be B^HB bridged and the third pair of edges would be B^NB bridged. A final decision on the structure must come from physical methods, for which it will be necessary to find a way to make larger samples. Hereinafter the compound will be designated as diamino-bis-diborane.

Experimental

The Reaction of Pentaborane with Trimethylamine.—In the 1937 experiment, 0.504 mmole of B_5H_9 and 13.12 mmoles of $(CH_3)_3N$ were allowed to react during 10 days at −79°. Then 12.05 mmoles of the amine could be recovered by distillation at −79°, leaving a loose white solid of average composition $B_5H_9 \cdot 2.12(CH_3)_3N$. This was warmed to room temperature under high vacuum, with the vapors led through a fractional-condensation train, and finally with warming to 66°. The volatile products were 0.290 mmole

of B_5H_9, 0.629 mmole of $(CH_3)_3N$ and 0.361 mmole of $(CH_3)_3NBH_3$. Thus 58% of the 2:1 adduct was recovered as the original reactants, while the remainder was partially converted to $(CH_3)_3NBH_3$. The glassy brilliant-yellow residue next was heated for 8 hr. at 100°, in an atmosphere of 3.00 mmoles of amine, converting 0.063 mmole of this to $(CH_3)_3NBH_3$ and leaving a nearly-white residue of composition $(BH)_x$ with possibly as much as 3 mole % of amine content. The yield of $(CH_3)_3NBH_3$ was 1.98 per unrecovered B_5H_9. The polymer did not react further with trimethylamine, but aqueous hydrochloric acid attacked it slightly, giving off 0.09 mmole of hydrogen, and a sodium hydroxide solution first turned it slightly brown, and then white, without appreciable dissolving.

In more recent experiments the 2:1 adduct was formed in 50 ml. sealed tubes at −78° and simply allowed to warm slowly to room temperature or higher, usually in the presence of excess amine. At intervals in the course of heating to higher temperatures, the volatile products were removed and determined, and the residue was heated further in the resealed tube or with connection to an automatic Sprengel pump for collection of non-condensable gases. The results of four such experiments are shown in Table I.

In all of these experiments the initial heating (usually slowly, to 100°) gave a polymer-residue having a B:H ratio near to 1:1 and this changed very little on heating up to the 200° range. When there was plenty of amine, this initial heating always produced very nearly $2(CH_3)_3NBH_3$ per B_5H_9. However in the exceptional expt. 2 the excess amine had been removed at −78°, establishing the composition of the adduct as $2.04(CH_3)_3N$ per B_5H_9, and then the initial heating of this adduct (24 hr. in a sealed tube at 102°) gave only $1.3(CH_3)_3NBH_3$ per B_5H_9, and 0.494 mmole of H_2 was produced. Thus it appears that the forming polymer competes with BH_3 groups for possession of the amine; but once formed, the polymer does not absorb any significant proportion of amine after being formed with a low amine content. And from expt. 4 it is apparent that the amine cannot be removed from its incorporation in the polymer by vacuum heating; instead there is a loss of methane to produce some $(CH_3)_2NBH_2$ and a far less volatile sublimate, presumably formed at the expense of the N–CH_3 and B–H linkages. Attempts to analyze this sublimate have not been successful, and there is no evidence that it is a pure substance.

Experiment 1 was of special interest because the polymer showed plastic character in the range 100–165°: in losing traces of volatile products *in vacuo* it slowly formed large bubbles which slowly collapsed and reformed in the manner of bubble gum. At room temperature the material was a brittle solid, very slightly yellow, and apparently unaffected by the open air. Thermoplastic behavior in such materials may be critically dependent upon their amine content, for in expt. 4 (B:N ratio, 5.16) the only such effect was the temporary appearance of a fine foam during the vacuum heating to 200°.

Formation of Aminoboron Compounds from Pentaborane.—The experiments on the reactions of B_5H_9 with dimethylamine and with dimethylaminoboron compounds are summarized in Table II. Experiment 1 was done in a vertical tube having an internal cold finger at 0° and attached to the high-vacuum manifold. The others were done in sealed tubes which could be opened to the vacuum system for isolation and measurement of the volatile products and possible reheatings of the residues with volatile materials in the resealed tubes. It is apparent that the best conversion of B_5H_9 to the triaminotriborane occurred in expt. 5, wherein more than two-thirds of the boron was recovered in that form. The sixth run did nearly as well, and gave also some of the diamino-bis-diborane—a product which could not be expected from expt. 5 because it has been found to react with $[(CH_3)_2N]_2BH$. Methods for obtaining high yields of this diamino-bis-diborane are yet to be found.

Physical Properties of the Aminopolyboranes.—The triaminotriborane and the diamino-bis-diborane apparently have nearly the same normal boiling point, but their vapor tensions at room temperature or lower are so different as to permit easy separation under high vacuum. The triaminotriborane was purified by fractional condensation at 15–20°, and the diamino-bis-diborane was isolated from it by a slow distillation from a tube at 0°.

The triaminotriborane melted sharply at 95.0°, and the vapor tensions of the solid, shown in Table III, determined the equation $\log_{10} p_{mm.} = 11.424 - 3723/T$. Assuming a normal value of the Trouton constant, the normal b.p. would be estimated as 220° and the heat of fusion approximately 6750 cal./mole. A preliminary crystal-structure determination by Professor Jerry Donohue showed orthorhombic symmetry and a density of 0.945 for a unit cell containing four molecules (a_0 = 8.03 Å.; b_0 = 11.14 Å.; c_0 = 13.22 Å., all ±0.8%). A complete structure determination from the X-ray data would be very time-consuming, but it could be argued from the Weissenberg photographs that the space group could be either C_{2v}^5-Pbc or D_{2h}^{11}-Pbcm— the latter affording the possibility of a mirror-plane in accord with the preferred molecular pattern.

The melting point of the diamino-bis-diborane was uncertain, for the transition from a glassy state to a viscous oil was hard to observe. There seemed to be melting in the range 11–15°. The vapor tensions of the liquid, shown in Table IV, determined the equation $\log_{10} p_{mm} = 8.070 - 2475/T$. This would imply a normal boiling point near 203°—probably lower than the true value, since the Trouton constant has the high value 23.8 cal./deg. mole.

Proofs of Formulas.—The molecular weights of the new aminoboron hydrides were determined from their gas densities: for the triaminotriborane the result was 169.3 (calcd., 168.7); for the diamino-bis-diborane, 140 ± 2 (calcd., 137.5). Each of these compounds was analyzed by heating with methanol and a measured quantity of HCl, in a sealed glass tube at 80–90°. The resulting H_2 was Sprengel-pumped into a gas-measuring tube. Methyl chloride, representing

the excess of the HCl over the amine, was isolated and measured. Methyl borate was distilled into water and titrated as the mannitol boro-spirane. In various experiments the amine hydrochloride was determined by direct weighing, by a micro-Kjeldahl analysis, by a chloride titration, or from the decrease of volatile chloride.

For the triaminotriborane, the two samples averaged 2.94 amine, 2.92 boron and 5.08 H_2 per molecule, no deviation being higher than 0.17 unit. These results uniquely require the equation $[(CH_3)_2N]_3B_3H_4 + 9\ CH_3OH + 3\ HCl \longrightarrow 5H_2 + 3(CH_3O)_3B + 3(CH_3)_2NH_2Cl$, for conformity to the observed molecular weight of the compound.

For the diamino-bis-diborane the ratio of amine to B to H_2 was 200:370:803. Boron usually runs a little low by the method here employed, for Pyrex glass is avoided and the formation of CH_3Cl from CH_3OH and the excess HCl produces a trace of water which interferes with the complete volatilization of boron as methyl borate. The results are consistent only with the equation $[(CH_3)_2N]_2B_4H_6 + 12CH_3OH + 2HCl \longrightarrow 8H_2 + 4(CH_3O)_3B + 2(CH_3)_2NH_2Cl$, requiring that the compound have two B–B links per molecule.

Chemical Behavior of the Aminopolyboranes.—The triaminotriborane $[(CH_3)_2N]_3B_3H_4$ proved to be inert toward water, acid, and methanol at room temperature, requiring many hours of heating for the analytical break-down by acid methanolysis. With an equi-molar proportion of dimethylamine in a sealed tube it failed to react during 100 hr. at 180°; but after 102 hr. at 300° the mixture had formed mole-for-mole yields of H_2, $(CH_3)_2NBH_2$ and $[(CH_3)_2N]_2BH$, the remaining aminoboron material appearing as a colorless non-volatile film on the tube-wall. Unlike some other B–B compounds,[5] the triaminotriborane is inert toward hydrogen, for a 0.245-mmole sample, after a series of heatings with 1.56 mmoles of H_2 (ending with 24 hr. at 300°) still had the same melting point. After 102 hr. at 360°, however, there was a considerable formation of a colorless oily film and the H_2 had increased to 1.88 mmoles. There was also 0.14 mmole of CH_4 and a trace of $(CH_3)_2NBH_2$. Thus it appears that the triaminotriborane is stable at 300°, but at 360° is converted to a still more stable material—probably a high polymer.

With 0.141 mmole of diborane, a 0.128-mmole sample of the triaminotriborane showed no effect of heating in a space of 130 ml. for 3 hr. at 99°; the recovery of diborane was 0.137 mmole. This result indicates that the nitrogen atoms are very firmly bonded in a four-coördinate situation, contrasting with the comparatively reactive state of nitrogen in $[(CH_3)_2NBH_2]_2$.

Little is known of the chemistry of the diamino-bis-diborane, for the samples so far have been too small for extensive study; but it does seem to be considerably less stable and more reactive than the triaminotriborane. Its presumed structure would permit the possibility of conversion to the triaminotriborane by reaction with $[(CH_3)_2N]_2BH$ but when 0.763 mmole of this was heated with 0.348 mmole of the diamino-bis-diborane for 5 hr. at 95°, only 2.2 mg. (0.013 mmole) of the triaminotriborane could be found, the main yield being a yellow resinous solid.

Such a yellow resinous solid was the chief by-product of the preparation of the triaminotriborane in expts. 5 and 6, Table II. From the reaction-balance of expt. 6 (first part), its empirical formula would be approximately $[(CH_3)_2N]_4B_{11}H_{16}$. As indicated in Table II, its further treatment with the bis-aminoborine gave a further yield of dimethylaminoborine and the triaminotriborane. At various points in this study trace amounts of very difficultly volatile aminoboron hydrides were noticed, indicating that a considerable variety of such compounds, probably merging into polymeric types, can be produced.

Vinyl Derivatives of the Metals. II. The Cleavage of Vinyltin Compounds by the Halogens and by Protonic Acids[1]

BY DIETMAR SEYFERTH

RECEIVED NOVEMBER 1, 1956

The halogens, hydrogen bromide, hydrogen chloride, organic acids and mercaptans cleave the vinyl group in vinyl derivatives of tin. No addition reactions were observed with these reagents. This behavior is attributed to the relatively low tin–carbon bond energy. Product studies of cleavage reactions of compounds of the type $R_2Sn(CH{=}CH_2)_2$ have shown that the vinyl group is cleaved more readily than normal alkyl groups but less readily than the phenyl group. Phenyldivinyltin halides have been found to undergo thermal redistribution, yielding trivinyltin halide and triphenyltin halide.

As part of a broad study of the reactions of the vinyl derivatives of tin,[1] we have investigated the behavior of these compounds toward the halogens and toward protonic acids. Such a study was of particular interest in view of the addition reactions that vinylsilicon compounds undergo when treated with these reagents.[2]

We have found that in all cases where completely alkylated vinyltin compounds are treated with the halogens or with protonic acids, such as the hydrogen halides, organic acids and mercaptans, *cleavage of one or more of the vinyl groups* occurs in preference to addition to the vinyl double bond, giving the corresponding organotin halide (or ester or sulfide) and the vinyl halide or ethylene, respectively

$$R_3SnCH{=}CH_2 + X_2 \longrightarrow R_3SnX + CH_2{=}CHX \quad (1)$$
$$(X = Cl, Br, I)$$
$$R_3SnCH{=}CH_2 + HX \longrightarrow R_3SnX + CH_2{=}CH_2 \quad (2)$$
$$(X = Cl, Br, O_2CR', SR')$$

An already extensive Kharasch-type[3] cleavage series for organotin compounds is known.[4] It was of theoretical interest to determine the position of the vinyl group in this series. We have carried out careful product studies of the cleavage reactions of compounds of the type $R_2Sn(CH{=}CH_2)_2$, where R is methyl, *n*-butyl and phenyl, with one equivalent of iodine in refluxing ether solution, with hydrogen bromide at −78° and with hydrogen chloride in chloroform solution at 50–60°. Use of the symmetrical $R_2Sn(CH{=}CH_2)_2$ compounds eliminated any possible probability factors which might obtain in the cleavage reactions of $R_3SnCH{=}CH_2$ and $RSn(CH{=}CH_2)_3$ compounds.

These studies, the results of which are summarized in Table I, show that the position of the vinyl group in the cleavage series is

$$C_6H_5 > CH_2{=}CH > CH_3 > C_2H_5 > n\text{-}C_3H_7 > n\text{-}C_4H_9$$

since vinyl group cleavage is the only observed reaction with dimethyl- and di-*n*-butyldivinyltin, while the phenyl group is cleaved in the case of diphenyldivinyltin.

TABLE I

PRODUCT STUDIES OF THE CLEAVAGE OF $R_2Sn(CH{=}CH_2)_2$ COMPOUNDS

R	Cleavage agent	Cleavage product	Yield, %
CH_3	I_2	$(CH_3)_2(CH_2{=}CH)SnI$	74
CH_3	HCl	$(CH_3)_2(CH_2{=}CH)SnCl$	70
CH_3	HBr	$(CH_3)_2(CH_2{=}CH)SnBr$	77
$n\text{-}C_4H_9$	I_2	$n\text{-}(C_4H_9)_2(CH_2{=}CH)SnI$	82
$n\text{-}C_4H_9$	HCl	$n\text{-}(C_4H_9)_2(CH_2{=}CH)SnCl$	79
$n\text{-}C_4H_9$	HBr	$n\text{-}(C_4H_9)_2(CH_2{=}CH)SnBr$	76
C_6H_5	I_2	C_6H_5I	88
C_6H_5	HBr	C_6H_6	100
$CH_2{=}CH$	I_2	$(CH_2{=}CH)_3SnI$	71

Extreme difficulties were encountered in the study of the cleavage reactions of diphenyldivinyltin by iodine, hydrogen bromide and hydrogen chloride. A careful study of the reaction of diphenyldivinyltin with iodine on a larger scale showed that thermal redistribution of the phenyldivinyltin iodide formed in the reaction had occurred during distillation of the reaction mixture

$$(C_6H_5)_2Sn(CH{=}CH_2)_2 + I_2 \longrightarrow C_6H_5(CH_2{=}CH)_2SnI + C_6H_5I \quad (3)$$
$$3C_6H_5(CH_2{=}CH)_2SnI \longrightarrow 2(CH_2{=}CH)_3SnI + (C_6H_5)_3SnI \quad (4)$$

The results of this product study are shown in Table II.

van der Kerk (ref. 4, p. 120) mention the possibility of such reactions in their discussion of the preparation of unsymmetrical organotin iodides.

Preliminary experiments have shown that organic acids cleave the vinyl group as well

$$R_3SnCH{=}CH_2 + R'CO_2H \longrightarrow R_3SnO_2CR' + CH_2{=}CH_2 \quad (5)$$

Indeed, this is an excellent method for preparing pure organotin esters in quantitative yield, and this reaction will be discussed in greater detail in a later communication. Qualitative observations of the reaction rate show that the greater the dissociation constant of the organic acid used, the faster is the cleavage of the vinyl group. Thus acetic acid reacts only very slowly with dimethyldivinyltin at room temperature, while dichloroacetic acid reacts exceedingly vigorously with the same compound.

Even weak acids such as mercaptans liberated ethylene from vinyltin compounds. When equivalent quantities of triethylvinyltin and ethyl mercaptoacetate were mixed and left to stand at room temperature for four days an 11% yield of ethyl S-(triethylstannyl)-mercaptoacetate thus resulted. Heating the reactants at 90–95° for ten hours gave a 41% yield of this cleavage product. This observed cleavage reaction again is in marked contrast to the well-known addition of mercaptans to vinylsilicon compounds.[2a,b] The structure of the cleavage product was proven by its independent synthesis by the reaction of bis-(triethyltin) oxide with ethyl mercaptoacetate

$$[(C_2H_5)_3Sn]_2O + 2HSCH_2CO_2C_2H_5 \longrightarrow 2(C_2H_5)_3SnSCH_2CO_2C_2H_5 + H_2O$$

Discussion

The results of this work are in accord with the extensive literature concerning cleavage reactions of organotin compounds.[4] However, an explanation of the ready cleavage of the vinyl group from tin, in contrast to the well-defined addition reactions exhibited by vinylsilanes, can no longer be sought in terms of a more polar metal–carbon bond in the case of organotin compounds. The most recent determinations of electronegativity[5] of the Group IVB elements have shown that the electronegativities of tin and silicon in their tetravalent organometallic compounds are about the same. The greatest differences, relevant to this discussion, between the organic compounds of silicon and tin lie in (a) the lower metal–carbon bond energy in the case of tin[6] and (b) the larger covalent radius of tin.[7] Of these, the former is probably the main contributor to the observed differences in the reactions of vinylsilicon and vinyltin compounds with the halogens and with protonic acids. Cleavage is clearly the thermodynamically favored reaction in the case of the tin compounds.

A detailed explanation of the cleavage series of organotin compounds and of the position of the vinyl group in this series must await kinetic studies which would give us an understanding of the transition state of the cleavage reaction. However, the results of this study are in harmony with that of Winstein and Traylor[8] on electrophilic substitution on saturated carbon atoms by means of acetic acid cleavage of dialkylmercury compounds. The anticipation of these authors that the rates of electrophilic substitution on carbon will fall off as attack is on: (a) an aromatic or vinyl carbon atom and (b) a saturated carbon atom, is borne out by the cleavage series for organotin compounds and by the position of the vinyl group in this series.

New compounds obtained by these reactions, their physical properties and analytical data are listed in Table III.

Experimental

1. Starting Materials.—The preparation of the vinyltin compounds used in this study, with the exception of diphenyldivinyltin, has been described previously.[1] **Diphenyldivinyltin** was prepared in 68% yield by treatment of 0.7 mole of crude diphenyltin dichloride with 2.0 mole of vinylmagnesium bromide[9] in tetrahydrofuran solution for 20

hours at reflux. Hydrolysis with a saturated aqueous solution of ammonium chloride, followed by distillation of the decanted organic layer, gave 152 g. of diphenyldivinyltin, b.p. 121.5° at 0.4 mm., d^{25}_4 1.334, $n^{25}D$ 1.5929.

Anal. Calcd. for $C_{16}H_{16}Sn$: C, 58.76; H, 4.93. Found: C, 58.88; H, 4.98.

2. **Iodine Cleavage Reactions. a. Dimethyldivinyltin, Di-*n*-butyldivinyltin and Tetravinyltin.**—The same procedure was used in the iodine cleavage of these three compounds. One such reaction is given as an example.

To a solution of 25 g. (0.123 mole) of dimethyldivinyltin in 500 ml. of diethyl ether was added 31.1 g. (0.123 mole) of iodine, and the mixture was refluxed for eight hours. A colorless solution resulted. The ether was distilled at atmospheric pressure, and the residue was distilled at reduced pressure to give 27.3 g. (74%) of dimethylvinyltin iodide.

b. **Diphenyldivinyltin.**—To a solution of 50 g. (0.153 mole) of diphenyldivinyltin in 400 ml. of ether was added 38.8 g. (0.153 mole) of iodine. After the mixture had been refluxed for eight hours the iodine color was discharged. The ether was removed at atmospheric pressure and then the distillation was continued at reduced pressure to give the following fractions: iodobenzene, b.p. 60.5–62° at 8.7 mm., $n^{24.5}D$ 1.6160, 27.5 g.; impure trivinyltin iodide, boiling from 54° at 1.3 mm. to 60° at 0.7 mm., $n^{25}D$ 1.5897, 28.2 g.; triphenyltin iodide, solid residue, 24.2 g. The latter was recrystallized from ether and identified by analysis:

Anal. Calcd. for $C_{18}H_{15}ISn$: C, 45.3; H, 3.17. Found: C, 45.00; H, 3.21.

The crude trivinyltin iodide was redistilled to give 25 g. of material, b.p. 60–62° at 1.8 mm., $n^{25}D$ 1.5835.

c. **Triphenylvinyltin.**—To a solution of 20 g. (0.053 mole) of triphenylvinyltin in 350 ml. of ether was added 13.5 g. (0.053 mole) of iodine, and the mixture was refluxed for 15 hours. The ether and part of the iodobenzene were removed by distillation. The residue could not be crystallized and for this reason it was treated with an excess of neutral aqueous-alcoholic potassium fluoride solution. Recrystallization of the precipitated organotin fluoride from a tetrahydrofuran–acetone–ethanol mixture gave pure **diphenylvinyltin fluoride**, 13 g., a yield of 77%.

3. **Bromine Cleavage Reactions.**—To a 25-g. (0.079 mole) sample of tri-*n*-butylvinyltin at −78° was added dropwise 12.6 g. (0.079 mole) of bromine. The bromine was decolorized immediately as it was added. After the addition had been completed the mixture was allowed to warm to room temperature. Distillation of the reaction mixture yielded: 1,1,2-tribromoethane, boiling from 58° at 4 mm. to 53° at 1.9 mm., $n^{25}D$ 1.5855, 8 g.; a center fraction boiling from 98° at 2.5 mm. to 110° at 1.8 mm.; tri-*n*-butyltin bromide, b.p. 120° at 1.8 mm. to 122° at 1.6 mm., d^{25}_4 1.338, $n^{25}D$ 1.5022; MR_D found, 81.64, calcd., 81.40, 15 g., a yield of 51.4%. Jones, *et al.*,[10] report d^{20}_4 1.3365 and $n^{20}D$ 1.5000 for tri-*n*-butyltin bromide. When a 100% excess of bromine was used, a 76% yield of tri-*n*-butyltin bromide resulted.

4. **Chlorine Cleavage Reactions.**—Into 23.5 g. (0.074 mole) of tri-*n*-butylvinyltin at −78° was bubbled 5.5 g. (0.08 mole) of dry chlorine. The reaction mixture subsequently was warmed up to room temperature and was fractionally distilled to give 20.4 g. (86.4%) of tri-*n*-butyltin chloride, b.p. 98° at 0.45 mm. to 100° at 0.35 mm., $n^{25}D$ 1.4903; $n^{22}D$ 1.4908 is reported by Manulkin[11] for this compound.

5. **Hydrogen Bromide Cleavage Reactions.** (a) **Dimethyldivinyltin.**—Into a cold trap at −78° was charged 25 g. (0.123 mole) of dimethyldivinyltin. The exit arm of the trap led to an Ascarite-filled tube which was connected to another trap containing a solution of 16 g. (0.1 mole) of bromine in chloroform. Hydrogen bromide gas was slowly bubbled into the organotin compound until the latter had nearly solidified. The organotin compound was then warmed up to −40°, and the addition of hydrogen bromide was continued until the bromine solution was completely decolorized. Fractional distillation of the reaction mixture gave 24.2 g. (77%) of dimethylvinyltin bromide. A small amount of dimethyltin dibromide (m.p. 74° after recrystallization from ether; m.p. in the literature,[12] 75–77°) remained in the still pot, indicating that the second vinyl group is more susceptible to cleavage than are the methyl groups after one vinyl group has been removed.

A similar procedure was followed in the hydrogen bromide cleavage of di-*n*-butyldivinyltin. In the latter case the 1,2-dibromoethane formed in the end trap was recovered in 80% yield by distillation, b.p. 129–130°.

b. **Diphenyldivinyltin.** (i).—Eight grams (0.10 mole) of liquid hydrogen bromide was allowed to vaporize slowly and was bubbled into 30 g. (0.0918 mole) of diphenyldivinyltin, initially at −78°. The organotin compound began to form a solid slush in the later stages of the reaction and therefore was warmed to −40°. Distillation at atmospheric pressure gave 8 g. (100% yield) of benzene, b.p. 79–80°.

(ii).—A similar procedure was used when 25 g. (0.0765 mole) of diphenyldivinyltin was treated with 6.2 g. (0.0765 mole) of hydrogen bromide. Fractional distillation of the high boiling organotin products gave: impure **trivinyltin bromide**, boiling from 54° at 0.4 mm. to 53° at 0.3 mm., 9 g.; a yellow oil, distilling continuously from 86° at 0.35 mm. to 132° at 0.35 mm., 10 g.; a solid residue, 4.5 g. The latter was recrystallized from ether to give triphenyltin bromide, m.p. 118–120°; m.p. reported by Krause,[13] 120.5°. The impure trivinyltin bromide was converted to pure **trivinyltin fluoride** by the potassium fluoride method.

(iii).—To 20 g. (0.061 mole) of diphenyldivinyltin was added 5 g. (0.061 mole) of hydrogen bromide in the manner described above. When the reaction mixture had warmed to room temperature it was treated with an excess of neutral aqueous-alcoholic potassium fluoride solution. A white, oily solid resulted that could be extracted with ether. Evaporation of the ethereal extracts yielded 8 g. of pure **phenyldivinyltin fluoride**. No attempt was made to recover the remaining portion of this fluoride from the precipitation solvent medium.

6. **Hydrogen Chloride Cleavage Reactions. a. Di-*n*-butyldivinyltin.**—A solution of 28.7 g. (0.1 mole) of di-*n*-butyldivinyltin in chloroform was prepared in a trap. The exit arm of the trap led to a tube filled with Ascarite which was connected to a trap containing 12.8 g. (0.08 mole) of bromine in chloroform solution. The di-*n*-butyldivinyltin solution was maintained at 50–60° with a hot water-bath and hydrogen chloride gas was bubbled through the solution until the bromine in the end trap was decolorized. The chloroform was removed by rapid distillation and the residue was fractionally distilled, giving 23.4 g. (79.3%) of di-*n*-butylvinyltin chloride, b.p. 82–83° at 0.6 mm.

A similar procedure was used in the hydrogen chloride cleavage of dimethyldivinyltin.

b. **Diphenyldivinyltin.**—Into a solution of 21.5 g. (0.0657 mole) of diphenyldivinyltin in chloroform, maintained at 60–70°, was bubbled about 2.4 g. (0.066 mole) of hydrogen chloride gas. After removal of the chloroform by rapid distillation the residue was distilled at reduced pressure. The following fractions were collected: 44° at 0.5 mm. to 64° at 0.35 mm., 4 g.; 65–68° at 0.35 mm., 5 g.; 83–105° at 0.35 mm., 3 g.; a solid residue, 4 g. The latter was recrystallized from ether to give fairly pure triphenyltin chloride, m.p. 100–102°; m.p. reported[14] 105–106°.

7. **Cleavage by Organic Acids. a. Acetic Acid.**—To 10 g. (0.0428 mole) of triethylvinyltin was added 2.57 g. (0.0428 mole) of glacial acetic acid. The reactants were heated on the steam-bath for 1.5 hours and then cooled to give a quantitative yield of triethyltin acetate, m.p. 132–134°; Luitjen and van der Kerk (ref. 10, p. 99) report a m.p. of 134–135°.

b. **α-Bromopropionic Acid.**—The same procedure was followed in the reaction of 5 g. (0.0243 mole) of dimethyldivinyltin with 3.06 g. (0.02 mole) of α-bromopropionic acid. A quantitative yield of dimethylvinyltin α-bromopropionate resulted after the crystals were washed with chilled petroleum ether and dried.

8. **Cleavage by Mercaptans.**—To 23.3 g. (0.1 mole) of triethylvinyltin was added 36.0 g. (0.3 mole) of ethyl mercaptoacetate. The mixture was heated on the steam-bath

for ten hours. Fractional distillation gave 27.5 g. of a mixture of unreacted starting materials, boiling from 44° to 52° at 8.9, mm, and 14.5 g. of ethyl S-(triethylstannyl)-mercaptoacetate, boiling from 99° at 0.44 mm. to 110° at 0.65 mm. This fraction was redistilled (107–109° at 1.0 mm.) to give the pure compound. Reference to the analytical data in Table III shows that this is not the addition product, $Et_3SnCH_2CH_2SCH_2CO_2Et$. (Calcd. for the addition product: C, 40.82; H, 7.42; S, 9.08.)

9. **Ethyl S-(Triethylstannyl)-mercaptoacetate: Proof of Structure.**—The method of Sasin[15] was used. To 6.2 g. (0.0144 mole) of bis-(triethyltin) oxide was added 5.2 g. (0.432 mole) of ethyl mercaptoacetate. After the initially vigorous reaction had subsided the mixture was refluxed for one hour and then was distilled to give a small fraction boiling at 115–117° at 1.5 mm., $n^{25}D$ 1.5099, whose infrared absorption spectrum was identical with that of the cleavage product described above.

The Preparation of Some Vinyltin Compounds with Vinylmagnesium Chloride

BY SANDERS D. ROSENBERG, AMBROSE J. GIBBONS, JR., AND HUGH E. RAMSDEN

RECEIVED OCTOBER 29, 1956

Tetravinyltin, dibutyldivinyltin, dimethyldivinyltin, diphenyldivinyltin, tributylvinyltin, triphenylvinyltin, butylvinyltin dichloride, dibutylvinyltin chloride and divinylbutyltin chloride have been prepared by the reaction of vinylmagnesium chloride with appropriate tin chlorides. In addition, dibutyldivinyltin and tributylvinyltin have been synthesized from vinylmagnesium chloride and dibutyltin oxide and bistributyltin oxide, respectively.

The development of vinylmagnesium chloride in this Laboratory[1] has made possible the synthesis of vinyltin compounds by classical Grignard techniques. The only vinyltin compounds previously reported in the literature are vinyltin tribromide[2] and several 2-chlorovinyltin compounds.[3,4]

Four general methods have been developed for the synthesis of organotin compounds: 1, the complete replacement of the halogen of tin tetrachloride or organotin halides by use of an active organometallic compound; 2, the stepwise partial replacement of the halogen of organotin halides by use of an active organometallic compound; 3, the disproportionation of symmetrical tetrasubstituted organotin compounds with tin tetrachloride; 4, the cleavage of organotin compounds with halogen or halogen acid. The use of the first two methods in the preparation of vinyltin compounds will be reported here and of the last two in a subsequent article.

Tetravinyltin (82%), di-*n*-butyldivinyltin (89%), dimethyldivinyltin (75%), diphenyldivinyltin (73%), tri-*n*-butylvinyltin (82%) and triphenylvinyltin (79%) have been prepared by the reaction of vinylmagnesium chloride in tetrahydrofuran solution with the appropriate tin halide in a hydrocarbon solvent. These compounds, with the exception of triphenylvinyltin, were purified by distillation under reduced pressure to give colorless liquids. Triphenylvinyltin, a colorless solid, was crystallized from ethanol.

$$4CH_2{=}CHMgCl + SnCl_4 \longrightarrow (CH_2{=}CH)_4Sn + 4MgCl_2$$

$$2CH_2{=}CHMgCl + (n\text{-}C_4H_9)_2SnCl_2 \longrightarrow (n\text{-}C_4H_9)_2Sn(CH{=}CH_2)_2 + 2MgCl_2$$

$$CH_2{=}CHMgCl + (C_6H_5)_3SnCl \longrightarrow (C_6H_5)_3SnCH{=}CH_2 + MgCl_2$$

n-Butylvinyltin dichloride (54%), divinyl-*n*-butyltin chloride (50%) and di-*n*-butylvinyltin chloride (56%) have been synthesized by the stepwise substitution of *n*-butyltin trichloride and di-*n*-butyltin dichloride, respectively, with vinylmagnesium chloride. The problem in this approach was one of limiting the substitution to a stepwise vinylation. Failure to do this led to a separation step in which the product had to be won from unreacted starting material and/or the completely substituted vinyltin compound. It was this difficult separation that caused the yield of desired product to be lower than in the preparation of completely substituted compounds.

$$CH_2{=}CHMgCl + n\text{-}C_4H_9SnCl_3 \longrightarrow (n\text{-}C_4H_9)(CH_2{=}CH)SnCl_2 + MgCl_2$$

$$2CH_2{=}CHMgCl + n\text{-}C_4H_9SnCl_3 \longrightarrow (CH_2{=}CH)_2(n\text{-}C_4H_9)SnCl + 2MgCl_2$$

$$CH_2{=}CHMgCl + (n\text{-}C_4H_9)_2SnCl_2 \longrightarrow (n\text{-}C_4H_9)_2(CH_2{=}CH)SnCl + MgCl_2$$

In a search for a shorter preparative method, it was found that di-*n*-butyldivinyltin could be prepared in a 58% yield from di-*n*-butyltin oxide[5] and vinylmagnesium chloride. Similarly tri-*n*-butylvinyltin (85%) was synthesized from bistri-*n*-butyltin oxide[5] and vinylmagnesium chloride.

$$2CH_2{=}CHMgCl + (n\text{-}C_4H_9)_2SnO \longrightarrow (n\text{-}C_4H_9)_2Sn(CH{=}CH_2)_2 + (MgCl)_2O$$

$$2CH_2{=}CHMgCl + (n\text{-}C_4H_9)_6Sn_2O \longrightarrow 2(n\text{-}C_4H_9)_3SnCH{=}CH_2 + (MgCl)_2O$$

These results demonstrate that the oxide bond in organotin compounds, and most likely in other similar organometallic compounds, is very different from those encountered in the chemistry of carbon. These oxides behave like the halides and esters of silicon and tin and undergo similar nucleophilic substitution reactions.

Experimental

Starting Materials.—Commercial tin tetrachloride was redistilled through a short column. Du Pont tetrahydrofuran and Matheson vinyl chloride were used without additional purification. Dow Grignard grade magnesium turnings were used. Triphenyltin chloride, diphenyltin dichloride, butyl trichloride, dibutyltin dichloride, tributyltin chloride and dimethyltin dichloride were obtained by disproportionation of the corresponding tetrasubstituted compounds.[6,7]

1. Tetravinyltin.—In a 22.0-l. flask[8] was placed 394.0 g. (16.2 g. atoms) of magnesium turnings. To this was added 100 ml. of a solution of 1212 g. (19.4 moles) of vinyl chloride in 3460 g. (48 moles) of tetrahydrofuran. The reaction was initiated by heating the flask to cause reflux, followed by the addition of 2.0 ml. of ethyl bromide. Once thoroughly initiated, the heating was stopped and the remainder of the mix added at a rate to maintain a pot temperature of 48–56°. The addition took 6.0 hr. The tem-

perature was maintained for 3.0 hr. longer by heating. Then a solution of 663.6 g. (3.5 moles) of tin tetrachloride in 10.8 l. of pentane was added at a rate to maintain reflux.[9] The addition took 4.0 hr. The mixture was refluxed for 5.0 hr.

On cooling, the reaction mixture was partially hydrolyzed by the cautious addition of 2.8 l. of 10% aqueous hydrochloric acid. At this point, a heavy solid[10] dropped out of the organic layer. The organic layer was decanted from the solid into a 22.0-l. flask. The hydrolysis was completed by the addition of 2.0 l. of water to the solid and two liquid phases resulted. The organic layer (*ca.* 300 ml.) was separated and added to the 22.0-l. flask. The solvents, pentane and tetrahydrofuran, were removed by rapid distillation at 1.0 atm. on a steam-bath. The residue was transferred to a 1.0-l. flask and carefully fractionally distilled under reduced pressure to yield: cut 1, b. 25–30° (100–120 mm.), 150 g. of tetrahydrofuran; cut 2, b. 55–57° (17 mm.), 642 g. (82%) of tetravinyltin.

2. **Di-*n*-butyldivinyltin.**—In a 5.0-l. flask equipped as above was placed 303.8 g. (1.0 mole) of di-*n*-butyltin dichloride in 2.0 l. of heptane. To this was added, at reflux, 2.5 moles of vinylmagnesium chloride in tetrahydrofuran over a 2.0-hr. period. The mix was refluxed an additional 4.0 hr. and worked-up as above to yield 254.0 g. (89%) of di-*n*-butyldivinyltin distilling at 78–80° (2.0 mm.).

3. **Triphenylvinyltin.**—In a 3.0-l. flask was placed 385.5 g. (1.0 mole) of triphenyltin chloride in 1.0 l. of heptane. Then 1.2 moles of vinylmagnesium chloride in tetrahydrofuran was added over a 2.0-hr. period at reflux followed by a 3.0-hr. reflux. The mix was hydrolyzed as above. The solvents were distilled at 1.0 atm. with the last traces taken off at water-pump pressure (20 mm.). A solid residue of 362.0 g. (93%) of crude product melting at 31–35° was obtained. This was recrystallized from methanol to yield 298.0 g. (79%) of triphenylvinyltin melting at 39–40°.

4. **Tri-*n*-butylvinyltin.**—In a 5.0-l. flask was placed 592.1 g. (1.0 mole) of bistri-*n*-butyltin oxide in 2.0 l. of heptane. Then 2.2 moles of vinylmagnesium chloride in tetrahydrofuran was added at a temperature of 70–80°. The mix was refluxed for 3.0 hr. and worked-up to yield 541.0 g. (85%) of tri-*n*-butylvinyltin distilling at 114° (3.0 mm.).

5. ***n*-Butylvinyltin Dichloride.**—In a 5.0-l. flask was placed 282.2 g. (1.0 mole) of *n*-butyltin trichloride in 2.5 l. of heptane. Then 1.0 mole of vinylmagnesium chloride in tetrahydrofuran was added over a 2.0-hr. period with the reaction temperature maintained between 25–40°. The mix was stirred for 3.0 hr. and filtered by suction through a Buchner funnel. The solvents were removed at 1.0 atm. and the residue carefully fractionally distilled under reduced pressure to yield 146.0 g. (53.5%) of *n*-butylvinyltin dichloride distilling at 99–101° (3.0 mm.).

6. **Divinyl-*n*-butyltin Chloride.**—In a 5.0-l. flask was placed 339.0 g. (1.2 moles) of *n*-butyltin trichloride in 2.5 l. of heptane. Then 2.4 moles of vinylmagnesium chloride in tetrahydrofuran was added, at reflux, over a 3.0-hr. period with stirring. On completion of addition, the mix was refluxed for 1.0 hr. and allowed to cool. Hydrolysis was accomplished as above. The organic phase was dried on sodium sulfate, freed of solvents at 1.0 atm. and carefully fractionally distilled under reduced pressure to yield 159.0 g. (50%) of divinyl-*n*-butyltin chloride distilling at 82–84° (3.0 mm.).

Acknowledgment.—The authors wish to thank Dr. Marie Farnsworth and her co-workers in the Physical and Analytical Section of this Laboratory for their assistance throughout this work.

RAHWAY, NEW JERSEY

(9) At this point, two large water condensers were substituted for the thermometer and cold condenser, and the excess vinyl chloride was allowed to vent up the hood. A thorough study of solvent systems has been made and pentane at this relative concentration was found to give maximum yield of product.

(10) The solid is thought to be $MgCl_2 \cdot 6H_2O$.

The Disproportionation of Tetravinyltin with Tin Tetrachloride and the Cleavage of Some Vinyltin Compounds with Bromine

BY SANDERS D. ROSENBERG AND AMBROSE J. GIBBONS, JR.

RECEIVED OCTOBER 29, 1956

Vinyltin trichloride, divinyltin dichloride and trivinyltin chloride have been prepared in excellent yields by the low temperature disproportionation of tetravinyltin with tin tetrachloride. Dibutyldivinyltin, dimethyldivinyltin and diphenyldivinyltin have been subjected to bromine cleavage, and it has been found that the ease of displacement of these groups from tin is phenyl > vinyl > methyl > butyl. Divinyltin oxide and trivinyltin hydroxide have been prepared by the hydrolysis of divinyltin dichloride and trivinyltin chloride, respectively, with aqueous sodium hydroxide.

The preparation of organotin chlorides by the disproportionation of symmetrical tetrasubstituted organotin compounds with tin tetrachloride has been reported by a number of workers.[1-3] Conditions have been outlined for the synthesis of such compounds as di-*n*-butyltin dichloride,[1,3] di-*n*-hexyltin dichloride[3] and triphenyltin chloride.[2]

In general the method involves heating the tetra-substituted organotin compound with tin tetrachloride at 200–240° for 1–3 hr. at 1.0 atmosphere.

$$3R_4Sn + SnCl_4 \longrightarrow 4R_3SnCl$$

$$R_4Sn + SnCl_4 \longrightarrow 2R_2SnCl_2$$

The product is purified by distillation under reduced pressure and/or recrystallization from a suitable solvent.

In the course of research in this Laboratory on the preparation of vinyltin compounds,[4] a need arose for vinyltin chlorides. As it was known that tetravinyltin was not stable at temperatures over 200°, it was decided to investigate the utility of the disproportionation reaction at low temperatures. It was found that vinyltin trichloride, divinyltin dichloride and trivinyltin chloride could be prepared in virtually quantitative yields simply by stirring tetravinyltin with tin tetrachloride, in stoichiometric quantities, for several hours and

$$(CH_2{=}CH)_4Sn + 3SnCl_4 \xrightarrow{75\text{–}90^\circ} 4CH_2{=}CHSnCl_3$$

$$(CH_2{=}CH)_4Sn + SnCl_4 \xrightarrow{0\text{–}10^\circ} 2(CH_2{=}CH)_2SnCl_2$$

$$3(CH_2{=}CH)_4Sn + SnCl_4 \xrightarrow{35\text{–}40^\circ} 4(CH_2{=}CH)_3SnCl$$

isolating the products by distillation under reduced pressure. The disproportionation took place with equal facility over a wide temperature range (0–150°).

Vinyltin trichloride and divinyltin dichloride are stable compounds, but it was found, after a series of vacuum distillations on a 3′-glass helix packed column, that trivinyltin chloride tends to rearrange to form divinyltin dichloride and tetravinyltin. Therefore, it is suggested that the crude trivinyltin chloride be used as such for the preparation of derivatives.

$$2(CH_2{=}CH)_3SnCl \longrightarrow (CH_2{=}CH)_2SnCl_2 + (CH_2{=}CH)_4Sn$$

Cleavage studies on organotin compounds with halogen[5] and halogen acid[6] have shown that the ease of displacement of organic groups from tin is α-thienyl > p-tolyl > phenyl > methyl > n-butyl > n-octyl. It was of interest to ascertain the relative position of the vinyl group in this series. Di-n-butyldivinyltin, dimethyldivinyltin and diphenyldivinyltin were allowed to react with bromine at 10–15°. The results are summarized in Table I. It was found that the preferential order of cleavage of these groups from tin is phenyl > vinyl > methyl > butyl.

$$R_2R_2'Sn + Br_2 \rightarrow \begin{cases} R_2R'SnBr + R'Br \\ RR'_2SnBr + RBr \end{cases}$$

Experimental

1. Vinyltin Trichloride.—In a 500-ml. flask was placed 50.0 g. (0.22 mole) of tetravinyltin. To this was added, with good stirring and over a 2.25-hr. period, 187.6 g. (0.66 mole plus 10%) of tin tetrachloride at a pot temperature of 30°. The solution was then heated to and maintained at 70° for 2.0 hr. and distilled to yield: cut 1, b.p. 115–125° (760 mm.), 32 g. of crude tin tetrachloride; cut 2, b.p. 64–65° (15 mm.), 190.0 g. (86%) of vinyltin trichloride.

Anal. Calcd. for $C_2H_3Cl_3Sn$: Cl, 42.19; Sn, 47.08. Found: Cl, 41.55; Sn, 47.13; $n^{25}D$ 1.5361; d^{25}_4 1.9981.

2. Divinyltin Dichloride.—In a 2.0-l. flask was placed 340.5 g. (1.5 moles) of tetravinyltin. To this was added, with good stirring and over a 2.25-hr. period, 390.8 g. (1.5 moles) of tin tetrachloride at a pot temperature of 30°. The solution was then stirred for 2.0 hr. and carefully fractionally distilled under reduced pressure to yield 718.0 g. (98%) of divinyltin dichloride distilling at 54–56° (3.0 mm.).

Anal. Calcd. for $C_4H_6Cl_2Sn$: Cl, 29.10; Sn, 48.71. Found: Cl, 28.81; Sn, 48.71; m.p. 13.2°; $n^{25}D$ 1.5490; d^{20}_4 1.7645.

3. Trivinyltin Chloride.—In a 2.0-l. flask was placed 600.0 g. (2.64 moles) of tetravinyltin. To this was added, with good stirring and over a 1.0-hr. period, 229.0 g. (0.88 mole) of tin tetrachloride at a pot temperature of 30°. The solution was stirred for 2.0 hr. and rapidly distilled under reduced pressure to yield 795.0 g. (96%) of trivinyltin chloride distilling at 59–60° (6.0 mm.).

Anal. Calcd. for C_6H_9ClSn: Cl, 15.07; Sn, 50.45. Found: Cl, 14.68; Sn, 50.50; $n^{25}D$ 1.5235; d^{20}_4 1.5139.

4. Di-n-butylvinyltin Bromide.—In a 500-ml. flask was placed 102.6 g. (0.358 mole) of di-n-butyldivinyltin. To this was added, with good stirring and over a 2.0-hr. period, 57.0 g. (0.357 mole) of bromine. Each drop of bromine was decolorized instantly on reaching the solution and the reaction was vigorous.

The solution was then carefully fractionally distilled in an adequately trapped system to yield: cut 1, b.p. 14–17° (760 mm.), 22.7 g. (59.5%) of vinyl bromide; cut 2, b.p. 72–73° (0.03 mm.), 82.7 g. (68.4%) of di-n-butylvinyltin bromide; cut 3, pot residue, 13.4 g. (9.1%) of crude di-n-butyltin dibromide.

Anal. Calcd. for $C_{10}H_{21}BrSn$: Br, 23.55; Sn, 34.98. Found: Br, 24.28; Sn, 34.63; $n^{25}D$ 1.4970; d^{25}_4 1.3913. Calcd. for $C_8H_{18}Br_2Sn$: Br, 40.60; Sn, 30.18. Found: Br, 39.58; Sn, 30.54.

In a second run 58.6 g. (0.368 mole) of bromine in 184 ml. of CCl_4 was added to 105.3 g. (0.368 mole) of di-n-butyldivinyltin in 184 ml. of CCl_4 with good stirring over a 2.0-hr. period at 15°. A total of 99.5 g. (78%) of di-n-butylvinyltin bromide and 17.3 g. (12%) of di-n-butyltin dibromide was obtained.

5. Trivinyltin Hydroxide and Divinyltin Oxide.—In a 500-ml. flask was placed 25.0 g. (0.625 mole) of sodium hydroxide in 300 ml. of water. To this was added, with good stirring and over a 0.5-hr. period, 100.0 g. (0.425 mole) of trivinyltin chloride. A white solid formed immediately. After stirring for 1.0 hr., the solid filtered from the reaction solution under nitrogen was dried under reduced pressure over potassium hydroxide pellets in a vacuum desiccator. A total of 68.0 g. (74%) of trivinyltin hydroxide melting at 67.5–69.0° was obtained.

TABLE I

REACTION OF VINYLTIN COMPOUNDS WITH BROMINE

Vinyltin compound	Products isolated
$(n\text{-}C_4H_9)_2Sn(CH{=}CH_2)_2$	$CH_2{=}CHBr$ (60%)
	$(n\text{-}C_4H_9)_2(CH_2{=}CH)SnBr$ (78%)
$(CH_3)_2Sn(CH{=}CH_2)_2$	$CH_2{=}CHBr$ (69%)
	$(CH_2{=}CH)(CH_3)_2SnBr$ (88%)[a]
$(C_6H_5)_2Sn(CH{=}CH_2)_2$	C_6H_5Br (90%)
	$(CH_2{=}CH)_2(C_6H_5)SnBr$[b]

[a] *Anal.* Calcd. for C_4H_9BrSn: Br, 31.25. Found: Br, 30.92; b.p. 72° (21.0 mm.). This compound gave evidence of disproportionation on prolonged distillation under reduced pressure. [b] This compound was not isolated as it apparently disproportionated on distillation under reduced pressure (20 mm.). The main products isolated were diphenyltin dibromide, divinyltin dibromide and trivinyltin bromide.

Arsonosiloxanes[1]

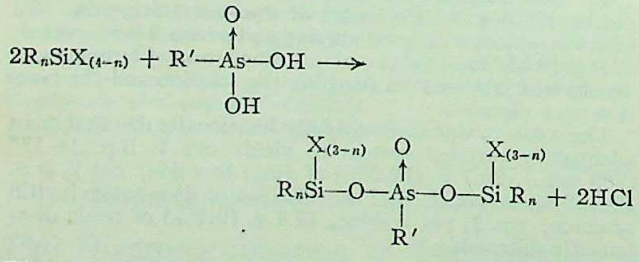
BY ROLAND M. KARY AND KURT C. FRISCH

RECEIVED APRIL 25, 1956

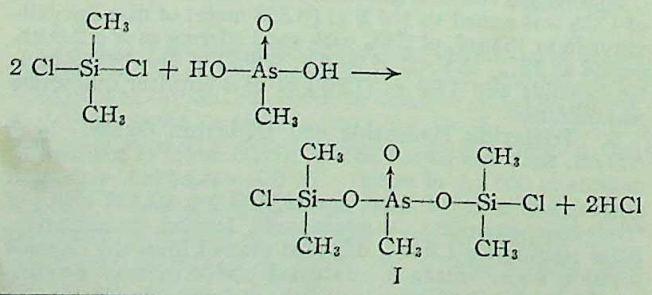
The well-known silicones, such as polymethylsiloxanes, do not exhibit pesticidal properties. Organic arsenical siloxanes could be used to control pest organism in addition to already existing utilities of conventional silicones. It was found that arsenic can be incorporated into siloxane structures by formation of Si–O–As bonds from a novel reaction between organic chlorosilanes and organic arsonic acids. Formation of arsonosiloxane polymers from hydrolysis of chlorosilylarsonates appears to be feasible. Methyl- and phenylchlorosilylarsonates were synthesized and hydrolyzed to the corresponding arsenical siloxane derivatives. Compounds found were identified by chemical analysis and infrared absorption characteristics.

The well-known utilities of silicones, particularly of methylsilicones, do not include action toward pest organisms. Organic arsenical siloxane derivatives could conceivably exhibit pesticidal properties which would add numerous possibilities of applications to those already existing. Therefore, the investigation of organic arsenical silanes and siloxane derivatives was undertaken in order to prepare compounds containing Si–O–As bonds. It was found that methyl- and phenylchlorosilanes react with methyl- and phenylarsonic acids in the presence of an inert solvent such as benzene or carbon tetrachloride, at the temperature of 80° at which these solvents are kept refluxing for about 24 hr. under agitation.

As is shown by the following equation, 2 moles of chlorosilane react with one mole arsonic acid to form a "bis" or neutral chlorosilylarsonate and 2 moles of hydrochloric acid

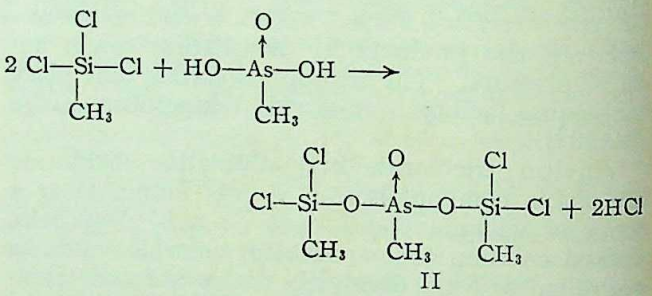


Thus, the reaction between dimethyldichlorosilane and methylarsonic acid resulted in bis-(dimethylchlorosilyl)-methylarsonate (I), shown by the equation



I

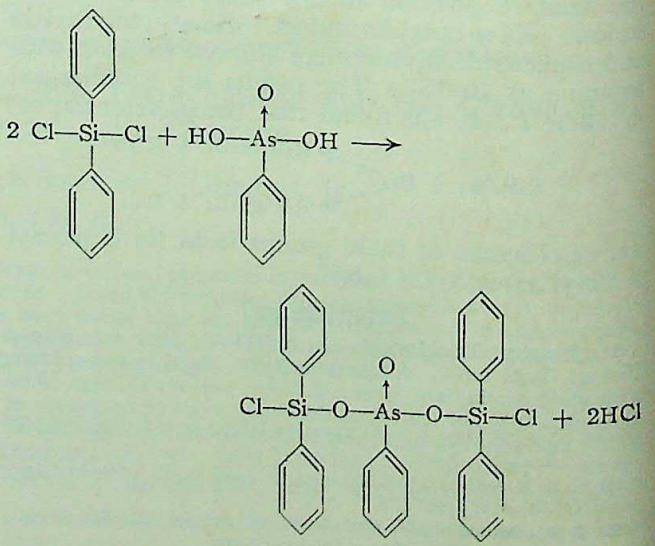
In similar manner, bis-(methyldichlorosilyl)-methylarsonate (II) was prepared from methyltrichlorosilane and methylarsonic acid



II

These reactions were carried out in 2:1 molar ratio of chlorosilane and methylarsonic acid. If a 1:1 molar ratio was employed, poor yields of the "bis" compounds were obtained, together with considerable amounts of unreacted starting materials.

Essentially, the same method was used to prepare the corresponding phenyl derivatives. Bis-(diphenylchlorosilyl)-phenylarsonate (III) was synthesized from diphenyldichlorosilane and phenyl arsonic acid



III

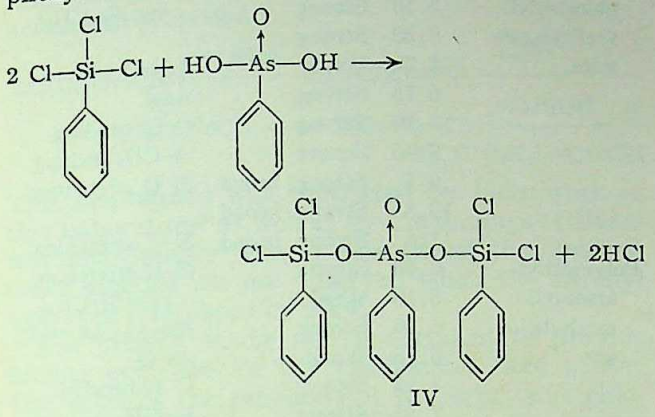
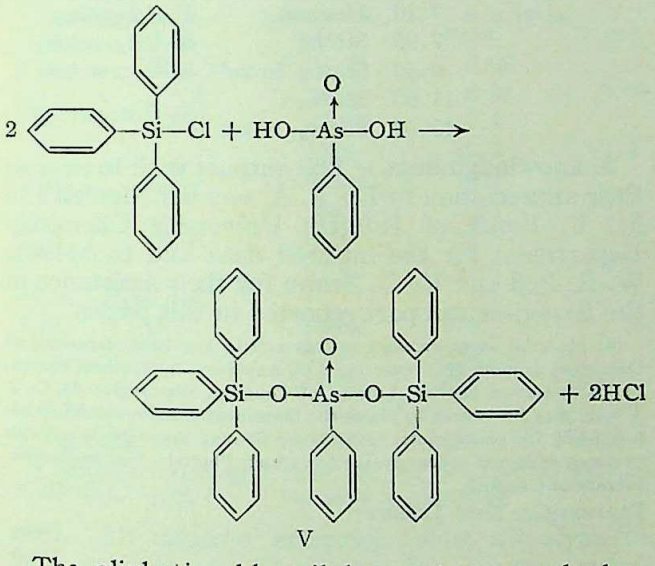
Similarly, bis-(phenyldichlorosilyl)-phenylarsonate (IV) was made, using phenyltrichlorosilane and phenylarsonic acid



IV

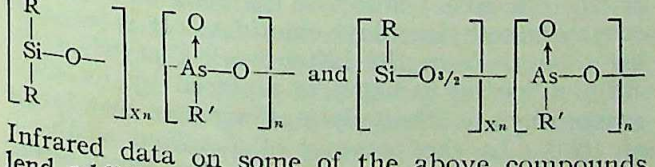
Bis-(triphenylsilyl)-phenylarsonate (V) was synthesized by treating triphenylchlorosilane with phenylarsonic acid, using pyridine as a hydrohalogen acceptor



V

The aliphatic chlorosilylarsonates were hydrolyzed either in water alone or in mixtures of their carbon tetrachloride solutions and water of a volume ratio of 1:3. The aromatic chlorosilylarsonates were hydrolyzed in mixtures of their chloro- or bromobenzene solutions and water of the same ratio. Upon removal of the solvents the recovered hydrolysis products ranged from transparent, rubbery materials to fine, white powders.

From the elementary analysis of the recovered products, it became apparent that some cleavage of the Si–O–As bond had taken place as could be expected from theoretical considerations. However, the resulting hydrolysis products still contained both arsenic and silicon, even after repeated washing with water, and appeared to be copolymers of the general formulas:



Infrared data on some of the above compounds lend additional evidence to the postulated structures.

Experimental

Methylarsonic Acid.—Methylarsonic acid was obtained as its disodium salt, according to Meyer's reaction from sodium arsenite and methyl chloride.[2] The free acid was isolated through the calcium salt by decomposition of the latter with sulfuric acid, followed by precipitation upon concentrating the filtrate (from $CaSO_4$), and recrystallization from ethanol.

Phenylarsonic Acid.—Phenylarsonic acid was used as the available "D.P.I.—Eastman Kodak—Benzenearsonic Acid" without further purification.

Methyl- and Phenylchlorosilanes.—The methyl- and phenylchlorosilanes were used as the available Linde Air Products or General Electric Co. preparations without further purification.

Bis-(dimethylchlorosilyl)-methylarsonate (I).—Seventy g. (0.5 mole) of methylarsonic acid was suspended in 400 ml. of dry benzene by stirring at room temperature. One hundred and twenty-nine g. of dichlorodimethylsilane was added slowly from a separatory funnel, so as to keep the ensuing exothermic increase in temperature to a minimum of 10–15°. After the initial reaction, indicated by a considerable evolution of HCl gas, had abated, the mixture was refluxed for 24 hr., under a drying tube containing "Drierite." Upon cooling to room temperature, the amount of unreacted methylarsonic acid, which is practically insoluble in benzene, was found to be 8%. It was subsequently removed by filtration.

After removal of the solvent under atmospheric and reduced pressure, 111 g. of I or 68% was obtained in form of a pale-yellow oil.

Anal. Calcd. for $C_5H_{15}O_3Cl_2Si_2As$: Si, 17.3; As, 23.1; Cl, 21.8; C, 17.8; H, 4.6. Found: Si, 17.4; As, 22.7; Cl, 21.9; C, 18.5; H, 5.4.

Bis-(methyldichlorosilyl)-methylarsonate (II).—Seventy g. (0.5 mole) of methylarsonic acid reacted with 150 g. (1.0 mole) of methyltrichlorosilane in the same manner as described before.

Removal of the solvent yielded II, a resinous, somewhat transparent solid. The yield was 154 g., corresponding to 84% of the theoretical. Since the purification of this material proved to be extremely difficult, the resulting product was hydrolyzed directly to the corresponding polymer VII.

Bis-(diphenylchlorosilyl)-phenylarsonate (III).—Twenty and two-tenths g. (0.1 mole) of phenylarsonic acid reacted in the same manner as described before with 50.6 g. (0.2 mole) of diphenyldichlorosilane resulting in formation of III as a white, amorphous solid. The yield was 51 g. or 80% of the theoretical.

Anal. Calcd. for $C_{30}H_{25}O_3Cl_2Si_2As$: Si, 8.8; As, 11.8; Cl, 11.2; C, 56.7; H, 4.0. Found: Si, 8.6; As, 11.8; Cl, 11.0; C, 57.0; H, 4.7.

Bis-(phenyldichlorosilyl)-phenylarsonate (IV).—Twenty and two-tenths g. (0.1 mole) of phenylarsonic acid reacted in the same manner as described before with 42.3 g. (0.2 mole) of phenyltrichlorosilane which resulted in formation of IV as a somewhat resinous, amorphous solid. The yield was 43 g. or 78.2% of the theoretical.

Here, again, purification of the resulting dichlorosilyl derivative presented some serious obstacles, and the product was hydrolyzed directly to the corresponding polymer.

Bis-(triphenylsilyl)-phenylarsonate (V).—Twenty and two-tenths g. (0.1 mole) of phenylarsonic acid was suspended in 400 ml. of dry benzene containing 79.1 g. of pyridine which latter is an excess over the theoretically required 15.8 g. (0.2 mole). To this mixture 59.0 g. (0.2 mole) of triphenylchlorosilane dissolved in 400 ml. of dry benzene was added gradually. The formation of a precipitate accompanied by an exothermic temperature increase of 7° was observed. The mixture was then heated to reflux (80–82°) which was maintained for 24 hr. After cooling to room temperature, the precipitate was filtered off and dried. It consisted almost entirely of pyridine monohydrochloride. The filtrate was subjected to solvent removal under atmospheric and reduced pressure upon which 66.5 g. or 92.6% was recovered as a white, waxy solid.

Anal. Calcd. for $C_{42}H_{35}O_3Si_2As$: Si, 7.8; As, 10.4; C, 70.3; H, 4.9. Found: Si, 7.0; As, 10.3; C, 69.6; H, 4.3.

Polymethylarsonodimethylsiloxane (VI).—Ten g. of bis-(dimethylchlorosilyl)-methylarsonate was dissolved in 100 ml. of carbon tetrachloride and added gradually from a separatory funnel through a tube reaching into 100 ml. of CCl_4 agitated with 300 ml. of water, at about 40–50°, during 25–35 minutes. After cooling to room temperature and subsequent washing with water to remove hydrochloric acid found during hydrolysis, the CCl_4 (bottom) layer was drawn off, dried over anhydrous Na_2SO_4 and the solvent removed under atmospheric and reduced pressure. Three and six-tenths g. of VI, a translucent, rubbery material was obtained.

Anal. Calcd. for $C_{25}H_{75}O_{14}Si_{12}As$: Si, 33.3; As, 7.4; C, 29.7; H, 7.4. Found: Si, 33.6; As, 7.7; C, 29.8; H, 8.1.

Polymethylarsonomethylsiloxane (VII).—One hundred and nine g. of bis-(methyldichlorosilyl)-methylarsonate was leached with boiling water for about 1 hr., washed thoroughly with water of room temperature, filtered off and dried. Forty-five g. of VII, a fine white powder, was obtained.

Anal. Calcd. for $C_{13}H_{39}O_{20}Si_{12}As$: Si, 36.3; As, 8.1; C, 15.5; H, 3.9. Found: Si, 37.1; As, 7.5; C, 15.8; H, 4.6.

The above VI and VII thus appear to be copolymers of the previously given formula where X is about 12.

The aromatic chlorosilylarsonates were found to be soluble in bromobenzene which is a suitable solvent for this type of controlled hydrolysis.[3] Essentially, the same method of hydrolysis was performed as described before. So far only impure polymers have been obtained as the result of this hydrolysis. The infrared data were obtained by means of a Perkin–Elmer Double Beam Recording Infrared Spectrophotometer, Model 21. Data on infrared absorption maxima, characteristic for regular siloxane compounds, were available from the literature.[4] Unpublished data on infrared absorption maxima, characteristic for organoarsenic compounds, were available from known or novel organic arsenicals, such as methylarsonic acid, arsenomethane As-1,2-disulfide[5] and others. Compound I was examined as liquid film in capillary thickness, whereas compound VII had to be used as 2% solution in chloroform. Polydimethylsiloxane, General Electric Co.—SF-96 (300), was used as a standard reference.

The Kinetics of the Hydrolysis of Acetylenic Chlorides and Their Reactions with Primary and Secondary Aliphatic Amines[1]

BY G. F. HENNION AND KENNETH W. NELSON[2]

RECEIVED NOVEMBER 30, 1956

Acetylenic chlorides of the type RR'C(Cl)—C≡CH undergo very slow solvolysis in 80% ethanol at 25°. The rate is accelerated by addition of sodium hydroxide, and the reactions then commonly follow second-order kinetics. Primary and secondary aliphatic amines are smoothly alkylated by these halides. The mechanisms of these reactions are discussed.

Discussion

It was reported in a previous paper[3] in this series that 3-chloro-3-methyl-1-butyne undergoes extremely slow solvolysis in 80% ethanol at 25° ($k_1 = 7.4 \times 10^{-4}$ hr.$^{-1}$). This was attributed to lack of steric strain, despite the tertiary structure, and the inductive (electron-withdrawing) effect of the ethynyl group. Burawoy and Spinner[4] have verified these findings (k_1 said to be 8.48×10^{-4} hr.$^{-1}$) in a recent study of the behavior of alkylethynyldimethylcarbinyl chlorides. It is interesting to note from the latter work that when the ethynyl hydrogen atom is replaced by an alkyl group, the rate of solvolysis is increased by a factor of 1000. In the presence of dissolved alkali, 3-chloro-3-methyl-1-butyne reacts by second-order

kinetics.[3,4] The product of this reaction is the unexpected 3-ethoxy-3-methyl-1-butyne.[3] To account for this product as well as the second-order rate observed for the reaction, the following mechanism was proposed.[3]

$$R_2C(Cl)C{\equiv}CH \xrightarrow{+OH^\ominus} R_2C(Cl)C{\equiv}C^\ominus \xrightarrow{-Cl^\ominus} (R_2\overset{\oplus}{C}C{\equiv}C^\ominus \longleftrightarrow R_2C{=}C{=}C:) \xrightarrow{C_2H_5OH} R_2C(OC_2H_5){-}C{\equiv}CH$$

This mechanism was supported by later work in this Laboratory[5] as well as by the findings of Burawoy and Spinner[4] who demonstrated that second-order kinetics are *not* observed when the ethynyl hydrogen is replaced by alkyl.

The present study was undertaken to provide further evidence for the mechanism cited above. The rates of the reactions of the acetylenic chlorides listed in Tables I and II have now been measured. All undergo extremely slow solvolysis in 80% ethanol at 25° (Table I). In two cases, namely, 1-ethynylcyclohexyl chloride and 3-chloro-1-hexyne, the rate was too slow to measure. Reinvestigation of the solvolysis of 3-chloro-3-methyl-1-butyne gave a rate constant of 9.0×10^{-4} hr.$^{-1}$ in agreement with the previously published values.[3,4] This rate is 1/61 of that for *t*-amyl chloride, the saturated analog, under the same conditions.[6] Likewise, the ratio of the rate of solvolysis of 3-chloro-3-methyl-1-pentyne to that of 3-chloro-3-methylpentane is 1/69, and the ratio of the rate for 3-chloro-3-ethyl-1-pentyne to that of 3-chloro-3-ethylpentane is 1/62. The unique stabilizing influence of the ethynyl group is thus clearly demonstrated. When sodium hydroxide was added, other conditions remaining the same, the reactions were faster and usually followed clean second-order kinetics (Table II). In the case of 3-chloro-3-methyl-1-butyne, the rate constant was 1.29 l./mole hr. in excellent agreement with the earlier value[3] (1.2–1.4 l./mole hr.) but in only fair agreement with the Burawoy and Spinner measurement[4] (2.56 l./mole hr.). In two cases, namely, 3-chloro-1-hexyne and 3-chloro-3-phenyl-1-propyne, both secondary halides, clean second-order kinetics could not be obtained.

While these data are in complete agreement with the mechanism cited above, additional evidence for this mechanism was sought and was found in the reactions of the acetylenic chlorides with primary and with secondary amines. It is well known that tertiary aliphatic halides are not suitable for the alkylation of amines since such halides are too sensitive to HX elimination. It has been stated[7] without qualification that "amines of tertiary alkyl groups are not obtainable from the halide." The mechanism pictured above suggests *a priori* that amines which are strong bases and good nucleophilic reagents should be alkylated by acetylenic halides. This has now been found to be true and the simple reaction

$$RR'C(Cl){-}C{\equiv}CH + 2R_2NH \longrightarrow RR'C(NR_2){-}C{\equiv}CH + R_2NH{\cdot}HCl$$

gives good yields of products in a variety of applications (Table III).

The reaction of 3-chloro-3-ethyl-1-pentyne with aqueous ammonia was tried in an attempt to prepare 3-amino-3-ethyl-1-pentyne. The reaction was carried out at 100° in an autoclave. Approximately 30% of the starting material suffered HCl elimination to produce 3-ethyl-3-pentene-1-yne, the remainder being hydrolyzed to the corresponding carbinol, 3-ethyl-1-pentyne-3-ol. It appears therefore that aqueous ammonia is not sufficiently basic, even though less steric hindrance is involved in comparison with the amines used, to initiate the mechanism necessary for amine formation.

Further work is in progress, particularly to determine the limitations of alkylation reactions with acetylenic halides.

Experimental

Acetylenic Carbinols.—Generous samples of 3-methyl-1-butyne-3-ol, 3-methyl-1-pentyne-3-ol, 3-ethyl-1-pentyne-3-ol, 3,5-dimethyl-1-hexyne-3-ol and 1-ethynyl-cyclohexanol were obtained from Air Reduction Chemical Co. and from Reilly Tar and Chemical Co. 1-Hexyne-3-ol was prepared by the reaction of freshly distilled butyraldehyde and sodium acetylide in anhydrous liquid ammonia as previously described.[8] Likewise, 3-phenyl-1-propyne-3-ol was prepared by the reaction of freshly distilled benzaldehyde with sodium acetylide in anhydrous liquid ammonia.

All fractional distillations, except as noted, were carried out with a 40 × 1.2 cm. column fitted with a total reflux, partial take-off distilling head, hereafter referred to as column A. All boiling points and melting points are uncorrected.

Preparation of 3-Chloro-3-methyl-1-butyne.—This compound was prepared by the reaction of 1300 ml. (15 moles) of cold concentrated hydrochloric acid (0°) containing three moles of anhydrous calcium chloride with three moles of 3-methyl-1-butyne-3-ol as described earlier.[9] The crude chloride was distilled from potassium carbonate through column A; yield, 138 g. (45%), b.p. 33–36° (175 mm.). Triple distilled material, b.p. 75.5–75.6°, $n^{25}D$ 1.4145, was used for kinetic studies.

Preparation of 3-Chloro-3-methyl-1-pentyne and 3-Chloro-3-ethyl-1-pentyne.—These compounds were prepared by the reaction of 3-methyl-1-pentyne-3-ol and 3-ethyl-1-pentyne-3-ol with five times the theoretical amount of cold concentrated hydrochloric acid as described previously.[5] Crude 3-chloro-3-methyl-1-pentyne was obtained in 53% yield, b.p. 51–54° (120 mm.). Triple distilled material, b.p. 51.9–52.2° (115 mm.), $n^{25}D$ 1.4307, was used for kinetic studies. Crude 3-chloro-3-ethyl-1-pentyne was obtained in 62% yield, b.p. 70–75° (100 mm.). Triple distilled material, b.p. 71.9–72.2° (101 mm.), $n^{25}D$ 1.4396, was used for kinetic studies.

Preparation of 3-Chloro-1-hexyne.—This compound was prepared by the reaction of 1 mole (100 g.) of 1-hexyne-3-ol with 1.1 moles (130 g.) of thionyl chloride, using 5 g. of pyridine as a catalyst.[8] Fifty-one grams (43% yield) of crude product, b.p. 61–65° (100 mm.), was obtained in this manner. Triple distilled material, b.p. 63.1–63.4° (97 mm.), $n^{25}D$ 1.4366, was used for the kinetic work.

Preparation of 3-Chloro-3-phenyl-1-propyne.—This compound was prepared by the reaction of 1.14 moles (150 g.) of 3-phenyl-1-propyne-3-ol with 1.25 moles (150 g.) of thionyl chloride using five grams of pyridine as a catalyst; yield 70 g. (41%), b.p. 100–104° (18 mm.). Triple distilled material, b.p. 45.8–46.0° (1.0 mm.), $n^{25}D$ 1.5478, was used for kinetic studies.

Preparation of 1-Ethynylcyclohexyl Chloride.—Approximately 0.2 mole of freshly prepared cuprous chloride (CuCl) was dissolved in 430 ml. (5 moles) of cold concentrated hydrochloric acid contained in a 2-l. separatory funnel. One hundred and twenty-four grams (1 mole) of freshly distilled 1-ethynylcyclohexanol was then added. After 1 hr. of intermittent shaking, the lower layer was separated and discarded. The upper layer was washed twice with 200-ml. portions of concentrated hydrochloric acid to remove most of the adhering cuprous chloride and then shaken with anhydrous potassium carbonate. After this preliminary neutralization, the reaction mixture was dried overnight over a fresh layer of anhydrous potassium carbonate. Distillation through column A gave 100 g. (70% yield) of crude 1-ethynylcyclohexyl chloride, b.p. 56–58° (10 mm.). Triple distilled material, b.p. 55.0° (13 mm.), $n^{25}D$ 1.4795, was used for kinetic studies.

Preparation of 3-Chloro-3,5-dimethyl-1-hexyne.—One hundred and twenty-six grams (1 mole) of 3,5-dimethyl-1-hexyne-3-ol and 5 ml. of concentrated hydrochloric acid were placed in a 500-ml. three-neck round-bottom flask fitted with a stirrer, gas inlet tube and thermometer. Dry hydrogen chloride gas was passed into the carbinol at a rate of approximately 4 to 5 bubbles per second. The reaction mixture was periodically cooled with running water to maintain the temperature at 20–25°. After 52 g. of hydrogen chloride had been absorbed, the addition of the gas was terminated. The reaction mixture was placed in a separatory funnel and the small water layer was removed. After two washings with 200 ml. of water, the organic layer was dried overnight with anhydrous potassium carbonate. Distillation through column A gave 55 g. (38%) of chloride, b.p. 56–63° (39 mm.). The first fractions from this distillation were found to contain a considerable amount of an unidentified impurity containing a conjugated double bond system as indicated by the infrared spectrum. Five distillations were required to give a product which was suitable for kinetic studies; b.p. 56.7–57.0° (39 mm.), $n^{25}D$ 1.4370.

Preparation of Solutions for Kinetic Studies.—The ethanol (80%) was prepared by mixing four volumes of absolute ethanol and one volume of freshly boiled distilled water. The densities of two batches prepared in this manner were found to be 0.8495 and 0.8498 at 25.0°. A carbonate-free solution of sodium hydroxide in 80% ethanol was prepared by dissolving approximately 17 g. of crushed sodium hydroxide pellets in 100 ml. of 80% ethanol. Filtration of this solution through a sintered glass funnel and dilution with one liter of 80% ethanol gave an approximately 0.4*N* sodium hydroxide solution. Standardization of the above solution as well as that of aqueous hydrochloric acid and aqueous sodium hydroxide were performed with potassium acid phthalate and sodium carbonate using as an indicator a mixture consisting of two parts of 0.1% methyl red solution and three parts of 0.1% brom cresol green solution, both in absolute ethanol.[10]

General Kinetic Procedures, First-order Rate Constants.—A sample of halide (*ca.* 1–2 g.) was weighed in a thin-walled glass ampoule and sealed. The ampoule was crushed under solvent previously adjusted to 25.0°. The solution was rapidly transferred to a 100-ml. volumetric flask, diluted to the mark with more solvent, mixed and returned to the constant temperature bath. Periodically, approximately every 24 hr., 10-ml. aliquots were removed by a pipet, quenched in 50 ml. of absolute methanol and titrated immediately with standard sodium hydroxide using the forementioned indicator. A total of six to eight aliquots were taken from each reaction, following the first 30–60% reaction. The first-order rate constants were calculated from the integrated rate expression.

Second-order Rate Constants.—A sample of halide (*ca.* 4–5 g.) was weighed in a 50-ml. volumetric flask. The flask was then filled to the mark with 80% ethanol, the temperature of which was previously adjusted to 25°; 5- or 10-ml. aliquots of this solution were placed in 100-ml. flasks. A predetermined amount of standard sodium hydroxide in 80% ethanol (delivered from a buret) was added to the 100-ml. flasks, and the flasks were filled to the mark with 80% ethanol, shaken and returned to the constant temperature bath. Periodically, approximately every hour, 10-ml. aliquots were removed and quenched in 5 or 10 ml. of standard acid dissolved in absolute methanol. Each aliquot was then back-titrated with standard base. A total of six to eight aliquots were taken from each reaction covering the first 30–70% reaction. The second-order rate constants were calculated from the appropriate integrated rate expressions.

Preparation of 3-Dimethylamino-3-methyl-1-butyne Hydrochloride.—Ten grams of 3-chloro-3-methyl-1-butyne and 50 ml. of 40% aqueous dimethylamine were placed in a stout bottle and shaken mechanically for a period of 15 hr. The orange colored solid was collected by filtration, dissolved in 100 ml. of ether and dried over potassium hydroxide pellets. The hydrochloride of this amine was precipitated by addition of excess hydrogen chloride dissolved in absolute ether. After collection by suction filtration, this material was recrystallized from an ethyl acetate–ethanol mixture; yield 10 g. (70%) of material melting at 241–242.5° dec. A small sample of the free base was isolated and purified by sublimation, m.p. 99–102°.

Preparation of 3-Pyrrolidino-3-methyl-1-butyne.—Twenty-five grams of 3-chloro-3-methyl-1-butyne, 60 ml. of pyrrolidine and 20 ml. of water were placed in a 125-ml. erlenmeyer flask and set aside for 24 hr. The product was collected by filtration and washed with water. Recrys-

tallization from a water–ethanol mixture gave 21 g. (62%) of material melting at 76–78°.

Preparation of 1-Pyrrolidino-1-ethynylcyclohexane.—Ten grams of 1-ethynylcyclohexyl chloride, 20 ml. of pyrrolidine and 10 ml. of water were placed in a 50 ml. erlenmeyer flask and set aside for 24 hr. The solid material was collected by filtration, washed with water and recrystallized from an ethanol–water mixture; yield 8 g. (73%) of material melting at 65–66.5°.

Preparation of 1-Piperidino-1-ethynylcyclohexane.—Twenty grams of 1-ethynylcyclohexyl chloride, 40 ml. of piperidine and 20 ml. of water were placed in a 125-ml. erlenmeyer flask. After 48 hr. had elapsed, the solid material was collected by filtration, washed with water and recrystallized from aqueous acetone; yield 16 g. (60%) of material melting at 94.5–95.5°.

Preparation of 1-Dimethylamino-1-ethynylcyclohexane.—Twenty grams of 1-ethynylcyclohexyl chloride, 60 ml. of 40% aqueous dimethylamine and 55 ml. of acetone were placed in a 125-ml. erlenmeyer flask. After 24 hr., 60 ml. of volatile solvent was removed by distillation. Solidification of the desired product resulted when the two-phase residue was cooled to approximately −10°. Filtration of the solid material and subsequent recrystallization from aqueous alcohol gave 14.5 g. (68%) of material melting at 57–58.5°.

Preparation of 3-Ethylamino-3-methyl-1-pentyne.—One hundred and fifty ml. of 70% aqueous ethylamine and 40 g. of 3-chloro-3-methyl-1-pentyne were placed in a stout bottle. After 12 hr., the reaction mixture appeared in two layers. The mixture was then shaken mechanically for an additional period of 30 hr. The upper layer was separated and the bottom layer was diluted with an equal volume of water. The upper layer was again separated and added to the first. After adding 100 ml. of ether and washing twice with water, the solution was dried over potassium hydroxide pellets. Distillation gave a 25.5-g. fraction, b.p. 70–79° (120 mm.). Redistillation gave 22 g. (52%), b.p. 74–79° (120 mm.), $n^{25}D$ 1.4308.

Preparation of 3-Pyrrolidino-1-hexyne.—Thirty grams of 3-chloro-1-hexyne, 90 ml. of pyrrolidine and 30 ml. of water were refluxed for 18 hr. (inside temperature, 95°). The upper layer was separated and the bottom layer was diluted with an equal volume of water. The upper layer was again separated and combined with the first. An equal volume of ether was added and the ether solution was washed twice with water and dried overnight over potassium hydroxide pellets. Distillation gave 25 g. (63%) of material boiling at 71–72° (12 mm.), $n^{25}D$ 1.4597, d^{25} 0.8693.

Preparation of 3-*n*-Butylamino-1-hexyne.—Thirty-four grams of 3-chloro-1-hexyne, 90 ml. of *n*-butylamine and 30 ml. of water were placed in a 300-ml. round-bottom flask and heated at about 65° for 5 days.

The upper layer was separated and the bottom layer was diluted with an equal amount of water. The upper layer was again separated and combined with the first. After an equal volume of ether had been added, the solution was washed with water and dried over potassium hydroxide pellets. Distillation gave a 29.5-g. fraction, b.p. 68–72.5° (11 mm.). Redistillation gave a fraction weighing 25 g. (56%) of material, b.p. 71–72° (11 mm.), $n^{25}D$ 1.4365, d^{25} 0.8043.

As derivatives, the hydrochlorides and methiodides of most of the amines were prepared. The hydrochlorides were prepared by treating 1 g. of the amine dissolved in 25 ml. of absolute ether with excess ethereal hydrogen chloride. Purification was achieved by recrystallization from an ethyl acetate–ethanol mixture. The methiodides were prepared by treating 1 g. of the amine dissolved in 15 ml. of absolute ethyl acetate with twice the theoretical amount of methyl iodide. They were crystallized from an ethyl acetate–ethanol mixture.

The physical properties and analyses of the amines and their derivatives are shown in Tables III and IV.

Acknowledgments.—The authors are indebted to Dr. F. E. Cislak, Reilly Tar and Chemical Corp., Indianapolis, Ind., and to Dr. C. O. Herman, Air Reduction Chemical Co., New York, for generous supplies of acetylenic carbinols. Thanks are due to G. M. Maciak and Miss Gloria Beckman of the Lilly Research Laboratories, Indianapolis, for the analyses reported in Table IV.

The Preparation of *t*-Acetylenic Carbinol Esters and Related Compounds[1]

BY G. F. HENNION AND S. OLIVIA BARRETT[2]

RECEIVED NOVEMBER 30, 1956

Acetylenic carbinols, notably the tertiary isomers, may be esterified with certain aromatic carboxylic acids in pyridine solution in the presence of *p*-toluenesulfonyl chloride (Brewster's method, ref. 3). *p*-Nitrobenzoic acid in particular gives excellent results, generally affording nicely crystalline derivatives of characteristic melting points in good yields. The esters may be semi-hydrogenated to the corresponding vinyl carbinol esters with 5% Pd–$BaCO_3$ in ethyl acetate.

Discussion

In connection with other problems under investigation in this Laboratory, need arose for a variety of acetylenic carbinol esters and their semi- and fully hydrogenated analogs, *i.e.*, the corresponding vinyl- and ethylcarbinyl compounds. Solid esters amenable to careful purification (for studies in kinetics) were particularly desired. Brewster's method[3] has been found to be exceptionally well suited for this purpose.

Excellent yields of 3,5-dinitrobenzoates were obtained when *p*-toluenesulfonyl chloride was mixed with pyridine solutions of the acid and a variety of tertiary alcohols at ice-bath temperature (Table III). Surprisingly, the attempted syntheses of the corresponding *p*-nitrobenzoates gave almost quantitative yields of the crystalline anhydride and no esters. The relative insolubility of this anhydride in cold pyridine in contrast to the dinitro anhydride seemed a reasonable explanation, since Brewster had suggested that this synthesis is actually a pyridine–acid anhydride esterification, the anhydride being formed *in situ*. Accordingly, the Brewster procedure when carried out at steam-bath temperature (thus maintaining homogeneity throughout the reaction time) proved satisfactory for the preparation of a large variety of *p*-nitrobenzoates and several monobromobenzoates (Tables I and IV). Anisic acid, however, at steam and ice-bath temperatures gave a quantitative yield of the anhydride, although this anhydride is soluble in both hot and cold pyridine. Apparently homogeneity is not the controlling factor.

Chemical stability of the "intermediate anhydride" probably determines the course of the reaction. The question arises, however, as to whether the reactive intermediate is a symmetrical anhydride as proposed by Brewster[3] or a mixed anhydride. Pyridine-catalyzed esterifications of 3-methyl-1-butyn-3-ol with anisic, *p*-chlorobenzoic and *p*-nitrobenzoic anhydrides at steam-bath temperature were unsatisfactory. The ester was isolated only in the case of the *p*-nitrobenzoate; and the yield, less than 10% in twice the normal reaction time, was not comparable to the 94% yield obtained in the presence of *p*-toluenesulfonyl chloride.

Furthermore, the trend of reactivity for the Brewster procedure is related to the acidic dissociation constants of the reacting acids—the stronger the acid the more facile the esterification. Reactions were on a 0.01-molar scale and the results are summarized in Table V.

4-Bromo	6.6×10^{-5}	Anhydride	Ester
4-Methyl	4.5×10^{-5}	Anhydride	Anhydride
4-Methoxy	3.2×10^{-5}	Anhydride	Anhydride

[a] Room temperature. [b] Probably liquid ester.

The dialkylvinylcarbinyl esters (Table II) were prepared by two independent routes, the esterification of the vinyl alcohol by the procedure just considered and the semi-hydrogenation of the tertiary acetylenic esters. Identity of products indicates that the Brewster procedure does not involve an allylic rearrangement.

Recently 5% palladium supported on barium carbonate was reported to be an excellent semi-hydrogenation catalyst for both acetylenic carbinols and their acetates.[4] Using ethyl acetate as the solvent, reduction of the tertiary acetylenic *p*-nitrobenzoates at room temperature was complete with the addition of two atoms of hydrogen per molecule. The yields are reported in Table II and in each case are 15 to 20% higher than the yields obtained by esterification of the vinyl alcohol.

Experimental

Carbinols.—Generous samples of 3-methyl-1-butyn-3-ol, 3-methyl-1-pentyn-3-ol, 3,5-dimethyl-1-hexyn-3-ol, 3-ethyl-1-pentyn-3-ol and 1-ethynylcyclohexanol were obtained from Air Reduction Chemical Co. and Reilly Tar and Chemical Corporation. Air Reduction Chemical Co. also supplied samples of 3,4-dimethyl-1-pentyn-3-ol, 3-methyl-1-hexyn-3-ol, 3,6-dimethyl-1-heptyn-3-ol, 3-methyl-1-nonyn-3-ol, 3-methyl-1-decyn-3-ol, 3-ethyl-1-heptyn-3-ol, 3-ethyl-1-octyn-3-ol, 3-phenyl-1-butyn-3-ol and 4-*t*-butyl-1-ethynylcyclohexanol. 4-Methyl-2-hexyn-4-ol was supplied by Dr. Raymond Fleck, St. Edwards University, Austin, Texas. 1-Hexyn-3-ol and 3-phenyl-1-propyn-3-ol as well as 3-ethyl-1-hexyn-3-ol and 3-propyl-1-hexyn-3-ol were prepared by the reaction of sodium acetylide in anhydrous liquid ammonia with the appropriate carbonyl compound and were supplied by Drs. Kenneth Nelson[1] and Eugene Teach.[5] 3-Phenyl-1-buten-3-ol, 3-methyl-1-penten-3-ol and

1-vinylcyclohexanol were prepared by the semihydrogenation of the corresponding acetylenic alcohols.[4]

Preparation of 3,5-Dinitrobenzoates.—These esters were prepared by the procedure described by Brewster.[3]

Preparation of *p*-Nitrobenzoates and Monobromobenzoates.—Molecular equivalents (0.05 mole) of acid and alcohol were dissolved in dry pyridine (*ca.* 65 ml.) by placing the mixture on a steam-bath. About 0.05–0.08 mole of *p*-toluenesulfonyl chloride was added and after 2 hr. at steam-bath temperature, the cooled solution was poured into three volumes of ice and water. The crude crystals were collected, washed with ice-water and usually recrystallized from aqueous ethanol.

Semi-hydrogenation of *p*-Nitrobenzoates.—Two-hundredths mole of the ester was dissolved in 50 ml. of ethyl acetate, and 5% Pd–$BaCO_3$ (0.03–0.08 g.) was added. The reduction was carried out at room temperature and an initial pressure of *ca.* 50 p.s.i.g. The solution was filtered and the filtrate allowed to evaporate at room temperature. The crude crystals were recrystallized from aqueous ethanol with the exception of 3-phenyl-1-buten-3-yl *p*-nitrobenzoate (XXII). This ester is very sensitive to solvolysis; consequently, recrystallization was most efficient using petroleum ether.

Acknowledgments.—The authors are indebted to Dr. F. E. Cislak, Reilly Tar and Chemical Corp., Indianapolis, Ind., and to Dr. C. O. Herman, Air Reduction Chemical Co., New York, for generous supplies of acetylenic carbinols. Appreciation is also expressed to G. M. Maciak and H. L. Hunter of the Lilly Research Laboratories, Indianapolis, for the analyses reported in Tables I–IV.

The Kinetics of the Saponification of Acetylenic Carbinol Esters and Related Compounds[1]

BY G. F. HENNION AND S. OLIVIA BARRETT[2]

RECEIVED NOVEMBER 30, 1956

Acetylenic carbinol esters, RR′C(C≡CH)OCOR″, undergo extremely slow solvolysis in mixed aqueous solvents, as do the chlorides, RR′C(Cl)C≡CH, and rapid saponification in the presence of base. The semi- and fully hydrogenated analogs (—CH=CH_2 and —CH_2CH_3 in place of —C≡CH) solvolyze more rapidly and saponify more slowly. Variations in R and R′ do not alter the saponification rates so significantly. In the acetylene series the ester group, —OCOR″, is not comparable to —Cl in reactions with bases.

Discussion

Tertiary acetylenic chlorides, RR′C(Cl)C≡CH, undergo remarkably slow solvolysis in aqueous solvents and react much more rapidly by second-order kinetics in the presence of base.[3,4] There is considerable evidence that the reactions with bases are initiated by attack on the acetylenic hydrogen atom.[3–5] It was, therefore, of interest to ascertain if acetylenic carbinol esters behave in a similar manner. The solvolysis of a variety of such compounds (as well as their hydrogenation products) and their behavior in alkaline solutions have now been studied.

In solvolytic reactions there is good correlation between halide and ester reactivities, the order of ease of carbonium ion formation in polar solvents being the same, vinyl >> ethyl > ethynyl. The stability of the carbon–halogen and carbon–oxygen bonds is considerably different, however. The solvolysis of 3-chloro-3-methyl-1-butyne at 25° in 80% aqueous ethanol is extremely slow but easily detectable[3,4] while 0.01 *N* solutions of the corresponding 3-bromobenzoate, 4-bromobenzoate, 4-chlorobenzoate, 4-nitrobenzoate and 2,4-dichlorobenzoate in 90% aqueous ethanol at room temperature were neutral to litmus after a period of 8 months. Solvolysis was evident only in the case of the 3,5-dinitrobenzoate. Moreover, the corresponding acetate was recovered in almost quantitative yield after boiling for 50 hr. in absolute ethanol. In 80% aqueous ethanol, 3-methyl-1-pentyn-3-yl *p*-nitrobenzoate was recovered in 96% yield after 50 hr. of refluxing. The corresponding vinyl ester under comparable conditions underwent considerable solvolysis. The order of solvolysis is more evident when one compares the reactivity of 3-phenyl-1-butyn-3-yl *p*-nitrobenzoate and the corresponding semi-hydrogenated ester. Introduction of a phenyl group facilitated alkyl–oxygen heterolysis in both compounds. Boiling the ethynyl compound in absolute ethanol for only 2.5 hr. gave *p*-nitrobenzoic acid in 59% yield. The vinyl ester, 3-phenyl-1-buten-3-yl *p*-nitrobenzoate, was still more sensitive to solvolysis. Recrystallization from aqueous solvents or absolute ethanol resulted in decomposition of the ester, and solvolysis in absolute methanol at room temperature was rapid (82% decomposition in four days.) Although the saturated esters were not included in this study, Cohen and Schneider[6] have demonstrated the sensitivity of *t*-butyl benzoate to alkyl–oxygen fission. When this ester was boiled for 4 days in absolute methanol, a 60% yield of *t*-butyl methyl ether was obtained.[6]

Product studies of tertiary acetylenic esters under saponification conditions clearly demonstrated the reaction to be a normal nucleophilic attack on the carbonyl carbon rather than on the acetylenic hydrogen atom. Both the acetate and the 3,5-dinitrobenzoate of 3-methyl-1-butyn-3-ol were saponified in aqueous ethanol at room temperature; the ethyl ether, the expected product of alkyl–oxygen fission,[3] was not produced. It may be concluded that the strong electrophilic character of

the ester carbonyl controls the mechanism and in effect eliminates the possibility of attack at the acetylenic hydrogen.

The data recorded in Table I indicate a remarkable similarity in saponification rate for all *p*-nitrobenzoates of the general type RR'C(OPNB)-C≡CH, regardless of the nature of R and R'. Presumably the linear electron-withdrawing ethynyl group influences the rate to the extent that steric and polar variations in R and R' affect the reaction less than in saturated tertiary esters (Table II).[7-9]

TABLE I

SAPONIFICATION RATES OF *p*-NITROBENZOATES, RR'C(C≡CH)OCOC$_6$H$_4$NO$_2$, IN 70% AQUEOUS ACETONE AT 25°

[a] 1-Ethynylcyclohexyl *p*-nitrobenzoate. [b] 4-*t*-Butyl-1-ethynylcyclohexyl *p*-nitrobenzoate.

The rate constants listed in Table II for the saponification of several yne–ene–ane series of *p*-nitrobenzoates confirms the trend observed by Meyers,[10] namely, ethynyl > vinyl > ethyl. The acetylenic ester reacts most rapidly, and there is a greater change in rate in replacing ethynyl by vinyl than vinyl by ethyl. Since the rate-controlling step in every case is an attack on the carbonyl carbon, the acetylenic esters react fastest because steric hindrance is at a minimum and electron distribution most favorable.

Kinetic rates of tertiary acetylenic benzoates, listed in Table III, illustrate again the importance of inductive and mesomeric as well as steric factors in the saponification of a variety of substituted benzoates. Although the acid dissociation constant of 2,4-dichlorobenzoic acid predicts rapid saponification, faster than that of the *p*-nitrobenzoate, the relatively slow rate indicates that the bulk of the *o*-chlorine is sufficient to hinder nucleophilic attack at the carbonyl carbon.[11]

TABLE II

SAPONIFICATION RATES OF *p*-NITROBENZOATES, RR'CR''(OCOC$_6$H$_4$NO$_2$), IN 70% AQUEOUS ACETONE AT 25°

R	R'	R'' and k_2, l./mole-sec. × 10⁴ C≡CH	CH=CH$_2$	CH$_2$–CH$_3$	H

Experimental

Preparation of Esters.—The esters were prepared as described in the previous paper[1] and were recrystallized at least three times.

Preparation of Solutions for Kinetic Studies.—The acetone was prepared by distilling C.P. acetone from an excess of potassium permanganate and allowing the distillate to stand at least one day over anhydrous potassium carbonate before redistillation through a Vigreux column. Car-

bonate-free alkali solutions were prepared by carefully pipetting the required amounts of clear solution from above the precipitated carbonate of a saturated sodium hydroxide solution. These were diluted with freshly boiled water and standardized against potassium acid phthalate using brom thymol blue. The approximately 0.05*N* hydrochloric acid was standardized with standard alkali.

General Kinetic Procedure.—The method was similar to that of Tommila and Hinshelwood.[12] The specific rates were determined by mixing equal volumes of alkali and ester solutions of the same concentration at the desired temperature, withdrawing aliquots at specific time intervals and quenching these in an excess of standard acid. The excess acid was back-titrated with standard base (*ca.* 0.03 *N*) using brom thymol blue.

The 70% acetone solution of alkali was prepared by diluting exactly 30.00 ml. of aqueous standard sodium hydroxide (*ca.* 0.1*N*) to 100 ml. of solution at 25° using purified acetone.

(12) E. Tommila and C. N. Hinshelwood, *J. Chem. Soc.*, 1802 (1938).

The ester solution was made by weighing on counterpoised watch glasses a quantity of ester exactly equivalent to 30.00 ml. of the standard alkali. This ester was quantitatively transferred to a 100-ml. volumetric flask with acetone; 30 ml. of water was added and the solution brought to volume at 25° with acetone.

Mixing was effected by simultaneously pouring the solutions through a powder funnel into a 250-ml. ground-glass stoppered erlenmeyer flask. An aliquot was withdrawn immediately, quenched in an ice-cold mixture of 5 ml. of standard hydrochloric acid and 10 ml. of acetone and back-titrated against standard alkali. Zero time was considered to be the contact time of this first aliquot and all time intervals were determined in a similar manner. The concentration of alkali in this first aliquot was considered to be the initial concentration (*a*). A total of 6 to 10 aliquots were withdrawn from each reaction mixture, following the first 30–50% reaction. The second-order rate constants were calculated from the customary equation for equal initial concentrations.

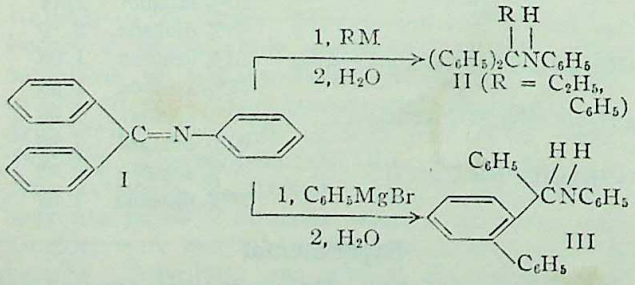
1,2-Addition of Allylmagnesium Bromide to N-Diphenylmethyleneaniline and Structurally Related Systems

BY HENRY GILMAN AND JOHN EISCH

RECEIVED NOVEMBER 24, 1956

Allylmagnesium bromide readily added in a 1,2-manner to the structurally related systems, N-diphenylmethyleneaniline (I), fluorenone anil (VIII) and 6-phenylphenanthridine (IX). The structure of the product from I was demonstrated by an unambiguous synthesis. The mechanism of 1,2-addition to the azomethine linkage is discussed and an explanation is advanced for the abnormal 1,4-addition of phenylmagnesium bromide to I.

The interaction of organometallic compounds with the –C=N– linkage in N-diphenylmethyleneaniline (I) (benzophenone anil) has received considerable study due to the peculiar behavior of this system. Although the organometallic compounds of lithium,[1,2] potassium,[3] sodium,[3] calcium,[4] barium[2] and strontium[2] add to the system in a 1,2-manner (II), the ordinary Grignard reagents fail to react with this azomethine linkage in refluxing ether.[5,6] Indeed, when the reaction between phenylmagnesium bromide and N-diphenylmethyleneaniline is forced by running it in ether–toluene solution at 90–105°, the only isolable product is the result of an apparent 1,4-addition (III).[5]



Previous studies in this Laboratory have demonstrated that the allyl Grignard reagent in its interactions with aza-aromatic heterocycles exhibits an exceptionally high order of reactivity when compared with that of ordinary Grignard reagents.[7] Consequently, its behavior with N-diphenylmethyleneaniline was investigated in order to see whether it would parallel the behavior of phenyllithium or phenylmagnesium bromide toward this system.

Surprisingly enough, it was found that allylmagnesium bromide reacted readily with N-diphenylmethyleneaniline in refluxing ether to give a 95% yield of product which was shown to be 1-allyl-1,1-diphenylmethylaniline (IV) in the following rigorous manner. By catalytic hydrogenation it was converted to the same substance (V) as obtained by the interaction of propyllithium and N-diphenylmethyleneaniline. Although this demonstrated that both reagents reacted with N-diphenylmethyleneaniline in the same manner, confirmation that indeed 1,2-addition had taken place was obtained by synthesizing V unambiguously.

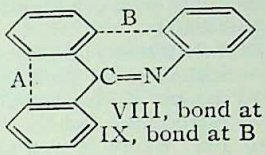
Thus butyrophenone (VI) was converted to its anil VII and the latter compound treated with phenyllithium. The 1-propyl-1,1-diphenylmethylaniline obtained upon hydrolysis was identical with that from the hydrogenation of IV.

The ease with which N-diphenylmethyleneaniline reacted with allylmagnesium bromide suggested that the azomethine linkage in related compounds also would be attacked readily. Chosen for this study were fluorenone anil (VIII) and 6-phenylphenanthridine (IX), as the former is formally derived from N-diphenylmethyleneaniline by forming bond A, while the latter results from forming bond B.

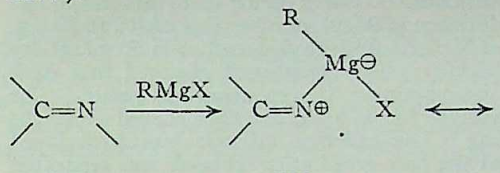


VIII, bond at A
IX, bond at B

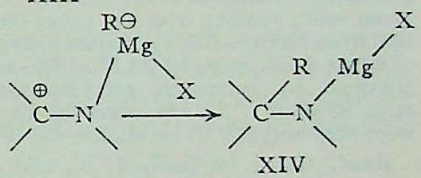
Allylmagnesium bromide added to the azomethine linkage of fluorenone anil extremely rapidly to yield α-allylfluorenylaniline (X) in 93% yield. 6-Phenylphenanthridine was attacked somewhat less readily to give 6-allyl-6-phenyl-5,6-dihydrophenanthridine (XI) in 67% yield. In the latter case it is remarkable that this endocyclic azomethine linkage reacts with such facility with this Grignard reagent. Previous studies have shown that the unsubstituted phenanthridine also has a heightened reactivity toward allylmagnesium bromide in comparison with pyridine, quinoline and isoquinoline.[7]

Based upon the previously observed behavior of N-diphenylmethyleneaniline with phenyllithium and with phenylmagnesium bromide, it was suggested that the abnormal 1,4-addition of the latter reagent might be owed to the greater steric demands of the Grignard reagent.[1,5] Subsequently, it was found that phenylcalcium iodide reacted with N-diphenylmethyleneaniline in a 1,2-manner[4] and this fact seriously weakened the case for steric hindrance. The steric bulk of the calcium and iodine atoms was not reflected in the mode of addition. In the course of studies employing N-diphenylmethyleneaniline and benzalacetophenone to index the reactivity of related organometallic compounds, it was concluded that the more reactive organometallic reagents added in a 1,2-manner, while the less reactive tended to add in a 1,4-fashion.[3] The present study shows that allylmagnesium bromide may well be classified among the more reactive organometallic reagents and that not only the metal but also the organic moiety can greatly influence the reactivity of the composite organometallic reagent. In support of this conclusion N-diphenylmethyleneaniline was allowed to react, in turn, with methylmagnesium iodide[6,8] and with propylmagnesium bromide under the conditions so successful with allylmagnesium bromide. However, almost all starting material was recovered with no sign of reaction.

In light of present knowledge it seems reasonable to view the mechanism of 1,2-addition to the azomethine linkage as proceeding through a nucleophilic attack of the organic anion of the reagent on the positive-polarized carbon atom adjacent to the nitrogen. The resonance stabilization of the allylic anion in allylmagnesium bromide seems to favor heterolysis of the magnesium–carbon bond and hence rationalizes the greater reactivity of this Grignard reagent. With certain organometallic reagents, especially those of the alkaline earth metals, it is quite probable that the reagent preliminarily complexes with the nitrogen[9] (XII → XIV).

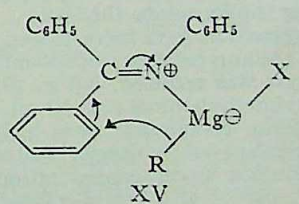


XII XIII



XIV

The abnormal 1,4-addition to N-diphenylmethyleneaniline by phenylmagnesium bromide can also be considered as a nucleophilic attack of $R^{\ominus}$ at the *o*-position of the benzene ring proceeding through a six-membered cyclic complex (XV). However,



XV

the stringent conditions necessary to obtain such a reaction make it quite probable that here radical processes play a part. Thus Kharasch, Goldberg and Mayo[10] have shown that aromatic Grignard reagents when heated in aromatic solvents yield products indicative of attack by aromatic radicals. It is therefore conceivable that 1,4-addition on N-diphenylmethyleneaniline may proceed by attack of phenyl radicals and that other phenylated isomers may also be formed.

Experimental

The melting points were determined on an electrically heated copper block and are corrected. Operations involved in the preparation and reactions of organometallic compounds were conducted in an atmosphere of dry oxygen-free nitrogen.

1-Allyl-1,1-diphenylmethylaniline (IV).—To 43.3 g. (0.169 mole) of N-diphenylmethyleneaniline partially dissolved in 100 ml. of dry ether was added 0.215 mole of allylmagnesium bromide[11] in 190 ml. of ether. During the 25-minute addition period the N-diphenylmethyleneaniline dissolved and spontaneous reflux set in. Toward the end, however, a white solid settled out of solution. After the mixture was stirred at the reflux temperature for 18 hours, it was hydrolyzed with 500 ml. of saturated ammonium chloride solution. The pale yellow ethereal layer, upon separation

and drying with anhydrous sodium sulfate, was distilled to remove the solvent. Chilling of the residual oil gave 48.1 g. (95%) of light tan solid, melting over the range 72–78°. Recrystallization from 200 ml. of 95% ethanol afforded 44.0 g. (87%) of white, close-packed crystals, m.p. 78.5–80°, and further recrystallizations did not alter the melting point.

Anal. Calcd. for $C_{22}H_{21}N$: N, 4.67. Found: N, 4.70.

The infrared spectrum in bromoform exhibited a sharp –NH band at 3.0 μ, but did not indicate the presence of any disubstituted benzene ring.

1-Propyl-1,1-diphenylmethylaniline (V). (a) From Propyllithium and N-Diphenylmethyleneaniline.—Propyllithium was prepared in 83% yield by adapting the published directions for butyllithium.[12] Over a period of 45 minutes, 0.097 mole of propyllithium in 90 ml. of ether was added to 20.0 g. (0.078 mole) of N-diphenylmethyleneaniline in 50 ml. of dry ether. The initially yellow suspension changed to a dark red solution accompanied by spontaneous reflux. The solution was refluxed for six hours and then stirred overnight without heating. The reaction mixture was hydrolyzed with water and the pale green ethereal layer was separated and dried. Removal of the ether left 21.2 g. (91%) of pale green solid, melting over the range 69–74°. Recrystallization from 100 ml. of 95% ethanol (Norit) gave 18.0 g. (77%) of white solid, m.p. 83–84.5°. The analytical sample was obtained by successive recrystallizations from ethanol, m.p. 85–85.5°. It was observed that the purer samples were very sluggish to crystallize out of solution.

Anal. Calcd. for $C_{22}H_{23}N$: N, 4.64. Found: N, 4.73.

The infrared spectrum in bromoform had a distinct band at 3.0 μ, but as with the product from allylmagnesium bromide and N-diphenylmethyleneaniline, no bands indicative of a disubstituted benzene ring.

(b) From 1-Allyl-1,1-diphenylmethylaniline (IV).—The hydrolyzed allyl Grignard adduct of N-diphenylmethyleneaniline was correlated with the hydrolyzed propyllithium adduct by reducing the former to the latter.

In the hydrogenation flask were placed 30 mg. of platinum(IV) oxide (Adams catalyst) and 50 ml. of 95% ethanol. After the catalyst was reduced, 3.0 g. (0.010 mole) of 1-allyl-1,1-diphenylmethylaniline and 50 ml. of ethyl acetate were added. The compound was hydrogenated until one molar equivalent of hydrogen had been taken up. The filtered solution upon concentration and refrigeration gave 2.5 g. (83%) of a cream-colored solid, m.p. 83–85°. This was shown to be identical with the 1-propyl-1,1-diphenylmethylaniline prepared in part a by a mixture melting point determination and comparison of infrared spectra. This verified that allylmagnesium bromide and propyllithium both added to N-diphenylmethyleneaniline in the same fashion. It remained to be confirmed that this was 1,2-addition.

(c) From Butyrophenone Anil (VII).—Phenyllithium was prepared in 99% yield according to published directions[13] by the interaction of 2.2 g. (0.33 g. atom) of lithium wire and 22.8 g. (0.145 mole) of bromobenzene in dry ether.

To 0.144 mole of phenyllithium in 100 ml. of dry ether was added a solution of 15.5 g. (0.069 mole) of butyrophenone anil in 75 ml. of dry ether over the course of 50 minutes. The mixture was stirred for four hours and then hydrolyzed. The ether layer upon separation, drying and removal of the solvent gave 22 g. of a somewhat sticky, pale yellow solid. After recrystallization from 100 ml. of 95% ethanol 12.4 g. (59%) of cream-colored solid was obtained, m.p. 80–83°. Additional recrystallizations from ethanol gave a white product, m.p. 83–84°. This solid was identical with the 1-propyl-1,1-diphenylmethylaniline obtained in parts a and b, as evidenced by mixture melting points and infrared spectra.

Butyrophenone (VI).—This compound was conveniently prepared by adaptation of procedures for the preparation of other aliphatic-aromatic ketones.[14]

To 0.60 mole of filtered propylmagnesium bromide in 600 ml. of ether was added a solution of 50.0 g. (0.485 mole) of redistilled benzonitrile in 60 ml. of dry ether during a 45-minute period. The dark yellow solution was refluxed overnight and subsequently poured into a mixture of 200 ml. of 6 *N* sulfuric acid and ice. The biphasic mixture was heated to distil off the ether and to hydrolyze the ketimine. The cooled mixture was then extracted with ether. The extracts were dried over anhydrous sodium sulfate and the ether distilled off. The residual oil was distilled under reduced pressure to yield 64.0 g. (90%) of colorless butyrophenone, b.p. 106.5–107° (13 mm.), lit.[14] b.p. 128° (27 mm.).

Butyrophenone Anil (VII).—This procedure is adapted from Reddelien's directions for acetophenone anil.[15] The necessary aniline–zinc chloride complex was prepared by adding 25 ml. of freshly distilled aniline to a solution of 25.0 g. of zinc chloride dihydrate in 40 ml. of water, 20 ml. of ethanol and 10 ml. of concentrated hydrochloric acid. The white suspension was stirred thoroughly and then filtered. The solid was washed twice with ether and upon drying the white complex weighed 30.0 g.

Freshly distilled aniline (30 ml.) and butyrophenone (30.0 g., 0.202 mole) were heated up to 100° (oil-bath) in a distillation flask. Two grams of the powdered aniline–zinc chloride complex was introduced and the bath temperature was raised slowly to 160° where it was maintained for 15 minutes. Steam began to evolve and continued to do so when the temperature was raised to 180° and held there for 30 minutes. The cooled reaction mixture was taken up in 200 ml. of chloroform and the undissolved zinc salts were filtered off. The filtrate was distilled to remove, in turn, chloroform and then the excess aniline and butyrophenone. Finally the butyrophenone anil came over as a clear yellow liquid weighing 15.8 g. (35% conversion), b.p. 183–185° (13 mm.), 128° (1.1 mm.), $n^{25}D$ 1.5926.

Anal. Calcd. for $C_{16}H_{17}N$: C, 86.05; H, 7.67; N, 6.27. Found: C, 85.96; H, 7.83; N, 6.22.

α-Allylfluorenylaniline (X).—To a yellow solution of 25.5 g. (0.100 mole) of fluorenone anil in 100 ml. of dry ether was added an equimolar quantity of allylmagnesium bromide in 110 ml. of ether during 20 minutes. Immediate reaction was evidenced by the discharge of the yellow color and occurrence of spontaneous reflux. After the solution was stirred at room temperature for an additional two hours, it was hydrolyzed with ammonium chloride solution. The ethereal layer upon drying and removal of the solvent yielded a tan solid melting over the range 130–134°, 27.6 g. (93%). Recrystallized from ethanol (Norit), the solid formed long, glistening white needles, 25.7 g. (87%), m.p. 136.5–137.5°.

Anal. Calcd. for $C_{22}H_{19}N$: N, 4.71. Found: N, 4.71.

6-Allyl-6-phenyl-5,6-dihydrophenanthridine (XI).—To 25.5 g. (0.100 mole) of 6-phenylphenanthridine[16] suspended in 150 ml. of dry ether was added 0.125 mole of allylmagnesium bromide in 125 ml. of ether over the course of 30 minutes. Upon heating at the reflux temperature overnight the reaction mixture formed a dark green, fluorescent solution. The cooled reaction mixture was hydrolyzed in the usual fashion and from the ethereal layer was obtained 28.1 g. of crude white product, melting over the range 90–100°. This product was difficult to free from contamination with 6-phenylphenanthridine (m.p. 107°) due to the similar properties of the product and starting material. Repeated recrystallization from 95% ethanol in excess afforded 20 g. (67%) of shiny white platelets, m.p. 101–103°. The analytical sample melted at 103–104.5°. As is characteristic of 5,6-dihydrophenanthridine types,[17] this compound in ethanolic solution possessed a marked blue fluorescence.

Anal. Calcd. for $C_{22}H_{19}N$: C, 88.84; H, 6.44; N, 4.71. Found: C, 89.14; H, 6.23; N, 4.66.

Reaction of Grignard Reagents with N-Diphenylmethyleneaniline.—Neither the methyl nor the propyl Grignard reagent reacted with N-diphenylmethyleneaniline under the conditions successful with allylmagnesium bromide. Thus, when 18.0 g. (0.070 mole) of N-diphenylmethyleneaniline in 100 ml. of dry ether was heated for 18 hours with 0.10 mole of either methylmagnesium iodide or propylmagnesium bromide in ether, the usual work-up yielded

A Kinetic Study of the Leuchs Anhydrides in Aqueous Solution. I[1]

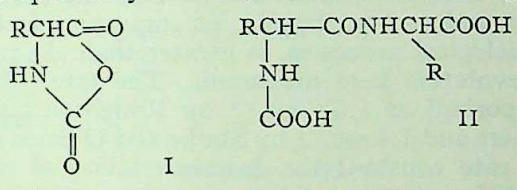
BY PAUL D. BARTLETT AND RICHARD H. JONES

RECEIVED SEPTEMBER 7, 1956

The reaction of an anhydro-N-carboxy-amino acid (Leuchs anhydride) with water is subject to general basic catalysis and is not catalyzed by acids. The reaction with the amino group of an amino acid anion is so rapid that it can compete successfully with hydrolysis. The reactions of anhydro-N-carboxyglycine, anhydro-N-carboxy-D- and L-alanine and anhydro-N-carboxy-α-aminoisobutyric acid with water and some amino acids have been followed kinetically by carbon dioxide evolution and their rate constants determined (Tables II and III). The possibility of controlled peptide synthesis in aqueous solution from the Leuchs anhydrides is discussed and experiments are reported showing the limitations of such a procedure.

Introduction

The anhydrides (I) of N-carboxy-α-amino-acids, first prepared by Leuchs,[2] have been investigated



I II

chiefly in inert solvents where with controlled amounts of active-hydrogen compounds as initiators they lead to polypeptides[3] of moderate or high molecular weight while at very low temperatures the decarboxylation of the initial carbamic acid (II) can be repressed sufficiently by salt formation[4] to afford good yields of simple peptides. Even more attractive possibilities of control of this reaction would present themselves if it were possible to operate in aqueous solutions; with this in mind, we have studied the nature and rates of the reactions of some simple N-carboxy-anhydrides in water.

Reactions of N-Carboxy-anhydrides with Water.—The N-carboxy-anhydrides of glycine, *dl*-alanine and α-amino-isobutyric acid, on solution in water at 0°, evolve carbon dioxide at a rate convenient for measurement. The reactions were followed by observing the increase in pressure in a closed, initially evacuated system; with the first and last of these anhydrides a rate measurement by following volume increase at constant pressure agreed with the results of the pressure method. Except for a short initial period (see below) the reactions, as followed in this manner, were of the first order, yielding rate constants as shown in Table I. Reactions of anhydro-N-carboxy-α-aminoisobutyric acid in 0.1 *M* barium chloride, 0.1 *M* hydrochloric acid and 1.0 *M* sulfuric acid yielded the same average rate constant, 2.4×10^{-3} sec.$^{-1}$, as the reaction in pure water, with a mean deviation of $\pm 0.07 \times 10^{-3}$. The effect of acid catalysis upon the hydrolysis of the anhydride is therefore negligible.

TABLE I

RATE CONSTANTS FOR UNCATALYZED HYDROLYSIS AT 0°

N-Carboxy-anhydride of	No. of runs	Concentration range	k_1, sec.$^{-1}$ $\times 10^3$	Mean deviation
Glycine	6	0.01– 0.028	4.1	0.23
dl-Alanine	3	.022– .028	6.4	.23
α-Aminoisobutyric acid	5	.019– .028	2.4	.12

Carbon dioxide is not evolved when a carboxy-anhydride reacts with two or more equivalents of sodium or barium hydroxide. An attempt was made to measure the rate of the reaction of anhydro-N-carboxyglycine with hydroxyl ion by following the conductivity of a solution of barium hydroxide to which the anhydride was added. There was a very rapid reaction which produced 74% of the expected change in conductivity within the first 40 seconds, followed by a slower process to which a second-order rate constant of 0.30 l./mole sec. could be assigned. The latter process is far too slow to be the reaction of anhydride with hydroxyl ion, as a later experiment proves. According to Stadie and O'Brien,[5] carbamates such as the Siegfried salts come rapidly to equilibrium with carbon dioxide and amino acid anion, but the carbon dioxide is much more slowly equilibrated with bicarbonate and carbonate. The calculated equilibrium concentration of carbonate ion during the preparation of a Siegfried barium salt is more than sufficient to precipitate barium carbonate; the non-appearance of such a precipitate is evidently the result of slow attainment of the carbonate equilibrium. The slow reaction observed in the conductivity experiments may well be the conversion of hydroxyl ion into carbonate.

Hydrolysis of N-Carboxy-anhydrides in Buffer Solutions.—During this work it became apparent that the amino acid formed by hydrolysis of the

anhydride was itself competing appreciably with water, especially in the case of glycine, for reaction with the anhydride after the reaction was under way. The effect of this competition could be reduced by operating either in excess base to prevent decarboxylation of N-carboxy-glycine or in a buffer solution sufficiently acid to keep the amino group of the amino acid overwhelmingly in the ammonium ion form. An acetate buffer was adopted containing 1.00 *M* sodium acetate and 0.875 *M* acetic acid and having a *p*H of 4.76. The experiments described above indicated that the hydrolysis of an N-carboxy-anhydride is subject to basic but not to acid catalysis. In view of the possibility of general basic catalysis (*e.g.*, catalysis by acetate ions as well as by hydroxyl ions), a series of rate determinations were made in which anhydro-N-carboxyglycine was hydrolyzed at 0° at concentrations from 0.023 to 0.026 *M* in this acetate buffer at various buffer dilutions up to tenfold, the ionic strength being maintained constant at 1.00 by means of potassium chloride. The results fit the equation

$$k = 0.00028 + 0.00049[OAc^-] \text{ (time in sec.)}$$

closely. That this is catalysis by the acetate ion and not by acetic acid is already indicated by the complete insensitivity of the rate to strong acids in the case of anhydro-N-carboxy-α-aminoisobutyric acid. From this result it appears that about 30% of the rate measured in pure water was due to the overlaying of the hydrolysis by a reaction with amino acid formed during the hydrolysis and existing at a varying *p*H during the reaction, which did not produce a clear deviation from first-order kinetics. Later work verified this indication that the carboxy-anhydrides do indeed react preferentially with amino groups even in aqueous solution.

Kinetic Salt Effect.—The salt effect on the hydrolysis of anhydro-N-carboxyglycine is negative, as shown by the first-order rate constants in buffer solutions consisting of 0.1 *M* sodium acetate and 0.0875 *M* acetic acid alone (k 0.00043 sec.$^{-1}$). No study was made to apportion this between "primary" and "secondary" kinetic salt effect.

The "Induction Period."—Most of the manometric runs had an initial period of ten minutes during which the reaction appeared to be very slow, before the uniform first-order rate of gas evolution was attained. Since the carbon dioxide is the product of the second of two successive reactions

$$I \longrightarrow \underset{\underset{NHCOOH}{|}}{RCHCOOH} \longrightarrow \underset{\underset{NH_2}{|}}{RCHCOOH} + CO_2$$

we considered the possibility that the decarboxylation of the carbamic acid was a slow enough reaction to account for this effect. This was tested by taking advantage of the fact that a stable salt of glycine N-carboxylic acid can be prepared[6] by saturating a solution of barium glycinate with carbon dioxide. At 0°, in the absence of excess barium hydroxide, this saturation was accomplished without any precipitation of barium carbonate. The decarboxylation of N-carboxyglycine was now observed by the rapid addition to the stable Siegfried salt of enough acetic acid to make an acetate buffer of *p*H 4.76, or in other experiments to give an unbuffered solution of *p*H 0–2. The evolution of carbon dioxide in these experiments followed an approximately first-order course with k_1 varying from 0.023 to 0.042 sec.$^{-1}$. However, when a solution of sodium carbonate was acidified in the same manner, similar results were obtained, k_1 being again from 0.023 to 0.042 sec.$^{-1}$. That the measurable reaction was just the rate of evolution of carbon dioxide from aqueous solution was verified in a series of experiments in which the rate constants varied from 0.005 to 0.030 sec.$^{-1}$ as the speed of the magnetic stirrer in the apparatus was varied over an approximately fivefold range. We conclude that the slow approach to linearity in the kinetic curves is due to the appreciable time required for the establishment of liquid–vapor equilibrium, a steady state being approached as the carbon dioxide evolved in a period of a few minutes becomes a smaller fraction of the total present.

The rate of equilibration of carbonic acid with water and carbon dioxide, an important factor in physiological processes, is greater than the rate of gas evolution here measured. The rate constant is reported[7] as 1.97 sec.$^{-1}$ by Roughton and coworkers and 1.4 sec.$^{-1}$ by Stadie and O'Brien at 0°. The rate constant for decarboxylation of unsubstituted carbamic acid at this temperature is reported[8] to be even greater, 80 sec.$^{-1}$. It appears that whatever the position of the equilibrium in the carbonation of glycine, this equilibrium is attained rapidly in comparison with the reactions whose rates are being measured here.

Reaction of N-Carboxy-anhydrides with Amino Acids.—With the information at hand it was possible to measure the rates of reaction of the N-carboxyanhydrides with various amino acids in aqueous systems. For this purpose it was not possible to suppress the hydrolysis of the anhydride entirely, but the rate constant of this process could be accurately evaluated and subtracted from the over-all pseudo-unimolecular rate constant observed in the presence of an excess of amino acid in the same buffer solution. The reactivity of an amino acid toward an N-carboxyanhydride resides entirely in the free amino group, and the fraction of the amino acid molecules possessing such a free amino group is controlled by the buffer solution. By knowing the second acid dissociation constant of an amino acid and the *p*H of the buffer, it should therefore be possible to determine the rate constant for reaction of an N-carboxyanhydride with the free-base form of any amino acid. In the 0.1 *M* acetate buffer of *p*H 4.74 the pseudo-unimolecular rate constant k_{obs} was used as follows to determine the second-order rate constant k_{AA} for the reaction of anhydro-N-carboxyglycine with amino acid

$$k_{obs} = 0.00043 + k_{AA} \text{ (amino acid)}$$

and for anhydro-N-carboxyalanine

$$k_{obs} = 0.00071 + k_{AA} \text{ (amino acid)}$$

In the latter case the correction to be made for hydrolysis rate amounted to as much as 80% of the quantity being measured; in most cases the relative rates were more favorable than this. An idea of the degree of reliability of the results may be had from the data in Table II, which were determined in order to learn how great the selectivity might be between the optical isomers of alanine in reaction with *d*- or *l*-anhydro-N-carboxyalanine.

The four possible pairs were run in triplicate, with mean deviations of 1–3% in the second-order rate constants determined. There was agreement between the values for *d*-anhydride with *d*-alanine and for *l*-anhydride with *l*-alanine and also between the constant for *d*-anhydride with *l*-alanine and that for *l*-anhydride with *d*-alanine. In each case the reaction between the configurationally similar reactants was about 20% faster than that between the configurationally opposite reactants. It is not surprising that the difference is small, since neither reacting center is itself asymmetric.

Table III summarizes the second-order rate constants for reaction of anhydro-N-carboxyglycine and alanine with several amino acids and peptides. These measurements are made under conditions where only a minute fraction of the amino acid exists with its amino group in the free-

[a] From an equation of H. S. Harned and R. A. Robinson, *Trans. Faraday Soc.*, **36**, 973 (1940), and data selected by J. T. Edsall in Cohn and Edsall, "Amino Acids, Peptides and Proteins," Reinhold Publ. Corp., New York, N. Y., 1943, p. 79. [b] J. Greenstein, *J. Biol. Chem.*, 101, 603 (1933). [c] Estimated assuming the same temperature coefficient as for the amino acids, from data in Cohn and Edsall, p. 84.

base form, yet even under these conditions the amino acid competes successfully with the water for reaction with the N-carboxyanhydride. It is of interest to calculate how fast the active form of the amino acid (having its amino group free) is reacting with the anhydride. For this purpose there are two molecular species to be considered, the anion $H_2NCHRCOO^-$ and the unfavored uncharged form $H_2NCHRCOOH$. The fraction of the former species present in our buffer solution is $10^{(4.74 - pK_2)}$, and the fraction of the latter species is 10^{pK_z} where K_2 is the second ionization constant of the amino acid, and K_z is the equilibrium constant between the dipolar ion and the uncharged amino acid.[9] The latter quantity has been evaluated by Edsall and Blanchard for most of the amino acids with which we are concerned. If for glycine we extrapolate their value of pK_z from 25 to 0° by means of their value of ΔH = 11,500 cal., we find that pK_z under our conditions is −5.79, and this leads to an estimate of the fraction of neutral glycine present at *p*H 4.74 as 1/1,500,000. From the values of pK_2 at 0° given in Table III, the fraction of anion has been estimated; for glycine it is 1/620,000. Thus about two-thirds of the free amino group which is responsible for the reaction with N-carboxyanhydride at *p*H 4.74 is situated on the glycine anion, and the other third is on neutral glycine. These are by no means accurate figures in view of the assumptions underlying the estimate of K_z, but they suggest that we should not be too far wrong in calculating the bimolecular rate constant for reaction between N-carboxyanhydride and glycine anion if we were to attribute all the reaction ob-

served at pH 4.74 to this species. In favor of this approximation is the expectation that a negative charge on the carboxyl group might enhance the nucleophilic reactivity of the amino group, so that the anion would be inherently more reactive than the neutral form. Against this is the possibility that an undissociated carboxyl group in the amino acid might be strategically located to assist catalytically in the reaction of its amino group with the carbonyl group in the anhydride, which might enhance the importance of the rare neutral species in contributing to the observed rate. In a series of experiments in acetate buffers at constant acetate concentration and ionic strength but varying acetic acid concentration and pH, the rate of reaction was inversely proportional to the acetic acid concentration.

This provides evidence that the amino acid anion is the dominant species in the reaction with anhydro-N-carboxyglycine, rather than the neutral form which is present at constant concentration in this series of buffers.

Accordingly, in Table III the corrected bimolecular rate constant for reaction of anhydride with each amino acid anion has been computed by multiplying k_{AA} by the factor $10^{(pK_2 - 4.74)}$. It will be seen that these rate constants are very large, indicating a surprising ability of the amino group to compete with solvent water. More will be said of this in a later section.

The rate constants for reaction of anhydro-N-carboxyglycine with glycine, glycylglycine and glycylglycylglycine are in the ratio of 1:6:7.5. This means experimentally that in the acetate buffer there is a strong tendency toward the formation of higher peptides through competition of the glycylglycine already formed during a run with the glycine added and so on for the higher peptides. As the last two columns show, *this is not due to an inherently higher reactivity of the peptide anions* toward the anhydride in comparison with glycine, but rather to the fact that the second ionization of di- and triglycine occurs at less basic pH values and there is more anion in proportion present at pH 4.74. The *corrected rate constants*, referred to the anions, are in the *reverse order:* 12:1.6:1. Likewise, anhydro-N-carboxyalanine reacts more than three times as fast with alanylalanine at pH 4.74 as with alanine, although the anion of the latter is the more reactive by a factor of almost eight.

A regularity is discernible in the anion rate constants when a "Brønsted plot" is made of the logarithms of the rate constants *referred to pure anion* against the logarithms of the second ionization constants, the measure of the thermodynamic basicity of the amino groups. The table contains data for three compounds with amino groups on primary carbon atoms reacting with anhydro-N-carboxyglycine and for three compounds with amino groups on secondary carbon atoms reacting with anhydro-N-carboxyalanine. Each class of amino compound determines a straight line (Fig. 1), the rates for the secondary amino acids and peptides being slower than for comparably basic primary compounds. In the case of the one amino acid examined which has an amino group on a tertiary carbon atom, the point if plotted would lie below either line. Toward alanine and leucine the reactivities of anhydro-N-carboxyglycine and the corresponding alanine derivative do not appear to be very different. Also plotted in Fig. 1 are the rate constants for three reactants in the "secondary" class, from Part II (see following paper).

The Possibility of Controlled Peptide Syntheses in Aqueous Solution.—The selective reaction of anhydro-N-carboxyglycine with amino acids in aqueous solution raises the question whether it would be possible to control this process with enough precision to synthesize a peptide step by step by the successive addition of a series of N-carboxyanhydrides to a growing peptide in solution in water without isolating the peptide at each step. Obviously this would require very high yields in each step in order to be feasible for chains of any length. Our measurements show that there are two competing reactions of importance to interfere with the clean production of a desired peptide. One of these is the reaction of the anhydride with hydroxyl ion, the other is the reaction of the product peptide with anhydride to give the peptide of one more amino acid unit. The rate of uncatalyzed or buffer-catalyzed hydrolysis can be negligible in the pH range above 7.

As far as the reaction with hydroxyl ion is concerned, we did not succeed in measuring its rate. We might attempt to estimate it by taking advantage of the relationship, shown in Fig. 1, between the strength of the basic amino group of an amino acid or peptide and its rate of attack on anhydro-N-carboxyglycine, extrapolating the glycine line to the right to an abscissa of 15.74 corresponding to the basic strength of the hydroxyl ion. This is an unjustified procedure, since the Brønsted relation holds only among acids or bases of the same chemical type, and there is reason to think that for a given basic strength a primary amine should be a more powerful reagent in attack on an anhydride carbonyl group than a corresponding oxygen reagent. The rate constant estimated in this way, 1.6×10^6 l./mole sec., is probably a generous upper limit for purposes of predicting the favorable conditions for producing dipeptide with a minimum of hydrolysis.

Since we know the rate constants for uncatalyzed hydrolysis and for reaction of the anhydride with glycine as a function of pH, we can make a hypothetical calculation to the effect that

$$\text{rate of hydrolysis} = [\text{A}]0.00041 + k_{OH}10^{pH-15.74}$$

$$\text{rate of diglycine formation} = \frac{2330\ [\text{A}]\,[\text{G}]}{1 + 10^{10.53-pH}}$$

By differentiating to make the ratio of the second rate to the first a maximum, we find that the pH should be most favorable around 8, at which point diglycine formation should be favored over hydrolysis by a factor of 3.3 times the glycine concentration. This factor is not very sensitive to pH in this region, being adversely affected by the constant water hydrolysis in the more acid media and by the fact that the hydroxyl ion concentration continues rising beyond pH 10–11 where the concentration of the reactive form of the amino acid ceases to in-

crease. The results reported below (Table IV) show that hydrolysis by hydroxyl ion cannot be as extensive as this, so that $K_{OH} < 1.6 \times 10^6$.

TABLE IV

ATTEMPTS AT SYNTHESIS OF DIPEPTIDES FROM ANHYDRO-N-CARBOXYGLYCINE AND GLYCINE AT 0°

Solution	*p*H[a]	% polymer with anhydride alone	G = final concn. glycine,[b] $M \times 10^2$	100 (1–50 G) % dipeptide (side reaction → triglycine)[d]	100 (1–12.5 G) % dipeptide (side reaction → glycine)[d]
0.174 N $Ba(OH)_2$	(13.2)	11	5.5	0	31
0.50 M Na_2CO_3	11.71	18	5.4	0	33
1.0 M NaH_2BO_3 + 0.2 M H_3BO_3	10.89	31	0.65	68	91
0.5 M NaH_2BO_3	10.61	50	0.35	83	96
0.5 M Na_2CO_3 + 0.5 M $NaHCO_3$	(10.3)	10	>5.5	0	31
Catalytic amount $Ba(OH)_2$	(9.5)	98	3.0[c]	0	63

[a] *p*H values are those of the solution before the addition of anhydride or amino acids. Values in parentheses are calculated. Others were measured at 28° using a Beckman *p*H meter with glass electrode for solutions of *p*H 10. [b] Initial concentrations of all solutions: 4.0×10^{-2} M glycine and 4×10^{-2} M N-carboxyglycine anhydride. [c] Calculated from a reaction where two portions of glycine anhydride were used in an attempt to synthesize triglycine. [d] If anhydride (A) reacts exclusively with either glycine (G) to yield diglycine (GG) or diglycine to yield triglycine (GGG) and zero subscripts denote concentrations at t =0, then at the end of the reaction: (G) + 2(GG) + 3(GGG) = $(A)_0 + (G)_0 = 0.08$. Since $(A)_0 = (G)_0$ in all cases, (G) = (GGG), and 4(G) + 2(GG) = 0.08, so that (GG) = 0.04 − 2(G) and $(GG)/(A)_0 = (0.04 - 2(G))/0.04 = 1 - 50(G)$. In similar fashion, if A reacts only with hydroxyl ion to yield G or with G to yield GG, then (G) + 2(GG) = 0.08, (GG) = 0.04 − (G)/2 and $(GG)/(A)_0 = 1 - 12.5(G)$.

The competition between glycine and the desired product, glycylglycine, for reaction with the N-carboxyanhydride can be estimated more reliably and is more serious. We have observed that because of the lower basicity of glycylglycine (pK_2 8.86) in comparison to glycine (pK_2 10.53), the dipeptide appears to be the stronger competitor toward the anhydride when examined in the buffer of *p*H 4.75. This situation should be reversed at *p*H 10–11, where both amino compounds are largely in their reactive forms, but the ratio between the rates of formation of diglycine and triglycine can never exceed 2330/311 (= 7.5) times the ratio of glycine and diglycine concentrations present (Table III). For this reaction to be useful, it would be necessary that we start with equivalent amounts of glycine (or other desired starting material) and N-carboxyanhydride. The concentration of diglycine in this example would start at zero and would approach a concentration whose ratio to that of glycine was equal to k_G/k_{GG} the ratio of the two rate constants. At the time of total consumption of the anhydride, an amount of tripeptide would have been formed which was equal to that of the glycine remaining unattacked, in this case 12% of the total hydrolysis being neglected. For higher peptides, where the differences between members of the series become less, the outlook is correspondingly less encouraging.

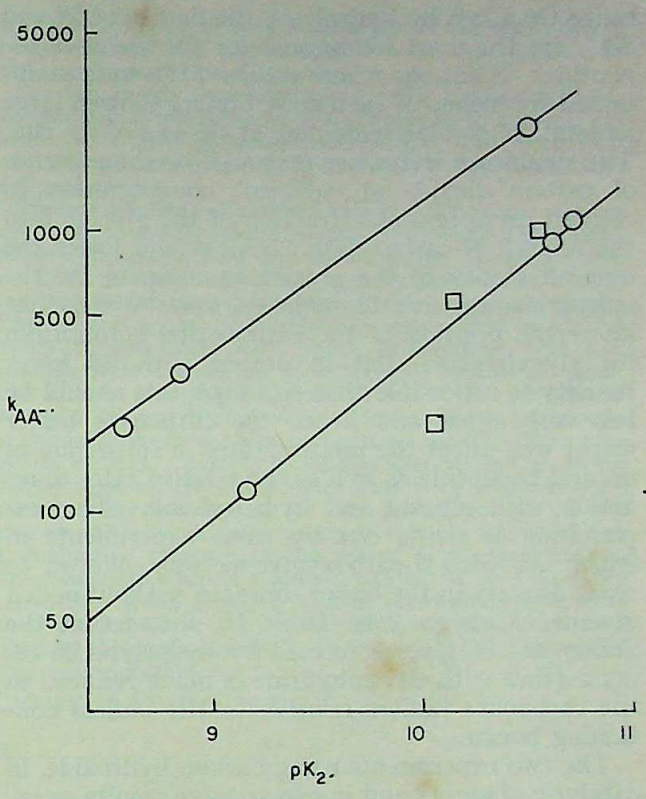

Fig. 1.—Logarithmic relationship between k_{AA^-}, the second-order rate constant for reaction in water at 0° between an anhydro-N-carboxy-amino-acid and an amino acid or peptide anion, and pK_2, the second ionization constant of the amino acid: upper line, anhydro-N-carboxyglycine with triglycine, glycylglycine and glycine anions; lower line, anhydro-N-carboxyalanine with alanylalanine, alanine and leucine (see Table III); square points, data from Part II, THIS JOURNAL, 79, 2159 (1957): phenylalanine, methionine, aspartic acid.

The experiments on peptide synthesis in water bear out these conclusions in general. Quantitative experiments were made in which, in each of a series of solutions of different *p*H, equimolar amounts of glycine and anhydro-N-carboxyglycine were introduced and the reaction was allowed to run to completion. The remaining glycine was then determined by the Van Slyke ninhydrin technique, by which amino acid can be estimated in the presence of peptides which do not evolve carbon dioxide on treatment with the reagent. Table IV lists the results obtained.

In a reaction yielding only hydrolysis and dipeptide formation there will be two molecules of amino acid remaining in excess for each anhydride molecule hydrolyzed, for this reaction not only wastes anhydride but adds to the store of amino acid. In a reaction yielding only di- and tripeptide, the amount of tripeptide will be equal to the amount of amino acid remaining unattacked. In Table IV the yield of the desired dipeptide has been computed on both assumptions and recorded in the last two columns.

Two solutions in which the *p*H was controlled by borate buffers at *p*H's of 10.89 and 10.61 gave results in the expected range. The above considerations having shown that competition from tr peptide formation is more important in this *p*

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

range than loss by hydrolysis, the figures of 68 and 83% are the most likely ones for the yields of dipeptide. Solutions where similar *p*H's were maintained by means of carbonate buffers showed large amounts of glycine remaining at the end of the run. The significant difference may well be the presence of carbon dioxide at sufficient concentration to convert an appreciable fraction of the glycine into the related N-carboxylate. This would lower the over-all ability of the glycine to compete for the anhydride, relative to hydroxyl ion. We do not know the position of the carbonation equilibrium for glycylglycine, but in accord with its lower basicity it is possible that this dipeptide should be less carbonated and hence the carbonate buffer might well affect the relative rates of formation of di- and tripeptide as well as the relative rates of reaction with glycine and hydroxyl ion. This explanation is borne out by some experiments in which anhydro-N-carboxyglycine was allowed to react directly in the buffer solutions without added glycine. Column 3 of Table IV shows that the ability of the glycine formed by hydrolysis to react further with the anhydride is much reduced in the carbonate buffers relative to the buffers containing borate.

The two experiments using barium hydroxide, in catalytic amounts and in excess, gave results as expected from the above kinetic discussion. With the small amount of base, the *p*H began at 9.5 and dropped. Polymerization was so important that only 2% of amino acid remained in the control experiment without added glycine. Obviously here the formation of tri- and higher peptides is the important side reaction and the yield of dipeptide from the 1:1 reaction mixture is zero, as indicated in column 5. In 0.174 *N* barium hydroxide, anhydride alone yields 89% of glycine. Hydrolysis is therefore rapid, as expected, and the results from the 1:1 experiment mean a 31% yield of diglycine. The upshot of these experiments is that the conditions for selective formation of glycylglycine are rather critical, and the selectivity is not sufficient to make this a useful general method for the stepwise synthesis of polypeptides.

Experimental

Reagents.—Various methods were used for preparing the Leuchs anhydrides but by far the most satisfactory was the method of Ben-Ishai and Katchalski[10] using the N-carbobenzoxy-amino acids and phosphorus tribromide. The purity of the anhydrides was best determined by the quantitative measurement of the carbon dioxide liberated. This was done during each kinetic run and consistent values were obtained from the various samples of anhydrides used. The anhydrides were stored in a desiccator over phosphorus pentoxide, being stable under these conditions for several weeks. In practice, however, the anhydrides were used within three days of the final recrystallization.

Benzyl chloroformate was obtained from three sources. It was prepared[11] by the method of reference 11, some was purchased from the Mann Research Laboratories and some was kindly donated by Dr. E. R. Blout.

N-Carbobenzoxyglycine was prepared from benzyl chloroformate and glycine by the method of reference 11.

N-Carbomethoxyglycine was prepared by the method described[12] by Schramm.

N-Carbethoxyglycine was prepared from ethyl chloroformate and glycine in a procedure similar to that used for N-carbomethoxyglycine; the melting point of the crude material was 74–78°.

Anhydro-N-carboxyglycine was prepared by the method of Katchalski. The crude product was recrystallized four or five times from dry ethyl acetate. Good yields of the anhydride were also obtained with 20.9 g. of N-carbobenzoxyglycine and 25 g. of phosphorus pentachloride dissolved in 150 ml. of dry ethyl acetate at 0°. The mixture was shaken every two or three minutes and the temperature maintained at 0° for 0.5 hr. The solution was allowed to warm to room temperature and was filtered to remove excess phosphorus pentachloride. The ethyl acetate was removed under vacuum at temperatures up to 60°. After the removal of most of the ethyl acetate, the residue was recrystallized from ethyl acetate.

N-Carbomethoxy-α-aminoisobutyric acid was prepared by the method of Schramm.

Anhydro-N-carboxy-α-aminoisobutyric acid was made from N-carbomethoxy-α-aminoisobutyric acid and thionyl chloride, according to the method of Schramm. The product was recrystallized six times from a benzene–cyclohexane mixture.

N-Carbomethoxy-*dl*-alanine, m.p. 75–77°, was prepared according to the method of Schramm.

N-Carbobenzoxy-*dl*-alanine, N-carbobenzoxy-*d*-alanine and N-carbobenzoxy-*l*-alanine were prepared in 90% yield by the "Organic Syntheses" procedure, described for N-carbobenzoxyglycine. The product was recrystallized by dissolving in chloroform and adding petroleum ether. The melting points were 111–115°, 85.2–86.0° and 85.0–85.5°, respectively.

Anhydro-N-carboxy-*dl*-alanine was prepared from N-carbobenzoxy-*dl*-alanine and phosphorus pentachloride, following Schramm's directions for the preparation using N-carbomethoxy-*dl*-alanine. The product was recrystallized several times from dry benzene, although it was necessary to seed each time. Several attempted preparations from the N-carbomethoxy-amino acid were unsuccessful, as was the attempted use of thionyl chloride or phosphorus tribromide on the N-carbobenzoxy-*dl*-alanine.

Anhydro-N-carboxy-*d*-alanine and anhydro-N-carboxy-*l*-alanine were prepared easily by the method of Katchalski from the corresponding N-carbobenzoxyalanine and phosphorus tribromide. The product was recrystallized three or more times from dry benzene. It was occasionally necessary to add dry petroleum ether to cause crystallization of the anhydrides.

Benzene, ether and petroleum ether (30–60°) were reagent grade dried over sodium wire.

Cyclohexane was Eastman Kodak Co. technical grade distilled and dried over sodium wire.

Reagent quality ethyl acetate was dried over calcium hydride and distilled.

Glycine and *dl*-alanine were obtained from the Eastman Kodak Co. and were twice recrystallized from ethyl alcohol–water solution, before being used in kinetic runs. These and all the other amino acids and peptides were dried at 110° before use.

α-Aminoisobutyric acid and *l*-leucine were obtained from Eastman Kodak Co. and were recrystallized once from an ethyl alcohol–water solution before being used in kinetic runs.

d-Alanine was obtained from Schwartz Laboratories and was used without further purification; $\alpha^{25}D$ −14.8 (c = 2 in 2 *N* hydrochloric acid).

l-Alanine was obtained from Schwartz Laboratories, $\alpha^{25}D$ +14.3° (c = 2 in 2 *N* hydrochloric acid).

Glycylglycine was obtained from the Nutritional Biochemical Corporation and was recrystallized from 50% ethyl alcohol before use.

Glycylglycylglycine was obtained from the Nutritional Biochemical Corporation and was recrystallized from water.

dl-Alanyl-*dl*-alanine was obtained from the Nutritional Biochemical Corporation and was used without further purification.

Kinetic Procedure.—The reaction vessel was a 250-ml. erlenmeyer flask equipped with a side arm to which a mercury manometer could be attached through a 10/30 joint. The mercury manometer was made of 1-mm. capillary tubing with a reservoir made of 20-mm. tubing, so that the change in height in the reservoir would be negligible during

the course of a run. Evacuation was accomplished through a stopcock attached to the arm between the flask and the manometer. The erlenmeyer flask was closed with a 24/40 cap equipped with a glass hook from which a glass bucket containing the anhydro-N-carboxy-amino acid could be suspended by a platinum wire.

First the weighed amino acid or peptide, when any was used, was added to the erlenmeyer flask, followed by the water or buffered solution (50 ml. for the runs with optically active anhydro-N-carboxy-alanine and 100 ml. in all other cases). The system was assembled using silicone stopcock grease, and the reaction flask was immersed in an ice-bath for 1 hr. before the start of the run. The ice-bath, stirred by air and surrounded by two concentric beakers, was so arranged as to permit magnetic stirring through the bottom by means of an Arthur H. Thomas Co. magnetic stirrer and a plastic coated magnet within the reaction flask.

After the attainment of thermal equilibrium, a weighed amount of the anhydride was suspended from the cap and the system was evacuated. After three or four minutes, the anhydride was dropped into the solution by agitation of the reaction vessel and the run was begun. The manometer was always tapped immediately before reading and its response characteristics were determined before use. The pressure at infinite time was that observed after at least ten times the half-life.

In studying the decomposition of the Siegfried salts, a solution of amino acid in barium hydroxide was placed in the reaction flask and carbon dioxide was bubbled through the solution until added phenolphthalein turned colorless. In this instance, acetic acid or sulfuric acid was suspended in the glass bucket and was dropped into the basic solution at zero time to start the reaction.

For the kinetic experiments using the volume method, the manometer was replaced by a connection to a 50-ml. gas buret and a butyl phthalate manometer. The connection was made almost completely from glass with two short joints of Tygon tubing.

Product Studies.—Exactly 5 ml. of 0.400 molar glycine and 50 ml. of an appropriate buffer were placed in a stoppered 250 ml. erlenmeyer flask and cooled to 0°. Exactly 0.202 g. (0.002 mol.) of anhydro-N-carboxy-glycine was added, and the mixture was rapidly stirred with a magnetic stirrer. After several hours the solution was neutralized to *p*H 7.0 (brom thymol blue) with dilute hydrochloric acid and quantitatively transferred to a 250 ml. volumetric flask. The solution was acidified with 50 ml. of *p*H 4.5 acetate buffer (1 *M*) and diluted with water to 250 ml. A sample of the solution (5 ml.) was analyzed by the Van Slyke ninhydrin method. Acetate buffer was used instead of citrate buffers since all the kinetic runs that were analyzed were already buffered with acetate. The procedure used did not give quantitative yields of carbon dioxide but was helpful as a qualitative measure of the amino acid concentration. Thus standard alanine solutions yielded 98 ± 1% of the calculated carbon dioxide, whereas standard glycine solutions yielded 92 ± 3%. Glycylglycylglycine, when analyzed by this method, gave 0.074 mole of glycine per mole of glycylglycylglycine.

A Kinetic Study of the Leuchs Anhydrides in Aqueous Solution. II[1]

BY PAUL D. BARTLETT AND DONALD C. DITTMER

RECEIVED SEPTEMBER 7, 1956

Rate constants are reported for the reaction in water at 0° between anhydro-N-carboxy-DL-alanine and DL-phenylalanine, DL-methionine, DL-aspartic acid, L-histidine, L-cysteine and glutathione. Cysteine reacts 45 times as fast as methionine. In the reaction of cysteine with anhydro-N-carboxy-DL-phenylalanine, the concentration of free SH groups shows an initial decline followed by a return to its original value. This is interpreted as an initial reaction of the anhydride with the thiol group followed by an intramolecular transfer of the phenylalanyl group from sulfur to nitrogen. Glutathione shows a similar rapid reaction, but the thiol titer drops much more and is slow to return, as would be expected from the less favorable location of groups for an intramolecular acylation. The effect of conditions upon the reaction of alanine with both anhydro-N-carboxy-DL-alanine and anhydro-N-carboxy-DL-phenylalanine in aqueous solution has been studied.

It was shown in Part I[2] that the anhydro-N-carboxy derivatives of certain amino acids reacted in aqueous solution with amino groups so rapidly as to raise the hope that this might be a useful method for controlled, stepwise peptide synthesis. In a further exploration of systems of this kind, we have measured the rate constants listed in Table I between anhydro-N-carboxy-DL-alanine and amino acids of different types. The rate constants were determined as described in Part I.[2] An attempt has been made in Table I, as in the cases previously reported, to refer the rate constants to the active anion of the amino acid by means of the published second ionization constants of the amino acids in question.

Table I shows that cysteine and glutathione react substantially faster with anhydro-N-carboxy-alanine than does the closely comparable methionine which lacks the sulfhydryl group. Some experiments were carried out in which the sulfhydryl group was titrated with iodine during the reaction between cysteine and anhydro-N-carboxy-DL-phenylalanine. The results are shown in Fig. 1, together with the results of a similar run on the tripeptide glutathione. In both cases there is an initial attack of the carboxy-anhydride on the sulfhydryl group. In the case of cysteine, the sulf-

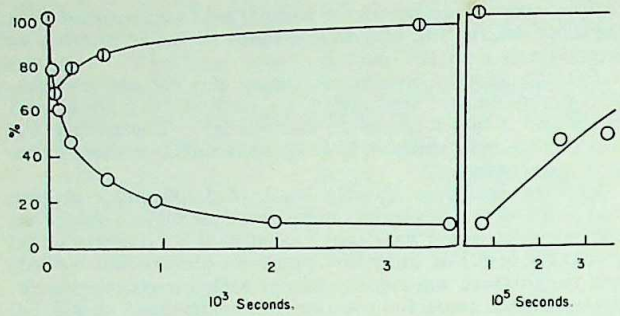

Fig. 1.—Decline and return of sulfhydryl titer during reaction of anhydro-N-carboxy-*dl*-phenylalanine with cysteine (dashed circles) and with glutathione (open circles). Note break in time scale.

hydryl titer had dropped at the end of one minute to 67% of that initially present but had already begun to rise again. The rapid formation of thioester evidently is followed up immediately by a transfer of the acyl group from sulfur to nitrogen with the formation of a normal peptide. Such transfer reactions have been observed before,[3] being a consequence of the reactivity of thioesters and the fact that such a transfer can take place here by way of a six-membered cyclic transition state.

In the case of glutathione the sulfhydryl titer also drops but does not return nearly so rapidly. At the end of an hour the sulfhydryl titer has reached 9% of that initially present and appears to be still dropping. After 20 hr. the titer is again 9%; after three days it has risen again to 45%. The difference between the cases of cysteine and glutathione would appear to be largely the less favorable situation in the latter case for the transfer of an alanyl group from sulfur to nitrogen internally.

The attempts reported in Part I to achieve high yields in the formation of specific peptides were extended to the use of anhydro-N-carboxy-DL-alanine and anhydro-N-carboxy-DL-phenylalanine. As judged by the amount of amino acid remaining after reaction, the yields obtained from these anhydrides and alanine were never as high as the best yields of glycylglycine under comparable conditions. Experiments were conducted at *p*H 9, 10, 11 and 12, the *p*H being generally controlled by the use of a Beckman auto-titrator. With anhydro-N-carboxy alanine as with anhydro-N-carboxyglycine, the highest yields of dipeptide were obtained at *p*H 10, but these yields never reached 90%. The presence or absence of a borate or phosphate buffer and the use of lithium, sodium or thallium hydroxide as the titrating base produced no marked effect upon the course of the reaction. In the case of anhydro-N-carboxy-*dl*-phenylalanine the yields were consistently below 80% and the sensitivity to *p*H appeared to be somewhat less. These results are all consistent with the view that the aqueous reactions of the anhydro-N-carboxyamino acids are determined by a set of protonation and carboxylation equilibria which are established rapidly compared to the speed of the attack of the water or amino acids upon the anhydride.

Experimental

Materials.—DL-Alanine, DL-methionine and DL-aspartic acid were Eastman Kodak Co. White Label grades. DL-Phenylalanine was the C.P. grade obtained from H. M. Co., Ltd. L-Cysteine, glutathione and L-histidine were from the Nutritional Biochemicals Corporation. Benzyl chloroformate was from Mann Biochemicals. N-Carbobenzoxy-DL-alanine and N-carbobenzoxy-DL-phenylalanine were prepared by the method of reference 4. Anhydro-N-carboxy-DL-alanine and anhydro-N-carboxy-DL-phenylalanine were prepared from the corresponding N-carbobenzoxy derivatives and phosphorus tribromide by the method of Ben-Ishai and Katchalski.[5] They were recrystallized from ethyl acetate and petroleum ether. Ethyl acetate was Merck reagent grade dried over calcium hydride.

The manometric kinetic determinations were carried out as described in Part I.

The reactions of L-cysteine and glutathione with anhydro-N-carboxy-DL-phenylalanine were done in an acetic acid–sodium acetate buffer (*p*H 4.66) at 0°. The anhydride was added in 10 ml. of dimethylformamide. Aliquots were taken at various times, quenched in 2 *N* hydrochloric acid and cooled in an ice-bath. A measured amount of standard iodine solution was added to react with the excess SH groups and the excess of iodine was back titrated with standard sodium thiosulfate solution using starch as an indicator. There was no reaction between cysteine and dimethylformamide under the reaction conditions employed. The accuracy of the glutathione reactions was impaired by precipitation early in the reaction.

The solution of the product of reaction between L-cysteine and anhydro-N-carboxy-DL-phenylalanine was oxidized with hydrogen peroxide. The resulting material was submitted to paper chromatography with butanol–acetic acid[6] resulting in three ninhydrin-positive spots. Two of these readily were identified as DL-phenylalanine and cysteic acid. From a large number of paper chromatograms carried out on small aliquots of the solution, the area of the unknown spot was cut out and eluted. The solution of the unknown was evaporated and the α-amino group of the peptide was removed with nitrosyl chloride.[7] The product was then hydrolyzed and chromatographed on paper. One ninhydrin-positive spot appeared which had the same R_f value as cysteic acid. The original dipeptide was accordingly probably DL-phenylalanylcysteine.

Seroflocculating Steroids. II.[1] General[2]

By Frederic C. Chang, Robert T. Blickenstaff, Aaron Feldstein,[3a] Jane Ransom Gray, George S. McCaleb[3b] and Douglas H. Sprunt

Received November 20, 1956

The chemical basis for the possible use of a new type of seroflocculation reaction, either for the detection of a disease like cancer or as a general health clearance test, is discussed. In this paper a program of study of the seroflocculating activity of certain steroids is outlined with these alternatives as the goal, and a first report of screening results is given. Accompanying papers III and IV of this series deal with the chemistry and synthesis of compounds reported here.

Although seroflocculation reactions are widely used in medicine for detection of disease, little fundamental knowledge concerning these reactions is available.[4] An understanding of the mechanism of such a reaction entails studying initially: (1) the nature of the substances that function as seroflocculating agents (seroflocculants), (2) the nature of the serum components that are flocculated, (3) the composition of the flocculated material (flocculates) and (4) the conditions under which the reaction takes place. We have been considering some of these factors in a new type of seroflocculation reaction[1,5] which is given by a high percentage of the sera of patients with moderately advanced cancer and of moderately advanced cases of other diseases such as tuberculosis.

Tests on three seroflocculants, the non-saponifiable fraction of cancerous livers,[5] ethyl choladienate[6] and ethyl 3β-chloro-11-cholenate[1] show that they can all be used to detect moderately advanced cancer and other diseases with good precision, but their "sensitivity"[7] was low in many diseases at an early stage, particularly in cancer, and their "selectivity"[7] seemed to decrease with increase in sensitivity. Whether this inverse relationship between sensitivity and selectivity is an inherent property of this series of seroflocculants will determine what applications can be made of the reaction for detection of disease.

Development of the reaction could give rise to two different uses in the detection of disease, depending on which of two alternative chemical situations exists in the serum. Ideally, the reaction would be used to detect specific diseases, or secondarily it might be able to distinguish normal sera from those of a group of diseases and thus be useful as a general health screening test.

From a chemical point of view, the problem can be stated as follows: if the flocculable material in the serum is a component uniquely associated with a specific disease, it would be potentially possible to detect that disease by finding a seroflocculant which will react with the unique component. On the other hand, if the serum component participating in the flocculation reaction is one produced by any of a group of diseases or by a process not necessarily limited to a single disease, then the reaction will be non-specific. In this case, any differences in activity found in flocculants of varying chemical structure will merely be measures of how effectively they combine with the common serum component. Thus, sensitivity appears to be a problem basic to the chemical structure of the flocculant, whereas selectivity is one that concerns the serum component primarily.

There is *a priori* no way of knowing which of these alternative situations prevails for any particular disease. In syphilis, at least, a unique component (or situation) apparently exists since a serological reaction for detection of syphilis is known and widely used. For cancer, there is no previous evidence of a unique cancer component detectable serologically. But because of the obvious importance of a good test for the detection of cancer, the existence of evidence that can be interpreted favorably,[8] and because we have a feasible method of study through the finding of a seroflocculant of known structure, an investigation of this problem appears to be desirable.

Our program involves a search for a sensitive flocculant based on the assumption that the seroflocculation reaction is a useful method of detecting early disease. The completed research will furnish information as to whether it will be possible to detect a specific disease like cancer or whether it will be useful as a health clearance test.

The two substances[6] first studied in this reaction were both oils. The chemical composition of the liver fraction is complex and largely unknown,[9] and

(7) The term "sensitivity" is used to indicate efficiency in confirming cancer (diagnosed by biopsy); "selectivity" to denote the degree with which a test is free from giving "false positives." Quotation marks will be omitted when these terms are used subsequently in this paper.

(8) C-Reactive protein antiserum parallels ethyl 3β-chloro-11-cholenate in activity [D. H. Sprunt, W. M. Hale, F. C. Chang, S. G. Richmond, C. C. Erickson, *Science*, **122**, 273 (1955)], but there are differences suggestive that C-Reactive protein and a cancer component are similar but not identical. Orosomucoid, a glycoprotein known to increase in the sera of patients with carcinoma [H. Goodman, S. Brennan and W. J. Simpson, *Proc. Am. Assoc. for Cancer Research*, **2** 111 (1956)], is immunologically distinct from C-Reactive protein. Both orosomucoid and C-Reactive protein seem to belong to a group of abnormal protein substances, another one of which might be unique for cancer. Furthermore, the inverse sensitivity and selectivity relationship mentioned earlier with seroflocculants tested does not hold strictly, suggesting that the serum components flocculated have chemical differences.

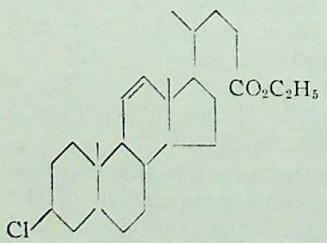
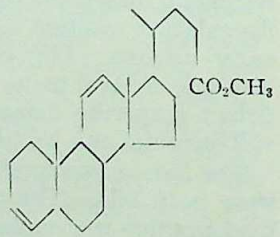
our experience with the desoxycholic acid-derived "antigen"[6,10]—an uncrystallizable oil of variable activity and stability—convinced us of its heterogeneous nature, although it is without doubt chiefly a mixture of ethyl choladienates. Thus it was desirable to find a stable active compound of known structure and our attention was first directed toward the preparation of a pure ethyl choladienate.

The pyrolytic methods used by Wieland[11] when applied to ethyl desoxycholate indeed gave active, crystalline material but appeared unpromising as a means of obtaining a pure isomer. Since elimination reactions involving ionic mechanisms have produced mixtures differing from products of pyrolysis, we decided to try dehydrotosylation, a method often used for introducing unsaturation in steroids.[12] When ethyl Δ^{11}-lithocholenate,[1] refluxed with *p*-toluenesulfonyl chloride in pyridine, yielded a crystalline product of constant melting point and good activity, we naturally assumed that we had in hand an ethyl choladienate. However, the material contained chlorine and was demonstrated to be a constant melting mixture of ethyl 3β-chloro-11-cholenate (28)[13] and unsaturated matter. A separate synthesis of 28 confirmed this. This compound 28, which showed the best seroflocculating activity of all the substances we had tested, was the first active compound of defined structure. Moreover, it had the requisite characteristics of stability, availability and reproducibility to use as a comparison standard for evaluation of other substances.

The preparation of a pure ethyl choladienate was pursued further and ethyl 3,11-choladienate (45) has been obtained by a satisfactory method.[14] Compound 45 when pure turned out to be somewhat too insoluble to be tested satisfactorily by the original test conditions, but the corresponding methyl ester (46) was found to have good activity. With 28 and 46, two compounds of known structure to serve as basic models, it was possible to plan a structure–activity study on a less empirical basis than a random screening would be.



28



46

The program followed is to prepare (or collect) accessible structural variations of these two substances and to test these related compounds for seroflocculating activity in a short screening test. The test, described briefly below, is designed to find compounds with the highest general sensitivity without regard in the first instance to their selectivity. This information, which has given some indications of the structural features associated with good activity, will be a guide in further work. When a sufficient number of representative compounds of high sensitivity but of different chemical structure is found, a parallel clinical test on a larger scale using these compounds will show whether they show selectivity and incidentally answer the question of the existence of a unique cancer component. The results, furthermore, should point to the significant molecular structural features which would be incorporated in the designing of more efficient flocculants. These in turn should facilitate the isolation of the hypothetical cancer component, the study of which would be of fundamental biochemical importance.

This paper is an interim report giving results of the screening to date. The two accompanying papers are concerned with the syntheses of compounds reported here.

Screening Method.—(Only a summary of the method is given; the testing particulars will be described in detail elsewhere.) The tests were performed by a modification of the original method[5]; only one-half the amount of flocculant and different serum dilutions are used. The test is a simple one to perform: a suspension, prepared from an alcoholic solution of the flocculant, a trace of cholesterol and buffered saline solution, is combined with the test serum, diluted serially and centrifuged. The tubes are shaken and read. A good positive test is one in which floccules are formed and the solution remains sparkling clear; a negative test is one in which there are no floccules and the solution is turbid.

Test sera used in the screening varied from three to ten depending on the supply of flocculant available. Cancer sera and normal sera were included in the same test run. Test cancer sera are from cancers (confirmed by biopsy) that give good tests with the standard flocculant, ethyl 3β-chloro-11-cholenate[14a] (28); test normal sera are from apparently healthy individuals and have given consistently negative tests with 28.

Screening Results.—Compounds are classified below in three groups. Group A consists of compounds which clearly can distinguish between test positives and normals and therefore have the same order of activity as the standard 28. Group B are compounds that show differences between the positive and normal standards but not as distinctly as those in group A. In general, there are floccules in the positive tubes but the solution is not clear. These are substances classified as lower activity compounds. Group C compounds do not distinguish between positive and normal sera; almost all give tests that remain turbid and have no floccules. A few flocculants which give positive tests on all sera indiscriminately are also included among this group.

54	Ethyl 12α-hydroxy-3-cholenate	14

Tentative Conclusions.—The compounds reported here are all derivatives of cholanic acid with the exception of several bisnorcholanic acid compounds. Compounds derived from other parent steroids are also being investigated and will be reported in the future. Many of the compounds on these lists were intermediates prepared during the course of synthesis of certain desired structures but were nevertheless included in the testing to provide additional information. Although speculation, at this stage, of the basic nature of the flocculation reaction seems premature and many more structurally different compounds should be examined before profitable conclusions can be drawn, certain empirical deductions already stand out: (1) only esters show activity, free acids are inactive; (2) with one exception (3,11-choladienate) the ethyl esters are more active than the corresponding methyl esters; (3) active groupings are unsaturation, chloro and acetoxy, and two such groups are needed for high activity; (4) inactive groups are hydroxy, tosyloxy, benzoxy and keto, and one such group can counteract the effect of an active group.

Whether a correlation exists between some well-defined physical property of the flocculants and their seroflocculating activity has not been investigated, and obviously this can be done more intelligently when the best flocculants have been discovered. However, from purely qualitative observations made during the handling of these compounds, it can be said that most likely there is no simple relationship between their solubilities and activity.

Acknowledgment.—We wish to acknowledge the able technical assistance of Mrs. Judith Beasley on the work reported in this series of papers, and the generous coöperation of Dr. M. T. Giachino and Mr. E. W. Lard of Grace Chemical Co. in infrared spectrophotometry.

Seroflocculating Steroids. III.[1] Chloro and Other Bile Acid Derivatives[2]

BY FREDERIC C. CHANG, ROBERT T. BLICKENSTAFF, AARON FELDSTEIN,[3a] JANE RANSOM GRAY, GEORGE S. McCALEB[3b] AND DOUGLAS H. SPRUNT

RECEIVED NOVEMBER 20, 1956

For study of their seroflocculating activity, a number of 3β-chloro bile acid derivatives were prepared by a new method involving replacement of a tosylate group in pyridine with pyridinium chloride. Several new acetates, tosylates and other related compounds are reported.

When the synthesis of ethyl 3β-chloro-11-cholenate (28)[4] by the method previously described[5] was attempted on a larger scale, the yield and quality of product were found to be considerably lowered. Various other direct methods for preparing halides also proved unsatisfactory for this compound. The presence of 28 among the products of a tosyl chloride reaction in pyridine described in the preceding paper[1] furnished a clue for a satisfactory new method for preparing the compound.

Since 28 obviously resulted from an intermediate tosylate, the commonly used reaction of a tosylate with lithium chloride in acetone (and in dioxane) was tried on the tosylate of ethyl 3α-hydroxy-11-cholenate. Intractable mixtures of unsaturated and chloro compound resulted. However, by substituting pyridine and pyridine hydrochloride for the solvent–halide system, a good quality chloro product was obtained in 51% yield. The yield is only moderate, and the superiority of the method lies in the purity of the product, which is very little contaminated by dienic impurity. A mixture of chloro compound containing more than traces of diene is separated only with much difficulty; the inferior products obtained in other halogenation methods are such mixtures. The reaction temperature is an important factor, as previous studies on replacement reactions would suggest,[6] and at elevated temperatures undesirable mixtures of chloro and dienic compounds are obtained. At temperatures between 78 and 90° the substitution reaction proceeds at a satisfactory rate, with little competition from the elimination reaction.

Methyl 3β-chlorocholanate, methyl and ethyl 3β-chloro-11-cholenate, methyl 3β-chloro-9(11)-cholenate and methyl 3β-chloro-12α-hydroxycholanate have all been prepared by this method, which we are studying further with the view of its use as a general method of preparing halides.[7]

For the preparation of ethyl 3β-chloro-9(11)-cholenate, because of the low melting points and poor crystallizing behavior of the corresponding 3α-hydroxy and 3α-tosyloxy compounds which are intermediates in the synthesis, conversion from the methyl ester is preferred. The sequence of reactions, part of which is also illustrative of other chloro compounds mentioned above, is shown.

Puzzling changes in melting point were encountered during crystallizations of several of the ethyl ester tosylates when methanol was used as solvent at 50°. Since the fractions continued to give correct analyses, replacement of tosylate group was not taking place, and ester interchange was not suspected, because numerous other ethyl esters in this related group of compounds can be crystallized unchanged from methanol. However, ester interchange did take place, as was evident when the supposed ethyl ester tosylate 24 was converted into methyl 3β-chloro-11-cholenate. Apparently a trace of *p*-toluenesulfonic acid resulting from hydrolysis of the 3-tosylate group (it is known that esters of the 3-hydroxy steroids are easily hydrolyzed) catalyzes the ester interchange. By adding *p*-toluenesulfonic acid to the refluxing methanol solution during crystallization, conversion of ethyl to methyl ester is fairly rapid and complete. The facile ester interchange of the bile acid esters might have been expected from the marked ease with which cholenic and substituted cholanic acids are esterified. For instance, 3α-hydroxy-11-cholenic acid is completely esterified in 40 minutes by methanol containing small amounts of aqueous hydrochloric acid at room temperature.[8] Yamasaki, Rosnati, Fieser and Fieser[9] recently encountered an ester interchange during the reduction of methyl 4β-bromodehydrolithocholate by sodium borohydride in the presence of ethanol. They also converted ethyl 3,4-dibromocholanate into the methyl ester by refluxing in methanol containing concentrated hydrochloric acid. Several of our esters underwent interchange similarly when refluxed, but a purer product usually resulted when the reaction was left at room temperature for 10 to 18 days. Ethyl 3β-chloro-11-cholenate (28) prepared in this way crystallized directly from the

reaction mixture in a state of highest purity in near quantitative yield. This ester interchange constitutes a good method for preparing higher esters of the bile acids from the often more readily available methyl esters.

The extreme ease of esterification of the C_{24}-bile acids is in contrast to the considerable resistance exhibited by the bisnorcholanic acids to this reaction. 3β-Hydroxy-5-bisnorcholenic acid forms the methyl and ethyl esters in poor yield even after several days of reflux with the respective alcohols. Perhaps for this reason, only the methyl ester prepared with diazomethane has been reported. The expected difference in the rates of reaction between the C_{20}-secondary and C_{23}-primary carboxyl groups is doubtless intensified considerably by the interference offered by the steroid nucleus.

Experimental[10,11]

ESTERS OF HYDROXY ACIDS. Esterification of Hydroxy Acids.—All of the C_{24}-acids were esterified readily by using the proportion of 1 g. of acid:10 ml. of absolute (methyl or ethyl) alcohol:0.1 ml. of concd. HCl. (The alcoholic solution is approximately 0.12 *N* in HCl.) With the 10:1 ratio of solvent to acid, the reaction is rapid and complete.

Methyl lithocholate (1),[12] was obtained from lithocholic acid in quantitative yield as large needles, m.p. 129–130°; recrystallized from methanol–water and dried at 100° (1 mm.) for 24 hr. for analysis, m.p. 125–127.5°, $[\alpha]_D$ +22°. *Anal.* Calcd. for $C_{25}H_{42}O_3$ (390.59): C, 76.87; H, 10.84. Found: C, 76.6; H, 10.8. This conflicts with the Reindel report[12] that the 125–127° melting product contains 1.5 moles of methanol as solvent of crystallization. Fieser and Ettore[13] reported m.p. 125–127°; Fieser and Rajagopalan,[14] 129–130°, $[\alpha]_D$ +29 ±2° (diox.).

Ethyl Lithocholate (2).[12] **By ester interchange** from 1 by refluxing 1.5 hr. in ethanol and concentrated hydrochloric acid; 74% of 92–95° melting product. Recrystallized from methanol–water, m.p. 94.5–96° (lit. m.p. 92–93°), $[\alpha]_D$ +28.8°*. *Anal.* Calcd. for $C_{26}H_{44}O_3$ (404.60): C, 77.18; H, 10.96. Found: C, 77.18; H, 10.84.

Methyl 12α-hydroxycholanate (3) was prepared according to Barnett and Reichstein,[15] m.p. 119.5–120.0° (lit. 120–121°), $[\alpha]_D$ +39°.

Ethyl 12α-hydroxycholanate (4) was prepared by the same method from ethyl 12α-hydroxy-3-cholenate (54)[16] in quantitative yield; crystallized from absolute ethanol, m.p. 135–136.5°, $[\alpha]_D$ +46°. *Anal.* Calcd. for $C_{26}H_{44}O_3$ (404.60): C, 77.2; H, 11.0. Found: C, 77.1; H, 10.9.

Compound 4 was also prepared by esterification of 12α-hydroxycholanic acid, m.p. 135–136.5°.

Ethyl 3α-hydroxy-9(11)-cholenate (5) was prepared by esterification of 3α-hydroxy-9(11)-cholenic acid,[17] m.p. 75.0–76.5°, $[\alpha]_D$ +35.6°. *Anal.* Calcd. for $C_{26}H_{42}O_3$ (402.60): C, 77.56; H, 10.52. Found: C, 77.25; H, 10.44.

Compound 5 also was obtained from methyl 3α-acetoxy-9(11)-cholenate (12) by treatment with ethanol and hydrochloric acid.

Methyl 3β-hydroxy-5-bisnorcholenate (6) was prepared by refluxing the corresponding acid in methanol and concd. hydrochloric acid for two days; 54% yield of product melting 140–144° out of ligroin (63–70°). A chromatographed sample for analysis melted at 142–143.7°, $[\alpha]_D$ −55.4°*. (This compound was previously prepared by use of diazomethane by Fernholz,[18] m.p. 140°.) *Anal.* Calcd. for $C_{23}H_{36}O_3$ (360.52): C, 76.62; H, 10.07. Found: C, 76.95; H. 9.97.

Ethyl 3β-Hydroxy-5-bisnorcholenate (7).—Two grams of 3β-hydroxy-5-bisnorcholenic acid (Nutritional Biochemical Corp.) in 150 ml. of absolute ethanol and 2 ml. of concd. sulfuric acid was refluxed for 45 hr. After usual processing a product melting at 162–164° was obtained in 34% yield, after recrystallization from ligroin (63–70°), $[\alpha]_D$ −65.6°. *Anal.* Calcd. for $C_{24}H_{38}O_3$(374.54): C, 76.96; H, 10.23. Found: C, 77.2; H, 10.5.

ACETATES.—The 3-acetates were made by room temperature acetylation using acetic anhydride and pyridine; the 12-acetates required heating to 100°, with the exception of those prepared using *p*-toluenesulfonic acid as catalyst (see compounds 18 and 19).

Ethyl 3α-acetoxycholanate (8)[12] was obtained from ethyl lithocholate, out of ethanol, m.p. 95–98° (lit. 90–91°), $[\alpha]_D$ +38.2°. *Anal.* Calcd. for $C_{28}H_{46}O_4$ (446.65): C, 75.29; H, 10.38. Found: C, 75.48; H, 10.56.

Methyl 12α-acetoxycholanate (9) from 3, heavy prisms out of methanol, m.p. 95.5–96.5°, $[\alpha]_D$ +69°. *Anal.* Calcd. for $C_{27}H_{44}O_4$ (432.62): C, 74.95; H, 10.25. Found: C, 75.03; H, 10.14.

Ethyl 12α-acetoxycholanate (10) from 4, out of absolute ethanol as short, thick prisms, m.p. 63–64°, $[\alpha]_D$ +69.9°.

(10) Microanalyses by the Microchemical Laboratory of New York University, and by Galbraith Microanalytical Laboratories, Knoxville, Tenn.

(11) Melting points were taken on an electrical micro-hotstage and are uncorrected. Optical rotations were determined in 1–2% chloroform solutions at about 25°, except where noted, using a Schmidt and Haensch polarimeter, and values are accurate to ±1°. The values marked with an asterisk (*) were obtained with a Keston polarimeter attachment (Standard Polarimeter Co., 225 E. 54th Street, N. Y. C.) to a Beckman DU spectrophotometer with accuracy estimated to be better than ±2°.

Anal. Calcd. for $C_{28}H_{46}O_4$ (446.65): C, 75.29; H, 10.38. Found: C, 75.33; H, 10.36.

Ethyl 3α-acetoxy-11-cholenate (11) from ethyl 3α-hydroxy-11-cholenate,[5] out of methanol as fine needles, m.p. 91.5–93.7°, $[\alpha]_D$ +42°. *Anal.* Calcd. for $C_{28}H_{44}O_4$ (444.63): C, 75.63; H, 9.97. Found: C, 75.6; H, 9.9.

Ethyl 3α-acetoxy-9(11)-cholenate (12) from 5, out of legroin (35–60°), m.p. 96.5–97.5°, $[\alpha]_D$ +64.8°. *Anal.* Calcd. for $C_{28}H_{44}O_4$ (444.63): C, 75.63; H, 9.97. Found: C, 75.44; H, 10.35.

Methyl 12α-acetoxy-3-cholenate (13) from 53,[16] flat prisms out of methanol, m.p. 107–108°, $[\alpha]_D$ +63.9°. *Anal.* Calcd. for $C_{27}H_{42}O_4$ (430.61): C, 75.31; H, 9.83. Found: C, 75.23; H, 9.72.

Ethyl 12α-acetoxy-3-cholenate (14) from 54,[16] out of acetone–H_2O (3:1), m.p. 86–87.5°, $[\alpha]_D$ +62°. *Anal.* Calcd. for $C_{28}H_{44}O_4$ (444.63): C, 75.63; H, 9.97. Found: C, 75.52; H, 10.12.

Methyl 3β-acetoxy-5-bisnorcholenate (15)[18] prepared by the action of diazomethane on 3β-acetoxy-5-bisnorcholenic acid (Nutritional Biochemicals Corp.) out of methanol in 76% yield, m.p. 153.5–156.5° (lit. m.p. 156–157°), $[\alpha]_D$ +63.4°*.

Ethyl 3β-acetoxy-5-bisnorcholenate (16) from 7 out of ligroin (35–60°), leaflets, which at 124–125° were transformed into needles, m.p. 129–130.5°, $[\alpha]_D$ +63.0°*. *Anal.*[19] Calcd. for $C_{26}H_{40}O_4$(416.58): C, 74.96; H, 9.68. Found: C, 75.13; H, 9.67.

Ethyl 3α,12α-diacetoxycholanate (17) was prepared from ethyl desoxycholate by refluxing in acetic anhydride and pyridine. All attempts at crystallization failed. This distilled as colorless oil in a molecular still at 0.07 mm., $[\alpha]_D$ +89.7° (*c* 2.05, chf); +98.2° (*c* 2.06, ethanol). *Anal.* Calcd. for $C_{30}H_{48}O_6$ (504.68): C, 71.39; H, 9.59. Found: C, 71.73, 71.86; H, 9.91, 9.93.

Methyl 3β-chloro-12α-acetoxycholanate (18) was obtained by the method recently reported[20] for difficultly acetylated hydroxyl groups, using acetic acid, acetic anhydride and *p*-toluenesulfonic acid at room temperature, as colorless needles when crystallized from methanol, m.p. 129–130°, $[\alpha]_D$ +56.8°*. *Anal.* Calcd. for $C_{27}H_{43}O_4Cl$(467.07): C, 69.43; H, 9.28; Cl, 7.59. Found: C, 69.32; H, 9.30; Cl, 7.53.

Ethyl 3β-chloro-12α-acetoxycholanate (19) was prepared as for 18, from 36, crystallizing from ethanol–water (3:1) as colorless needles, m.p. 82.0–83.5°, $[\alpha]_D$ +72.2°*. *Anal.* Calcd. for $C_{28}H_{45}O_4Cl$ (481.10): C, 69.89; H, 9.43; Cl, 7.37. Found: C, 70.00; H, 9.46; Cl, 7.35.

When prepared by the acetic anhydride and pyridine method at 100°, the product was poor.

TOSYLATES.—All are 3α-tosylates, prepared by room temperature addition of *p*-toluenesulfonyl chloride and pyridine to the 3-hydroxy compound. In general, yields were nearly quantitative. Where they were lower than expected, it was possible to increase the yield by first drying the hydroxy compound by an azeotropic distillation in benzene.

Methyl 3α-tosyloxycholanate (methyl lithocholate tosylate) (20)[21] from methyl lithocholate, out of methanol as lovely, light-refracting, thin, square plates, m.p. 120–121.5° (lit.[21] 107–109°), $[\alpha]_D$ +35°. *Anal.* Calcd. for $C_{32}H_{48}O_5S$ (544.75): C, 70.56; H, 8.88. Found: C, 70.6; H, 8.9.

Ethyl 3α-tosyloxy cholanate (21) by ester interchange of 20 in ethanol and HCl by 2-hr. reflux, a low yield of crystalline material out of hexane, m.p. 94.5–95.5°. *Anal.* Calcd. for $C_{33}H_{50}O_5S$ (558.8): C, 70.93; H, 9.02; S, 5.74. Found: C, 71.25; H, 9.17; S, 5.65, $[\alpha]_D$ +33.0°*.

Methyl 3α-tosyloxy-9(11)-cholenate (22)[21] was prepared by tosylation of methyl 3α-hydroxy-9(11)-cholenate at room temperature, out of methanol or acetone as colorless crystals, m.p. 112.5–114°, $[\alpha]_D$ +33° (lit. 111–112°). *Anal.* Calcd. for $C_{32}H_{46}O_5S$ (542.69): C, 70.82; H, 8.54; S, 5.90. Found: C, 70.60; H, 8.61; S, 5.77.

Methyl 3α-tosyloxy-11-cholenate (23) was prepared by (a) tosylation of methyl 3α-hydroxy-11-cholenate to give a 91% yield of lustrous plates, m.p. 103–107°, from methanol. Recrystallized from warm methanol (not refluxed), m.p. 104.5–107°, $[\alpha]_D$ +40°. *Anal.* Calcd. for $C_{32}H_{46}O_5S$ (542.69): C, 70.81; H, 8.54. Found: C, 70.9; H, 8.9. (b) **By ester interchange**: When the ethyl ester (24) was first prepared, crystallization from methanol at 50° brought out colorless crystals, the melting point of which on continued crystallization rose from 65 to 104.5°. That an ester interchange from the ethyl to methyl ester had taken place was proved by the conversion of the product to methyl 3β-chloro-11-cholenate (27).

Ethyl 3α-tosyloxy-11-cholenate (24) by tosylation of ethyl 3α-hydroxy-11-cholenate.[5] Well-shaped needles out of absolute ethanol; has double melting point 57.5–61° and 95–96.5°, $[\alpha]_D$ +30.2°*. *Anal.* Calcd. for $C_{33}H_{48}O_5S$ (556.77): C, 71.18; H, 8.69. Found: C, 71.1; H, 8.90.

Methyl 3α-tosyloxy-12α-hydroxycholanate (25) was prepared by tosylation of methyl desoxycholate according to Barnett and Reichstein.[15] The compound decomposes at slightly above its melting point, which varies between 139 and 150° depending on the rate and length of heating. When put on the m.p. block at 149°, melting was observed at 149–150°, the melt turning yellow and effervescing, $[\alpha]_D$ +40.4°. (Barnett and Reichstein reported a m.p. of 149°.) *Anal.* Calcd. for $C_{32}H_{48}O_6S$ (560.70): C, 68.54; H, 8.63. Found: C, 68.36; H, 8.89.

Ethyl 3α-tosyloxy-12α-hydroxycholanate (26) was obtained by tosylation at room temperature of ethyl desoxycholate (crystallized originally from ether but had been on the shelf for about one year) in poor yield. A second tosylation using ethyl desoxycholate that had first received a preliminary azeotropic distillation with benzene gave a nearly quantitative yield of product of melting point 98–100°. Recrystallization out of ether–Skellysolve F (1:1) gave good, colorless needles, m.p. 101–103.5°. Dissolved in benzene and diluted with ligroin (63–70°), long needles separated, m.p. 114–116.5°, $[\alpha]_D$ +38.8°. *Anal.* Calcd. for $C_{33}H_{50}O_6S$ (574.8): C, 69.00; H, 8.78; S, 5.59. Found: C, 68.81; H, 8.73; S, 5.5.

CHLORO COMPOUNDS.—The 3-chlorocholanic acid derivatives were made by the pyridine–pyridine hydrochloride method; the bisnorcholenic acid compounds were made with thionyl chloride. The pyridinium chloride method is described in detail only for the preparation of compound 27.

Methyl 3β-chloro-11-cholenate (27) was made by the pyridinium chloride method. The tosylate 23 (1.4 g.) was heated for 21 hr. at 90° in 12 ml. of pyridine containing 1.4 g. of pyridine hydrochloride. Chips of ice and water were added and the mixture was stirred and refrigerated. The solid which precipitated was shaken with cold 3% hydrochloric acid and filtered. After washing with water and drying, the solid was crystallized from methanol. A small amount of insoluble material was first removed and the clear methanol solution deposited thin flakes, 446 mg. (42.5%), m.p. 96–100°. Two crystallizations raised the m.p. to 100.5–102°, $[\alpha]_D$ +24.5°. (Another run starting with 400 mg. of tosylate, and heated at 90° for 11 hr. gave a 53.5% yield of comparable product.) *Anal.* Calcd. for $C_{24}H_{37}O_2Cl$ (407.02): C, 73.77; H, 9.66. Found: C, 73.6; H, 9.8.

Ethyl 3β-Chloro-11-cholenate (28).[5]—(a) By the pyridinium chloride method from the tosylate (24), from 95% ethanol in 51% yield, in long laths with hexagonal ends, m.p. 78.5–79.5°, $[\alpha]_D$ +25°. *Anal.* Calcd. for $C_{26}H_{41}O_2Cl$(421.05): C, 74.16; H, 9.82. Found: C, 73.9; H, 9.7.

(b) By esterification of the acid 29, long prismatic needles by slow crystallization out of dilute 95% ethanol solution, m.p. 78–79.5°.

3β-Chloro-11-cholenic acid (29) was obtained in nearly quantitative yield by hydrolysis of the methyl ester and was recrystallized from acetic acid as well-shaped elongated prisms, m.p. 167–170.5°, $[\alpha]_D$ +24.5°. *Anal.* Calcd. for $C_{24}H_{37}O_2Cl$ (393.00): C, 73.34; H, 9.49. Found: C, 73.7; H, 9.5.

Methyl 3β-chloro-9(11)-cholenate (30) was obtained by the pyridinium chloride method on the tosylate 22 at 76.5° for 26 hr., as crystals from methanol in 51.5% yield, m.p. 86.5–88°, $[\alpha]_D$ +31°. *Anal.* Calcd. for $C_{25}H_{39}O_2Cl$ (407.02): C, 73.75; H, 9.66. Found: C, 74.2; H, 9.9.

Ethyl 3β-chloro-9(11)-cholenate (31) by esterification of the acid 32. Recrystallization in 95% ethanol gave colorless prisms, m.p. 67–68°, $[\alpha]_D$ +33.0°. *Anal.* Calcd. for $C_{26}H_{41}O_2Cl$ (421.05): C, 74.16; H, 9.82. Found: C, 73.8; H, 10.0.

3β-Chloro-9(11)-cholenic acid (32), prepared by hydrolysis of its methyl ester, crystallized from ethanol, m.p. 150–153°, $[\alpha]_D$ +33.4°. *Anal.* Calcd. for $C_{24}H_{37}O_2Cl$ (393.00): C, 73.34; H, 9.49. Found: C, 73.4; H, 9.8.

Methyl 3β-chlorocholanate (33) by pyridinium chloride method on methyl lithocholate tosylate (20), in 80% yield of crude product melting about 80°. After recrystallization from methanol, well-shaped, elongated prisms of m.p. 86–87.5° were obtained, $[\alpha]_D$ +17°. *Anal.* Calcd. for $C_{25}H_{41}O_2Cl$ (409.03): C, 73.41; H, 10.1. Found: H, 73.1; H, 9.8.

3β-Chlorocholanic acid (34), prepared by hydrolysis of the methyl ester 33, separated in long needles, from acetone, m.p. 186–190°, $[\alpha]_D$ +14.3°. *Anal.* Calcd. for $C_{24}H_{39}O_2Cl$ (395.01): C, 72.97; H, 9.95; Cl, 8.98. Found: C, 73.22; H, 9.91; Cl, 9.07.

Methyl 3β-chloro-12α-hydroxycholanate (35), by pyridinium chloride on the tosylate 25, crystallized out of methanol as transparent, dense prisms, m.p. 141.5–143°, $[\alpha]_D$ +29.6°*. *Anal.* Calcd. for $C_{26}H_{41}O_3Cl$ (425.04): C, 70.64; H, 9.72; Cl, 8.34. Found: C, 70.81; H, 9.85; Cl, 8.28.

Ethyl 3β-chloro-12α-hydroxycholanate (36) by ester interchange on 35, by refluxing for 3.5 hr. with hydrochloric acid in ethanol, 86% yield of fine needles, m.p. 116.5–118.8°. Analytical sample out of ligroin (35–60°)–benzene (20:1), m.p. 117.5–118.8°, $[\alpha]_D$ +28.6°*. *Anal.* Calcd. for $C_{26}H_{43}O_3Cl$ (439.06): C, 71.12; H, 9.87; Cl, 8.08. Found: C, 71.05; H, 9.73; Cl, 7.96.

Methyl 3β-chloro-5-bisnorcholenate (37) by the action of thionyl chloride on the 3β-hydroxy compound, m.p. 130–133°, out of methanol in 79% yield, $[\alpha]_D$ −48°. *Anal.* Calcd. for $C_{23}H_{35}O_2Cl$ (378.97): C, 72.89; H, 9.31; Cl, 9.36. Found: C, 72.96; H, 9.01; Cl, 9.44.

Ethyl 3β-chloro-5-bisnorcholenate (38) was prepared in a room temperature reaction of thionyl chloride on the hydroxy ester 7 to give a crystalline product from ethanol, m.p. 120–123°, $[\alpha]_D$ −47.3°. *Anal.* Calcd. for $C_{24}H_{37}O_2Cl$ (393.00): C, 73.34; H, 9.49; Cl, 9.02. Found: C, 73.5; H, 9.5; Cl, 8.9.

OTHER COMPOUNDS.—**Ethyl 12α-benzoxycholanate** (39) by reaction of benzoyl chloride in pyridine on the 12-hydroxy compound 4, 4 hr. reflux. The oil, after processing and chromatography, did not crystallize; distilled at 0.1 mm., $[\alpha]_D$ +51°. *Anal.* Calcd. for $C_{23}H_{48}O_4$ (508.7): C, 77.91; H, 9.51. Found: C, 78.0; H, 9.6.

Ethyl 3α-benzoxy-12α-hydroxycholanate (40) was prepared by benzoylation in pyridine at room temperature; 75% of product, m.p. 103–114°. Recrystallization from methanol, m.p. 118.8–120.7°, $[\alpha]_D$ +51.9°*. *Anal.* Calcd. for $C_{33}H_{48}O_5$ (524.68): C, 75.53; H, 9.22. Found: C, 75.80; H, 9.28.

Ethyl 3α,12α-dibenzoxycholanate (41) from ethyl desoxycholate with benzoyl chloride and pyridine by 3 hr. reflux, crystalline product from ethanol, m.p. 139.2–141.4°, $[\alpha]_D$ +89.7°*. *Anal.* Calcd. for $C_{40}H_{52}O_6$ (628.80): C, 76.40; H, 8.33. Found: C, 76.43; H, 8.59.

Ethyl 3-ketocholanate (42)[22] by esterification of 3-ketocholanic acid,[23] crystallized out of ethanol–water as dense prisms, m.p. 94.5–95.5°, $[\alpha]_D$ +28.9°. *Anal.* Calcd. for $C_{26}H_{42}O_3$ (402.60): C, 77.56; H, 10.52. Found: C, 77.52; H, 10.70.

Methyl 3-keto-9(11)-cholenate (43)[21] was prepared from methyl 3α-hydroxy-9(11)-cholenate by the chromium trioxide–pyridine method[24] to give an 82% yield of colorless crystals, m.p. 117–120°, $[\alpha]_D$ +31.3° (lit. m.p. 117–119°, $[\alpha]_D$ +35°).

Methyl 3-keto-11-cholenate (44)[25] from chromium trioxide–pyridine oxidation of the corresponding 3α-hydroxy compound, out of isopropyl ether–acetone (9:1) giving transparent flat plates, m.p. 125–127° (lit. m.p. 125.5–126°), $[\alpha]_D$ +37.3°. *Anal.* Calcd. for $C_{25}H_{38}O_3$ (386.55): C, 77.67; H, 9.91. Found: C, 77.4; H, 10.2.

Seroflocculating Steroids. IV.[1] Unsaturated Bile Acid Esters[2]

BY FREDERIC C. CHANG, AARON FELDSTEIN,[3a] JANE RANSOM GRAY, GEORGE S. MCCALEB[3b] AND DOUGLAS H. SPRUNT

RECEIVED NOVEMBER 20, 1956

For study of their seroflocculating activity, methyl and ethyl 3;11-choladienate, methyl 3,9(11)-choladienate, methyl and ethyl 3-cholenate, methyl and ethyl 12α-hydroxy-3-cholenate were prepared by elimination of suitably constituted 3α-tosylates. Each elimination reaction appears to give a single (or highly predominant) olefinic product. The assignment of the Δ^3-structure to these compounds is based on the identity of our methyl cholenate with the product prepared previously by Fieser and Ettore and proved by them to be methyl 3-cholenate.

Our first attempts to prepare a pure ethyl cholaienate for seroflocculation studies were by pyrolysis of diacyl derivatives of ethyl desoxycholate by the methods used by Wieland[4] and subsequently by Reichstein.[5] Solid products were obtained readily enough, but isolation of pure material by crystallization, or even by chromatography and crystallization, was tedious and gave low yield. For example, with ethyl 3α,12α-dibenzoxycholanate, the pyrolysis product yielded a minute amount of pure material only after chromatography and eight crystallizations. The diacyl methyl esters were no more amenable than the ethyl compounds.

The difficulty of isolation of pure product induced us to try an elimination reaction on a tosylate. Dehydrotosylation in a pyridine base which presumably takes place through a heterolytic mechanism might be expected to yield a different and possibly more tractable mixture than that resulting from pyrolysis. This method of producing unsaturation in steroids has been applied frequently,[6] but the

composition of the olefinic products obtained in the elimination of cholestanyl tosylates has been studied only recently.[7] And no similar information is available on the A-ring unsaturated products resulting from the 3-tosylates of the coprostane (A/B *cis*) series.

To limit the number of derived products, an ethyl desoxycholate derivative with the preformed 11-unsaturated group, ethyl 3α-hydroxy-11-cholenate[8] was chosen as the starting material. By reflux with tosyl chloride in pyridine solution, a nicely crystalline product was obtained, which, however, proved to be a difficultly separable mixture of diene and 3β-chloro compound, as described in paper II.[9]

When the tosylate 24[10] was first prepared and refluxed in 2,6-lutidine, a solid dienic product was obtained readily from the reaction mixture, but first efforts at purification by fractional crystallization seemed to indicate that, as with the pyrolysis products, the mixture yielded to separation reluctantly. However, by simply passing the material through an alumina column in ligroin, the persistent contaminant was removed and an excellent yield of homogeneous product could be achieved after one or two crystallizations.[10a] The impurity is a minor component that remains adsorbed on the alumina and apparently is not an isomeric diene.

Methyl 3,11-choladienate, methyl 3,9(11)-choladienate, methyl and ethyl 3-cholenate and methyl and ethyl 12α-hydroxy-3-cholenate were all prepared from the respective 3-tosylates in lutidine and purified in analogous manner satisfactorily. Methyl 12α-hydroxy-3-cholenate was obtained in pyridine in only 32% as compared with a 98% yield when lutidine was used. The improved yield when lutidine is used as dehydrotosylation medium in place of pyridine may be attributed partly to the increase in temperature of reaction (pyridine, b.p. 116°; 2,6-lutidine, 143°) but may also possibly be due to the greater steric strain in the transition state required for the formation of the salt when lutidine is the base, as suggested in a similar previous study by King.[11] The replacement reaction competing with elimination would result in the lutidinium (or pyridinium) salt.

Assignment of the Δ^3-Structure.—Fieser and Ettore[12] prepared methyl 3-cholenate by the zinc treatment of the methyl 3-hydroxy-4-bromocholanates, and Yamasaki, Rosnati, Fieser and Fieser[13] showed that it is identical with the methyl ester of an unsaturated acid (originally given the assignment of 2-cholenic acid by Wieland)[14] obtained by pyrolysis of lithocholic acid. They further confirmed the 3-unsaturation by conversion of the methyl cholenate to a 3,4-diol with osmium tetroxide and oxidation of this diol to lithobilianic acid.

Our methyl cholenate obtained from the dehydrotosylation reaction has been compared with the Fieser compound,[13] and the identity of the two preparations was established by comparisons of melting points, optical rotations and infrared spectra and by a mixed melting point determination. Moreover, our compound was converted to the ethyl ester which in turn was shown to be identical with authentic ethyl 3-cholenate provided by Professor Fieser.[13]

The Δ^3-compounds appear to be the sole olefin products of the dehydrotosylation reaction; no Δ^2-isomers were isolated. Wieland[14] reported a 9:1 ratio of isomers in the pyrolysis of lithocholic acid, and in fact his isolation and characterization of the minor component as 3-cholenic acid (now 2-cholenic acid) were extremely tentative. Therefore, the Δ^3-isomer appears to be the sole or highly predominant olefinic product[15] of both the pyrolysis and dehydrotosylation reactions. This is in interesting contrast to the situation of the cholestanyl derivatives; pyrolysis of the 3β-benzoates[16] gave both Δ^2- and Δ^3-cholestene, and elimination of 3α- and 3β-tosylates both afforded a Δ^2- and Δ^3-cholestene mixture in 1:1 ratio.

Consequently, the Δ^3-structure has been assigned to the other compounds made through the dehydrotosylation reaction: ethyl 3-cholenate, methyl 3,9(11)-choladienate, methyl and ethyl 3,11-choladienate, methyl and ethyl 12α-hydroxy-3-cholenate. Methyl 3,11-choladienate, also prepared by the pyrolysis of methyl desoxycholate dibenzoate and brought to satisfactory purity after fourteen recrystallizations, is probably identical with the material reported (m.p. 86°) obtained by Wieland and Kapitel[4] by a similar pyrolysis after "repeated" crystallizations and is most likely the methyl ester of choladienic acid-A. Choladienic acid-A was tentatively considered to be the $\Delta^{2,11}$-compound by Wieland, but Fieser[13] has recently proposed revision to the $\Delta^{3,11}$-structure. Reichstein and his coworkers[5] obtained as a side-product in a pyrolysis reaction of methyl 3α-acetoxy-12α-benzoxycholanate a 76° melting product which they regarded as a mixture of the methyl 2,11- and 3,11-choladienates. The unsaturated compound made by Barnett and Reichstein[17] by dehydrotosylation in pyridine is undoubtedly identical with our methyl 12α-hydroxy-3-cholenate. No supporting evidence or comment was given in the designation of the Δ^3-structure of their product; the preparation appar-

ently served only as intermediary in the synthesis of 12α-hydroxycholanic acid.

The 9(11)-cholenic acid methyl ester was conveniently prepared from the 3,9(11)-dienic compound by selective hydrogenation; the 9(11)-double bond was not hydrogenated with platinum oxide catalyst. Methyl 9(11)-cholenate had been prepared previously by Reich and Reichstein[18] and by Fieser, Heymann and Rajagopalan.[19]

Experimental[20,21]

Dehydrotosylation.—This method is used in the preparation of several compounds reported in this paper. Only the first preparation will be given in detail. In the case of the methyl esters, the procedure becomes simpler in that solid (usually crystalline) product separated from the lutidine reaction mixture on addition of ice chips. By washing the solid on a filter with ice-cold 3% hydrochloric acid, a satisfactory preliminary purification is effected.

Ethyl 3,11-Choladienate (45).—(a) Ethyl 3α-tosyloxy-11-cholenate (24),[1] 3.0 g., was refluxed for 3 hr. in 36 ml. of 2,6-lutidine (Eastman Kodak Co. practical grade). Large colorless crystals of lutidine *p*-toluenesulfonate separated on cooling the mixture to room temperature and redissolved when chips of ice were added. The mixture was transferred to a separatory funnel with ether and extracted in order with ice-cold 3% hydrochloric acid, 10% $NaHCO_3$ solution and water to neutrality. The ethereal solution was dried with Drierite and evaporated to a clear residual oil weighing 2.04 g. The oil was dissolved in purified ligroin (63–70°) and chromatographed, using alumina (Fisher) in the ratio of 30:1. ligroin (63–70°) eluted material amounting to 1.32 g. (64%) was dissolved in 95% ethanol and seeded, yielding good crystals. One crystallization gave colorless hexagonal plates with m.p. 67–68.5°, $[\alpha]_D$ + 32.4°*.

Anal. Calcd for $C_{26}H_{40}O_2$ (384.58): C, 81.20; H, 10.48. Found: C, 80.98; H, 10.72.

(b) **By Pyrolysis.**—Ethyl 3α,12α-dibenzoxycholanate (41), 5.0 g., was pyrolyzed at 200–350° for 160 min. at 28 mm. to yield 3.01 g. of oil. Chromatography of 1.78 g. of the oil gave 218 mg. of a ligroin (35–60°) eluted material of m.p. 45–54°. After eight recrystallizations, 41 mg. of colorless needles of m.p. 68–69° was obtained. A mixed m.p. with material obtained in (a) gave no depression.

Anal. Calcd. for $C_{26}H_{40}O_2$: C, 81.20; H, 10.48. Found: C, 81.44; H, 10.62.

(c) **By Esterification.**—Saponification of methyl 3,11-choladienate (46) in methanolic KOH, acidification and re-esterification of the resulting acid in absolute ethanol containing concentrated HCl gave dense, colorless prisms, m.p. 66–68°, melting point not depressed when mixed with (a).

Methyl 3,11-Choladienate (46). (a) **By Dehydrotosylation.**—Three grams of methyl 3α-tosyloxy-11-cholenate (23) gave 1.97 g. (95%) of colorless solid with m.p. 76–78° on addition of ice chips to the lutidine mixture. Fractional crystallization in methanol raised the melting point very gradually, although after several crystallizations the product assumed a regular flat hexagonal form. After eleven recrystallizations the top material melted 82.5–83.5°, weight 116 mg. However, by passing the crude solid dissolved in ligroin (63–70°) through an alumina column, the persistent impurity was removed and shiny flat hexagons melting at 83.5–84.5° were obtained after two crystallizations, $[\alpha]_D$ +33.4°*.

Anal. Calcd. for $C_{25}H_{38}O_2$ (370.55): C, 81.03; H, 10.34. Found: C, 80.8; H, 10.1.

(b) **By Pyrolysis.**[4]—The product of pyrolysis of 10 g. of methyl 3α,12α-dibenzoxycholanate[22] after chromatography melted 50–75° and weighed 2.54 g. After fourteen crystallizations, colorless needles melting 84–85° were obtained, mixed m.p. with product in (a), no depression.

Methyl 3,9(11)-choladienate (47) was prepared by dehydrotosylation of methyl 3α-tosyloxy-9(11)-cholenate (22)[1] in 75% yield as colorless needles when crystallized from methanol, m.p. 61–63°, $[\alpha]_D$ +21.4°*.

Anal. Calcd. for $C_{25}H_{38}O_2$ (370.55): C, 81.03; H, 10.34. Found: C, 80.9; H, 10.5.

Methyl 3-Cholenate (48).—By dehydrotosylation of methyl 3-tosyloxycholanate (methyl lithocholate tosylate) (20), a 95% yield of solid with m.p. 69–72.5° separated on addition of water to the lutidine solution. After chromatography and one crystallization in methanol, shiny, thin rectangular plates, m.p. 74.5–75°, resulted, $[\alpha]_D$ +17.0°.

Anal. Calcd. for $C_{25}H_{40}O_2$ (372.57): C, 80.59; H, 10.82. Found: C, 80.4; H, 10.8.

Admixed with authentic methyl 3-cholenate,[13] m.p. 73–74°, $[\alpha]_D$ +19°, no depression in melting point was found, and the infrared spectra of the two preparations were identical.

Ethyl 3-Cholenate (49).—(a) Dehydrotosylation of ethyl lithocholate tosylate (21) resulted in 52% yield of product melting at 76–80°, after crystallization from aqueous methanol, not chromatographed. (b) By ester interchange: Two hundred mg. of methyl 3-cholenate (48) of m.p. 74.5–75° in 16 ml. of an ethanolic HCl solution (made up by addition of 0.4 ml. of concd. HCl to 25 ml. of absolute ethanol) after standing at room temperature (25–28°) for 18 days, when diluted with water to near turbidity, afforded feathery needles melting at 80–81.5° which recrystallized from aqueous ethanol as colorless needles, m.p. 82.5–83.5°, $[\alpha]_D$ +16.7°. No depression in a mixed m.p. determination with authentic ethyl 3-cholenate[13] (m.p. 82–83°).

Anal. Calcd. for $C_{26}H_{42}O_2$ (386.60): C, 80.77; H, 10.95. Found: C, 80.5; H, 11.0.

Methyl 9(11)-cholenate (50), prepared by partial hydrogenation of methyl 3,9(11)-choladienate (47) in methanol and Adams catalyst, was crystallized from methanol, m.p. 68.5–72°. Chromatographed, it crystallized from methanol and melted at 45–49°; but from a dilute solution, separated slowly as long, colorless needles, m.p. 72–72.8°, giving a positive tetranitromethane test, $[\alpha]_D$ +34.8°*. (Reich and Reichstein's product[18] prepared by another method melted 49.5–50°, 67–67.5°; the preparation of Fieser, Heymann and Rajagopalan[19] had a m.p. of 67.4–68.2°.)

Anal.[23] Calcd. for $C_{25}H_{40}O_2$ (372.57): C, 80.59; H, 10.82. Found: C, 80.62; H, 11.00.

Methyl 11-cholenate (51) was prepared in poor yield following the pyrolysis method of Alther and Reichstein.[24] The product which recrystallized from methanol melted at 58–59°, $[\alpha]_D$ +29.0°.

Anal.[23] Calcd. for $C_{25}H_{40}O_2$ (372.57): C, 80.59; H, 10.82. Found: C, 80.44; H, 10.69. (Analysis on material dried at room temperature and 1 mm. indicates solvation with 0.5 mole of CH_3OH.)

Ethyl 11-cholenate (52) was made by hydrolysis of methyl 11-cholenate (51) to 11-cholenic acid and subsequent esterification of the acid (not crystallized) with ethanol (HCl). Crystallization from absolute ethanol first yielded needles melting at 33–34.5°. These low-melting crystals after standing in a desiccator melted 51–52° and when recrystallized retained the 52° m.p., $[\alpha]_D$ +30.8°.

Anal.[23] Calcd. for $C_{26}H_{42}O_2$: C, 80.77; H, 10.95. Found: C, 80.80; H, 10.85.

Methyl 12α-Hydroxy-3-cholenate (53).—(a) By dehydrotosylation of methyl 3α-tosyloxy-12α-hydroxycholanate (25) a product melting 102–109° was obtained in 90% yield.

Digitized by Arya Samaj Foundation Chennai and eGangotri

Two crystallizations from methanol brought the m.p. to 111–112°, not raised by further recrystallization, $[\alpha]_D$ +24.0°. *Anal.* Calcd. for $C_{25}H_{40}O_3$ (388.6): C, 77.27; H, 10.38. Found: C, 77.1; H, 10.2. This was probably identical with the product of Barnett and Reichstein[17] prepared similarly but with pyridine as solvent and assigned the Δ^3-structure with no comment. Their material had m.p. 110–111° out of methanol; no rotation reported. (b) By pyrolysis of methyl desoxycholate 3-cathylate,[25] a product in 88% yield, m.p. 106.5–109° after recrystallization from methanol, was obtained.

(25) L. F. Fieser and S. Rajagopalan, THIS JOURNAL, **72**, 5530 (1950).

Ethyl 12α-Hydroxy-3-cholenate (54).—(a) By dehydrotosylation of ethyl 3α-tosyloxy-12α-hydroxycholanate (26) a 98% yield of 92–95° melting material was produced, which, when recrystallized from methanol, melted at 92–97°. When pyridine was used instead of lutidine, the yield of product dropped to 32%. (b) By ester interchange: After 13 days at room temperature in ethanolic HCl methyl 12α-hydroxy-3-cholenate (53) gave a 60% yield of product melting 96–99° out of ethanol–H_2O (2:1). After chromatography, the m.p. was 97.5–99.2°, $[\alpha]_D$ +27.0°*.

Anal. Calcd. for $C_{26}H_{42}O_3$ (402.60): C, 77.56; H, 10.52. Found: C, 77.53; H, 10.26.

Potentiometric Study of Gelatin and its Methyl Ester[1a-c]

BY SAM KATZ AND PAUL H. MAURER

RECEIVED NOVEMBER 9, 1956

The proton dissociation isotherm for gelatin was established by both titration and equilibration techniques at 37.0 ± 0.02°, 0.15 ionic strength. It was demonstrated that even though the isotherms obtained by titration were reproducible and reversible they were approximately 10% lower than those obtained by the equilibration technique. Similar curves evaluated from equilibration data were analyzed in terms of the number and dissociation constants of the constituent prototropic groups. The resulting values are in good accord with those established by amino acid analyses. A method is proposed for the quantitative determination of the degree of esterification of the methyl ester of gelatin. This is based on the selective alkaline hydrolysis of the ester linkages. The analytical values are considered accurate to 4%.

Introduction

In the course of the investigation of gelatin and some of its derivatives as possible plasma expanders, it was observed that the solubility and gelation properties of the methyl ester of gelatin were markedly different from the parent material.[2] This observation suggested that if this effect were real, *i.e.*, not due to the hydrolysis of gelatin during the esterification procedure, some information relevant to gelation might be derived.

The information derived from potentiometric titrations is important for the interpretation of the results obtained from the other physical techniques such as viscosity, osmometry, etc.[3] From these data a provisional estimate of the electrostatic charge of the gelatin as a function of *p*H may be made. Furthermore, the analysis of the dissociation isotherm will reveal not only the number and the dissociation constants of the prototropic groups but also their relative distribution as a function of *p*H. By comparison of the titration curves of the original and modified gelatins, a quantitative measure of the extent of reaction can be made. If extensive hydrolysis of the protein were to occur, this would be reflected by an increase either in the number of the carboxyl and/or amino groups.

Experimental

Materials.—The beef bone gelatin, lot #148-1B, was kindly supplied by Dr. D. Tourtellote of the Knox Gelatine Company. Analytical grade reagents were utilized without further purification. The standard solutions of NaOH (0.2 *N*) and HCl (0.2 *N*) were prepared by diluting Stansol solutions (Standard Solution Company, Menasha, Wisconsin) to the desired concentrations and restandardized before use. The NaOH was protected from the atmosphere by a tube packed with activated Alumina and Caroxite, a CO_2 absorbent. Nitrogen, water pumped, stated as being 99.6% pure was employed whenever necessary.

Prior to titration, the gelatin solutions were dialyzed at 37° in the presence of toluene against 6 changes of solvent (0.15 *M* KCl) for at least 3 days; the ratio of the gelatin (inner solution) to the solvent being 1:4. The dialysis sac was rotated during this period.

Protein concentrations were determined by dried weight at 115 ± 5°, correcting for the salt content. The validity of this correction was established by demonstrating that the dry weight of the outer solution differed from that of the 0.15 *M* KCl by less than 0.1%.

The methyl ester of gelatin (Metgel) was prepared by the procedure of Fraenkel-Conrat and Olcott.[4] The preparation was washed once with methanol and then repeatedly with acetone. The solvent was removed *in vacuo* at room temperature. The product, which was obtained in 80% yield, was identical in gross appearance to the parent substance.

Equipment.—The *p*H was determined with a Beckman Model G *p*H meter with a type E-2 all-*p*H glass electrode in conjunction with a saturated calomel electrode. The instrument was calibrated at 37° against 0.05 *M* potassium hydrogen phthalate, *p*H 4.03,[5] and at 6.98 and 9.88 using 2 standard buffers.

The iso-ionic *p*H for gelatin was established by electrodialysis employing both parchment paper membrane and Amberplex ion resin membranes (donated by Rohm and Haas).

Titration.—The standard acid or alkali was introduced with a Koch micro-buret, 5-ml. capacity, into 15.00 ml. of 2% gelatin solution contained in a 50-ml. water-jacketed beaker. The temperature was maintained at 37.0 ± 0.2°. Control experiments in which the protein was eliminated were performed in order to evaluate the activity coefficient of the reactants. Prior to the initiation of any experiment, the electrodes were standardized against two of the buffers, and upon completion of the run they were rechecked. In any case, where the drift in reading exceeded 0.03 *p*H unit the experiment was discarded. In the alkaline range of ti-

tration, absorption of atmospheric CO_2 was minimized by continuously bubbling nitrogen gas through the system. The reversibility of the reaction was demonstrated by back-titration and agreed to within 4% of theoretical values. The resulting isotherms were calculated in the conventional manner making the customary assumptions with respect to the additivity of volumes, junction potentials and activity coefficients.[6]

Equilibration.—The equilibration method for determining the association isotherm for gelatin was performed by adding measured quantities of reagents to 50-ml. weighing bottles so that the total volume was 20.0 ml. and the resultant gelatin concentration was about 2%. The system was equilibrated at 37 ± 0.02° for about 24 hr. before *p*H measurements. The electrodes were standardized at frequent intervals. The deviation of any individual reading about the average as a rule did not exceed 0.01 *p*H unit at *p*H values lower than 5. When alkali was added a nitrogen atmosphere was maintained as previously described. The reversibility of the process was established by addition of the appropriate reagent to the equilibrated system, after which another equilibration period was allowed before *p*H measurement. The results agreed within 3% on the acid and 5% on the alkaline[7] sections of the curve.

Alkaline Hydrolysis.—The alkaline hydrolytic method for assaying the methoxyl content of Metgel was performed as follows. A measured excess of NaOH was added to 50.00-ml. aliquots previously adjusted to *p*H 6.2. The solution was then transferred to a 100-ml. volumetric flask, sealed with a greased stopper and allowed to equilibrate for 24 hr. at 37°. The residual alkali was determined by back-titration of 25.00-ml. aliquots.

Formol Titrations.—The procedure was essentially similar to that reported in the review by French and Edsall.[8] In order to determine the α- and ε-ammonium residues and minimize the imidazolium contribution, the solution of gelatin was adjusted to *p*H 7.8. To aliquots containing approximately 2% gelatin, measured volumes of 36% reagent grade formaldehyde, *p*H 7.0, were added so that the final formaldehyde concentration was 8 ± 1%. The end-point was determined by plotting Δ *p*H/Δ ml., the incremental change of *p*H with respect to alkali, *versus* ml. of NaOH added.[9]

Results and Discussion

The iso-ionic point[10] for beef bone gelatin was found to be 4.96 ± 0.02 at 37° by electrodialysis. Equilibration required 24 hr. when parchment-paper membranes were used; however, with ion-exchange resins, Amberplex C-1 and A-1, the time was decreased to 5 hr. When a 2% salt-free gelatin solution was made 0.15 *M* with respect to KCl the resultant iso-ionic *p*H of 4.94 indicated little or no binding of KCl by gelatin, in agreement with Carr and Topol.[11]

Potentiometric Titrations.—The proton dissociation curves for gelatin are given in Fig. 1. The titration isotherm represented by the lower curve was reproducible to within 3% and was found to be reversible. However, when compared with the data obtained by equilibration these proved to be 10% too low. Subsequent investigation revealed that the 30-min. period allowed for reaction during titration was not sufficient to permit equilibration. In contrast with these findings, Kenchington and Ward[12] titrated another type of gelatin successfully; however, the time allowed for equilibration was not indicated. It is difficult to attribute this deviation to heat effects, change of ionic strength (the change was less than 4%), or the 20% dilution of the protein. Assuming the absence of systematic errors, the most plausible explanation is that equilibration of the gelatin with the acid requires an appreciable time. It should be noted that a variation of 0.10 *p*H unit at *p*H 2.2 for the system studied would be equivalent to a change of 0.08 milliequivalent protons bound per g. gelatin. On this basis, no attempt was made to analyze the gelatin isotherms derived from titration.

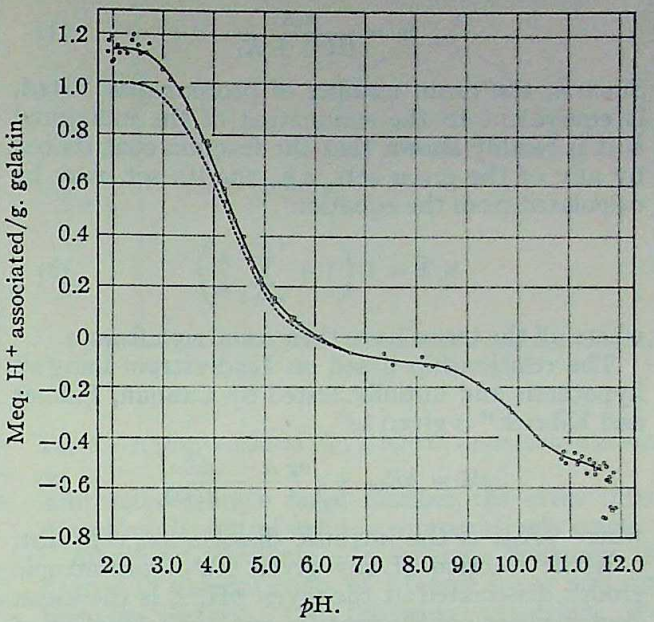

Fig. 1.—The proton association isotherm for beef bone gelatin as determined at 37°; μ = 0.15. The titration data are represented by the broken line; the equilibration data by the curve through the open circles.

The equilibration isotherm, upper curve, is typical for this process,[12,13a-c] except for the region more alkaline than *p*H 11.5. That the downward trend of the data is due to the effect of the guanidinium residues and not due to the experimental error was demonstrated by reversibility experiments.

The theory of the analysis of similar isotherms has been the subject of many reviews[14a-c]; therefore, this aspect of the discussion will be limited to some of the essential equations.

The relationship between h_i, the number of protons dissociated from the ith set of n proton donor groups and the apparent dissociation constant, K_i, for any statistically equivalent unit in this set is given by equation 1 where (H^+) is the proton concentration.

$$h_i = \frac{n_i K_i}{(H^+) + K_i} \qquad (1)$$

Since $\bar{h}$, the mean number of protons dissociated, is equivalent to the summation of the individual h_i it is readily shown that the fraction contributed by any of the given sets, *e.g.*, the lth set, may be calculated from the equation

$$h_1/\bar{h} = 1/\left(1 + \sum_{i=2}^{i=n} \frac{h_i}{h_1}\right) \qquad (2)$$

where all the terms have their usual significance.

The relationship based on Linderstrøm-Lang's[15] hypothesis and initially tested by Cannan, Palmer and Kibrick[16] is given as

$$p\mathrm{H} = pK_{\mathrm{int}} + \frac{\log \alpha}{1-\alpha} - \frac{2\bar{Z}\omega}{2.303} \qquad (3)$$

where pK_{int} is the intrinsic dissociation constant, α is the fraction of any given set of prototropic groups dissociated at the given pH, $\bar{Z}$ is the mean electric charge of the protein, and ω is a function of electrostatic potential of the protein species involved.[14a]

In order to evaluate the contribution of the imidazolium groups a tentative assignment of the α-ammonium groups was made on the premise that the gelatin studied was essentially a linear polymer with a number average molecular weight of about 50,000.[13a,17,18] The number and the pK's of the imidazolium and the α-ammonium groups were obtained by solving simultaneous equations[19] for values of $\bar{h}$ at pH 6.5 and 7.5.

The number of ϵ-ammonium groups was determined from the titration values between pH 8.0 and 11.25 as corrected for the residual contribution of the α-ammonium, imidazolium and guanidinium groups. The greatest single source of error is the difficulty in ascertaining the guanidinium contribution since its pK is not well established even at 25°, while the extrapolation to 37° (van't Hoff equation) introduces another element of error. If the pK were taken as being 13.0 then its contribution would be 0.009 meq./g., if it were 12.5 the corresponding value would be 0.027 meq./g., and similarly for pK 12 it would be 0.078 meq./g. By inspection of the curve it appeared that the value of about 12.5 would be justified for this calculation.

The pK_{int} of the carboxylate groups (uncorrected for α-carboxyl) was determined by plotting $p\mathrm{H} - \log \alpha/(1-\alpha)$ as ordinate *versus* $\bar{Z}^*$, the electronic charge of the protein calculated on a gram basis. The term $\bar{Z}^*$ was calculated from the titration curve, implicitly omitting any salt correction.[11] From Fig. 2, the value for pK_{int} of 4.35 ± 0.04 at 37° was determined in good agreement with that of 4.28, at 25° reported by Salvinien and Combet.[13c] The plot is linear over 80% of the range. The reversal of the curve is too large to be attributed to the α-carboxyl contribution and must be ascribed to higher order effects which have been neglected in the simple model used. A similar plot for the ϵ-ammonium groups is given in Fig. 3. The apparently anomalous behavior may be explained by considering that the ϵ-ammonium groups are contributed by both the lysine and hydroxylysine residues whose pK's are 10.28 and 9.50, respectively.[20] Therefore it is apparent that equation 4 is not applicable.

A comparison of the number of dissociable groups deduced from titration data with that determined by Eastoe[21] from amino acid analysis is offered in Table I. The titration value for the free carboxyl groups (inclusive of the α-carboxyl) of 1.13 ± 0.03 meq./g. gelatin, is in excellent accord with Eastoe's. The figure for the imidazolium residues obtained by titration, though corrected for the α-ammonium contribution, is somewhat high but within the experimental error. If the titration value for the ϵ-ammonium groups is adjusted for the tyrosyl hydroxyls the resulting value of 0.37 meq./g. is again in excellent accord with the English work. This is further corroborated by the value of 0.36 meq./g. obtained by formol titrations. The number of guanidinium residues, 0.46 meq./g., was calculated from the difference between the maximum acid binding quantity, 0.923 meq./g., and the anionic basic groups. This value is lower than that established by amino acid analysis. Furthermore it must be recognized that the initial quantity is more suspect due to incorporation of accumulative errors.

TABLE I

IONIZABLE GROUPS—BEEF BONE GELATIN

Group	Meq. per gram: Titration[a]	Meq. per gram: Analysis[b]	pK: This study	pK: Lit.[c]
Carboxyl (free)	1.13[d]	1.12[e]	4.35 ± 0.04[f]	3.0–4.7
Imidazolium	0.075	0.045	6.7	5.4–6.8
α-Ammonium	.019	...	8.2	7.3–8.1
ϵ-Ammonium	.38[g]	.346	...	9.1–10.3
Phenolic hydroxyl	...	.013	...	.....
Guanidinium	.46	.52	...	.....

[a] Determined at 37.0 ± 0.02°, μ = 0.15. [b] J. E. Eastoe, *Biochem. J.*, 61, 589 (1955). [c] These values, corrected to 37°, are from E. J. Cohn and J. T. Edsall, "Proteins, Amino Acids and Peptides," Reinhold Publ. Corp., New York, N. Y., 1943, p. 445. [d] This includes the contribution of the α-carboxyl groups. [e] This value is corrected for the amide contribution. [f] This corresponds to pK_{int}. [g] This includes the phenolic hydroxyl contribution.

(15) K. U. Linderstrøm-Lang, *Compt. rend. trav. lab. Carlsberg*, **15**, No. 7 (1925).

Phys.*, **47**, 11 (1950); G. Scatchard, J. L. Oncley, J. W. Williams and A. Brown, THIS JOURNAL, **66**, 1980 (1944).

(18) If the gelatin contains an appreciable fraction with a molecular weight much less than 30,000 the validity of this assumption is seriously compromised. However, the trend to the other extreme would not introduce as serious an error.

(19) The equations used were

at pH 6.5

$$2 = \frac{K_1}{3.16 \times 10^{-7} + K_1} + \frac{5K_2}{3.16 \times 10^{-7} + K_2}$$

at pH 7.5 =

$$4.5 = \frac{K_1}{3.16 \times 10^{-8} \times K_1} + \frac{5K_2}{3.16 \times 10^{-8} + K_2}$$

The values for h were corrected for carboxyl contribution. Even though these equations are based on an estimated molecular weight of 50,000, the results are independent of this assumption.

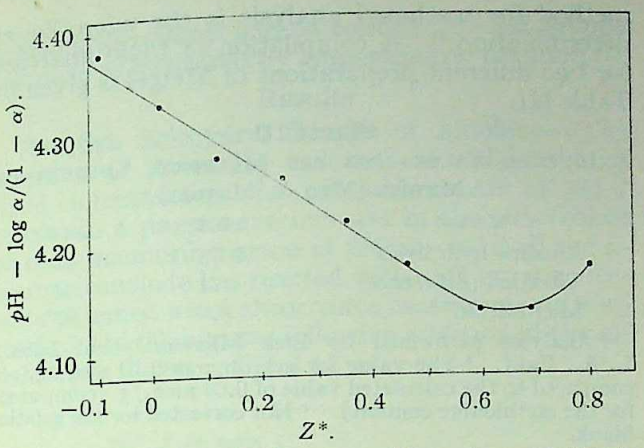

Fig. 2.—The plot of pH − log $\alpha/(1-\alpha)$ *versus* Z^*, the mean electric charge on gelatin calculated on a gram basis. This curve is for the free carboxyl group of beef bone gelatin at 37°, $\pi = 0.15$.

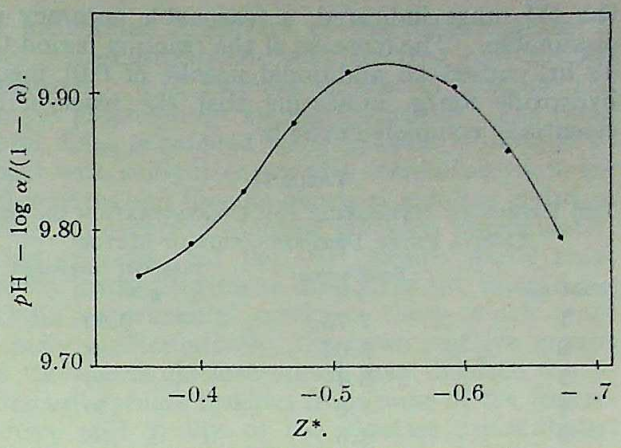

Fig. 3.—A plot, similar to Fig. 2, for the ϵ-ammonium groups.

Another method for interpreting this isotherm is the approach of Cannan, *et al.*,[14a,16] whereby certain arbitrary sections of the titration curve are attributed to given acidic groups. This analysis gave the following results: 1.145 meq./g. for the carboxyl groups (pH 2.0–6.125), 0.10 meq./g. for the imidazolium and α-ammonium groups (pH 6.125–8.0), 0.395 meq./g. for the ϵ-ammonium and phenolic hydroxyl groups (pH 8.0–11.25) and the calculated value for guanidinium was 0.44 meq./g. Thus it may be concluded that this approach is a successful first approximation.

Metgel.—From the difference between the carboxyl content of the original and modified proteins as determined potentiometrically, the extent of esterification of these polar groups may be evaluated. However, when the equilibration method was attempted for Metgel, it was observed that the readings were apparently stable at pH values lower than 5 but that there was a negative drift at higher pH values, *e.g.*, at pH 6.9 the rate of decrease was about 0.01 pH unit/min. When Metgel, with an initial pH of 4.4, was electrodialyzed the pH reached a maximum of about 9; however, upon prolonged electrodialysis the pH dropped asymptotically to 5. These observations are in general agreement with the findings of Saroff, *et al.*,[22b] for the methylated ester of bovine serum albumin which were interpreted as an indication of the lability of the methyl ester linkage in alkaline medium.

On this basis, the titration technique was employed to determine the acid section of the isotherm since it could be completed before extensive hydrolysis would occur. Even though the resulting data did not deviate more than 5% about the mean, no attempt was made to evaluate the reliability of these results due to the variables involved. Yet, if reference is made to Table III, where the degree of methylation was determined using these somewhat doubtful results, the conclusions appear to be quite satisfactory. This apparent anomaly may be rationalized by recognition of the fact that when a small value with a relatively large uncertainty is subtracted from a large number the error introduced by the initial value is comparatively small.

Alkaline Hydrolysis.—In order to determine the degree of esterification of Metgel by a less ambiguous method, the following procedure was developed which is based on the lability of the methyl ester bond in an excess of base.

The stoichiometry of the alkaline hydrolysis of the methyl ester bond in Metgel is indicated by the equation

$$\text{G—}\overset{\overset{\text{O}}{\|}}{\text{C}}\text{—OR} + \text{OH}^- \longrightarrow \text{G—}\overset{\overset{\text{O}}{\|}}{\text{C}}\text{—O}^- + \text{ROH} \quad (4)$$

For quantitative results, an excess of alkali must be employed in order to drive the reaction to the right. The possibility exists that this determination might be complicated by the competitive hydrolysis of either amide and/or peptide bonds. However, Bowes and Kenten[23] have shown that the peptide bond is resistant to alkaline hydrolysis under conditions more drastic than those used here, but that the amide group is somewhat more labile. If peptide hydrolysis were to occur it is evident that the back-titration to pH 6.2 would compensate for this effect since the liberated amino groups would be titrated. Evidence indicating that the ester hydrolysis was quantitative was the observation that the value for the free carboxyl groups as determined by continuing the titration to pH 2.1[24] agreed with that for the original gelatin (±2%). The possibility exists that this agreement may have been due to a fortuitous combination of incomplete ester hydrolysis coupled with amide and/or peptide cleavage. However, the fact that the latter effect was negligible was demonstrated by the results of formol titrations on regenerated Metgel, *i.e.*, Metgel neutralized after exposure to alkali, which were about 0.015 meq./g. higher than that of gelatin. Further corroboration was offered by the observation that a 24 hr. exposure of gelatin at pH 13, 37°, resulted in a consumption of ± 0.015 meq. alkali/g.

The effect of different concentrations of hydroxide ion on the ester hydrolysis is summarized in Table II. From these data it appears that providing the final hydroxide ion concentration is in

the *p*H range indicated, a reasonable accuracy is obtainable. The increase of the reaction period to 48 hr. caused an additional uptake of 0.01 meq. hydroxide ion/g. indicating that the reaction is essentially completed in 24 hr.

TABLE II

THE EFFECT OF HYDROXIDE ION CONCENTRATION ON THE METHYL ESTER DETERMINATION OF METGEL

Expt. no.	Equilibrium[a] *p*H	Meq. OH^- consumed / g. Metgel
1	7.75	0.90
2	8.00	.88
3	8.4	.90
4	8.5	.90
5	8.5	.93
6	9.0	.94
		.91

[a] The *p*H of the system after 24 hr. incubation.

A check of the validity of this technique is offered by a comparison of these results with those derived by other methods. The methyl ester content of Metgel may be calculated from the difference in the titration curves of the initial and final materials. The validity of these results has been discussed in a previous section. Still another method for methoxyl analysis is the micro-Zeisel determination.[25] A compilation of these analyses for two different preparations of Metgel is given in Table III.

TABLE III

ANALYTICAL VALUES FOR THE METHOXYL CONTENT OF METGEL (MEQ./G. METGEL)

Method	Lot 2	Lot 3
Alkaline hydrolysis	0.71	0.91
Titration (difference)	.71	.94
Micro-Zeisel[a,b]	..	.87[c]

[a] Analyses performed by Elek Microanalytical Labs., L. A., Calif. [b] The value for gelatin was 0.10 meq./g. as compared to the calculated value of 0.04 meq./g. (computed for the methionine content). [c] Not corrected for the gelatin blank.

From these data it may be concluded that the alkaline hydrolysis method for methoxyl analysis is relatively simple and reliable to ± 4%.

Sulfhydryl Groups in Relation to Aldolase Structure and Catalytic Activity[1]

BY A. D. SWENSON AND P. D. BOYER

RECEIVED OCTOBER 26, 1956

Spectrophotometric measurements readily reveal a graded reactivity of *p*-mercuribenzoate with the –SH groups of rabbit muscle aldolase; some react rapidly at *p*H 7 and 25°, some react much more slowly, and others react only in the presence of urea. With 4.8 *M* or higher urea concentrations, 28 *p*-mercuribenzoate molecules react rapidly per aldolase molecule. The catalytic activity is progressively decreased to 0 as urea concentration is increased up to 3.6 *M;* inactivation by up to 4 *M* urea is completely reversible upon dilution. The rate and extent of reaction with *p*-mercuribenzoate is not influenced by the presence of an excess of substrates. Up to 10 –SH groups per mole of aldolase can react with *p*-mercuribenzoate without decrease in the catalytic activity. Additional reaction with *p*-mercuribenzoate causes a reversible loss of catalytic activity which appears to be associated with structural changes in the aldolase.

Introduction

Considerable information has been accumulated about the status of sulfhydryl groups in enzymes and their catalytic activity.[2] For example, the pioneering studies of Hellerman, *et al.*,[3] with urease showed that the most reactive –SH groups were not essential for catalytic activity but that reaction of additional –SH groups resulted in marked activity loss. Quantitative observations on the relationships between enzyme structure, number of –SH groups reacted with a particular reagent, and the catalytic activity have been limited. Particularly lacking are results which give a clear indication of whether the essential –SH groups have a primary role in the catalysis or whether reaction of the –SH groups results in secondary changes leading to loss of activity. The latter possibility has been suggested by others, including Desnuelle and Rovery[4] and Nygaard.[5]

The rate and extent of the reaction of –SH groups of proteins with the mercaptide forming agent, *p*-mercuribenzoate, at neutral *p*H and under mild conditions, may be measured conveniently by a spectrophotometric technique.[6] This paper gives results of application of the spectrophotometric procedure to measurements of the –SH groups of rabbit muscle aldolase together with catalytic activity measurements in the presence and absence of various urea concentrations. Rabbit muscle aldolase was chosen for study because it is readily obtainable in pure form,[7] conveniently assayed, and has been reported to be inhibited by reaction with

p-mercuribenzoate[8] and to contain 29 –SH groups per mole as measured by amperometric titration.[9]

Results

Reactive Sulfhydryl Groups of Aldolase.—The addition of increasing amounts of aldolase to a fixed concentration of *p*-mercuribenzoate at *p*H 7 results in a progressive increase in the absorbance of the *p*-mercuribenzoate at 250 mμ until all the *p*-mercuribenzoate has reacted with –SH groups. Results obtained when absorbance measurements were made 3 and 60 minutes following addition of the aldolase are shown in Fig. 1A.

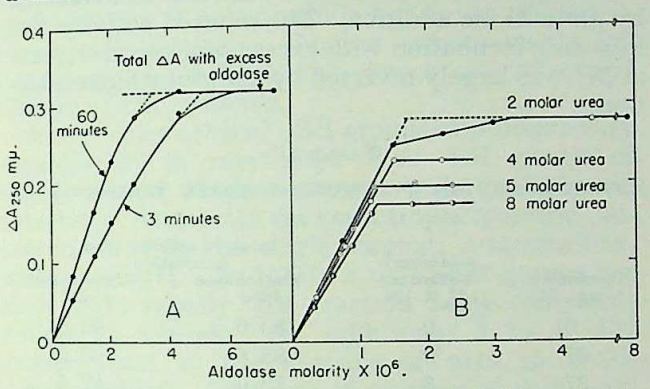

Fig. 1.—Spectrophotometric shift from addition of aldolase to *p*-mercuribenzoate in (A) 0.05 *M* phosphate buffer and 3.5×10^{-5} *M* *p*-mercuribenzoate *p*H 7.0, 25°, and (B) as in A but with indicated urea concentrations.

The presence of urea increases both the rate and the extent of reaction of aldolase –SH groups with *p*-mercuribenzoate. Figure 1B shows results obtained with various urea concentrations after the maximum spectral shift had been obtained. This was 3 minutes or less when 5 *M* or greater urea was present; with 2 *M* urea readings were at 180 minutes. Data showing the cause of the decrease in the total ΔA_{250} in the presence of urea will be presented later.

The fraction of the *p*-mercuribenzoate which has reacted with aldolase under a given set of conditions may be taken as approximately equal to the ratio of the observed ΔA_{250} to the total possible ΔA_{250}. This calculation will give an accurate value for the number of –SH groups reacted only if the absorbance at 250 mμ is the same for each –SH which reacts or if all –SH groups have a statistically equal reactivity with *p*-mercuribenzoate. Different proteins show a variation in the spectral shift at 250 mμ accompanying mercaptide formation,[2] and it thus seems feasible that variation may be encountered with different –SH groups on the same protein. One or both of the aforementioned requisites is met within experimental error for aldolase in the presence of 4 *M* or greater urea concentration, as shown by the straight line relationship between ΔA_{250} and aldolase concentration until a maximum is reached (for example, curve 4, Fig. 1). The lack of a straight line relationship for the experiments in the absence of urea is principally and perhaps entirely a reflection of the decrease in rate of mercaptide formation as the concentration of free *p*-mercuribenzoate and reactive –SH groups decreases; with increase in time of reaction the curves progressively approach linearity. The same total ΔA_{250} is reached when aldolase is allowed to react with a slight excess of *p*-mercuribenzoate for 60 minutes and then an excess of aldolase added as when an excess of aldolase is added immediately. This suggests that the –SH groups which react slowly in the absence of urea show the same ΔA_{250} within experimental error, as those which react rapidly. Alternatively, the more reactive groups of the excess aldolase added may displace the *p*-mercuribenzoate residues from some of the less reactive –SH groups of the aldolase preincubated with excess *p*-mercuribenzoate.

From the fraction of the *p*-mercuribenzoate which has reacted, the number of –SH groups per mole of aldolase which have formed mercaptides can be calculated readily. Figure 2 shows the –SH groups reacted per mole of aldolase as a function of urea concentration and of time. Readings made under comparable conditions 15 seconds after addition of an excess of *p*-mercuribenzoate to aldolase without urea present showed, in various trials, 5 to 7 –SH groups per mole which reacted within this period. These groups are clearly distinct in their reactivity from those reacting slowly over a several hour period. They are likely those responsible for the positive nitroprusside test mentioned by Racker.[10]

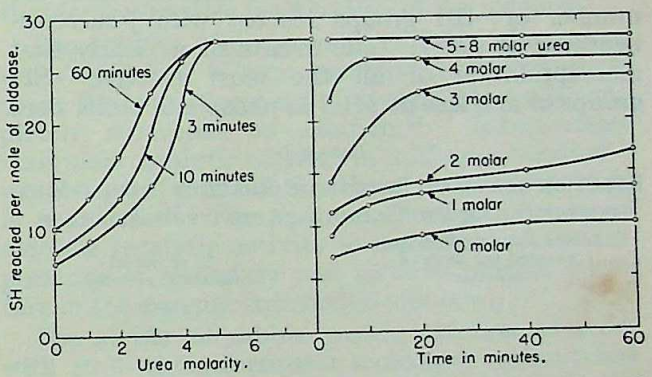

Fig. 2.—Effect of urea on rate and extent of reaction of aldolase SH groups with *p*-mercuribenzoate. Reaction mixtures contained 0.05 *M* phosphate buffer, 3.5×10^{-5} *M* *p*-mercuribenzoate, and urea as indicated, *p*H 7.0, 25°.

The effect of urea in decreasing the ΔA_{250} noted in Fig. 1B results from an increase in the absorbance of the *p*-mercuribenzoate in the presence of the urea, as shown in Fig. 3. The absorbance of the mercaptide of *p*-mercuribenzoate at 250 mμ is not increased by urea; this is illustrated in Fig. 3 for the mercaptide with glutathione. The increase in the absorbance of the *p*-mercuribenzoate undoubtedly results from formation of a urea-*p*-mercuribenzoate compound, very likely involving the mercury, which, on the appearance of the SH compound, gives way to the formation of the mercaptide with the *p*-mercuribenzoate.

Role of Aldolase –SH Groups in the Catalytic Activity.—The data in Table I summarize the

not significantly decrease the catalytic activity. Exposure at 37° for 1 hour was necessary to get 12 –SH groups to react in the absence of urea and to show a definite decrease (30%) in catalytic activity.

In Fig. 4 are shown data on the rate of reaction of aldolase with *p*-mercuribenzoate in the presence

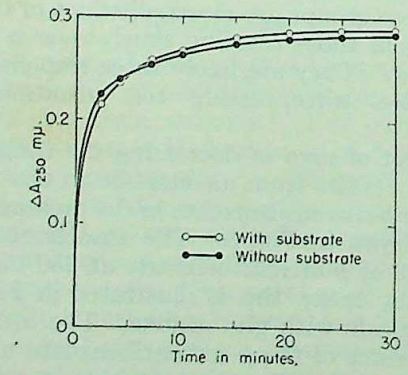

Fig. 4.—Lack of effect of substrate on the reaction of aldolase with *p*-mercuribenzoate. Reaction mixtures contained 0.05 *M* phosphate buffer, 2.6×10^{-6} *M* aldolase, 3.6×10^{-5} *M* *p*-mercuribenzoate with or without 0.07 *M* fructose, 6-diphosphate, *p*H 7.0, 25°.

and absence of substrates. With the concentration of enzyme used, the 0.07 *M* added fructose 1,6-diphosphate would be converted to an equilibrium mixture of the fructose and triose phosphates.[11] Clearly the presence of substrates in relatively high concentration had no effect within experimental error on the rate or extent of reaction of aldolase –SH with *p*-mercuribenzoate.

Reversibility of Aldolase Inactivation.—Table II gives results obtained when aldolase was incubated with or without *p*-mercuribenzoate present, followed by activity tests in the presence and absence of added glutathione. A control sample without *p*-mercuribenzoate incubated 1 hour at 0° showed no loss of activity, and that incubated at 37° a slight loss of activity. This loss was restored by glutathione addition. The marked activity loss following incubation with excess *p*-mercuribenzoate at 37° was largely reversed by the glutathione addition.

[a] See Experimental section for details.

Effect of Urea on Aldolase Activity.—The catalytic activity of aldolase when assayed in the presence of urea progressively decreases as the urea concentration increases and falls rather abruptly to zero as the urea level reaches 3.6 *M* (Fig. 5).

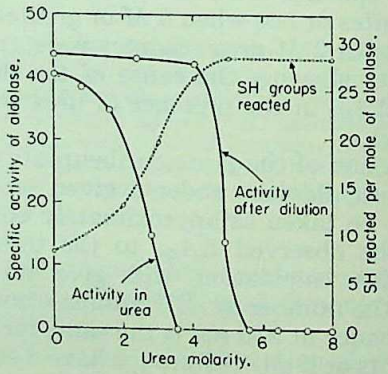

Fig. 5.—The effect of urea on the catalytic activity of aldolase. For details see the experimental section.

The loss in activity resulting from exposure to urea up to 4.0 *M* is essentially completely reversible as shown by the activity measured after a 100-fold dilution of the urea (Fig. 5). The extent of reversal of urea denaturation fell off sharply above 4.0 *M*; only 30% of the original activity was regained after exposure to 4.8 *M* urea, and exposure to 5.6 *M* urea or higher resulted in irretrievable activity loss. The loss in activity with exposure to 5.6 *M* urea varied with aldolase concentration; with $^1/_{10}$ as much aldolase as used for the experiments reported in Fig. 5, approximately $^1/_4$ of the activity was regained following dilution.

Discussion

The data show that in the presence of 5.0 *M* or higher urea concentration 28 moles of *p*-mercuribenzoate react rapidly with one mole of aldolase. This figure likely represents the total number of –SH present in the aldolase, and agrees well with the value of 29 –SH per mole reported by Benesch, *et al.*, from amperometric Ag titration measurements in 8 *M* urea solution[9] using the same values for molecular weight and absorbance at 280 mμ for determination of aldolase molarity. These values for total –SH considerably exceed the number of reported half-cysteine residues per mole,[12] and suggest that few if any disulfide bonds are present in the native aldolase. Further measurements are necessary to establish this important structural feature of the molecule.

As noted by others,[2] –SH groups of proteins vary considerably in reactivity. The –SH groups of rabbit muscle aldolase show a wide gradation in reactivity detectable by spectrophotometric observations with the single reagent, *p*-mercuribenzoate. At *p*H 7 and 25°, 5 to 7 –SH groups per mole react rapidly, the reaction being completed within 15 seconds. An additional 3 to 4 –SH groups react in the absence of urea in a 90-minute period. The rate of reaction of these –SH groups is sufficiently slow to distinguish them clearly from those which react in 15 seconds. The addition of urea is required to bring about reaction of the remaining –SH groups. Further, differences in the reactivity of these –SH groups can also readily be recognized. This is shown by the increase in total number of –SH groups reacting in the presence of 3, 4 and 5 *M* urea (Fig. 2).

The graded reactivity of the aldolase –SH groups and the ability of urea to increase their reactivity strongly suggests that the lack of reactivity of the aldolase –SH groups results from their unfavorable steric position within the molecule. Similar interpretations have been suggested earlier for "sluggish" –SH groups of proteins.[2,9] Although Benesch, Benesch and Rogers[13] have shown that urea may increase the reactivity of the –SH of glutathione toward nitroprusside, glutathione and other low molecular weight thiols react very rapidly with *p*-mercuribenzoate. Therefore structural features of the protein molecule likely account for reduced reactivity of some –SH groups.

That the –SH groups of the muscle aldolase may not participate directly in the enzyme catalysis is suggested by three facets of the experimental data. First, up to 10 –SH groups per mole, which includes all the rapidly reacting –SH groups, can react with *p*-mercuribenzoate without decrease in the catalytic activity; second, an excess of substrate fails to diminish the reactivity of the –SH groups with *p*-mercuribenzoate; and third, the decrease in catalytic activity occurs only when the less reactive –SH groups combine with *p*-mercuribenzoate. Such combination could logically result in changes of the secondary structure of the aldolase molecule. This possibility also draws support from correlations of the effects of urea and *p*-mercuribenzoate on the enzyme. Such correlations are well shown by the data of Fig. 5, which further define the relationship between structure, –SH reactivity and catalytic activity. The loss of activity resulting from increase in urea concentration is roughly paralleled by an increase in reactivity of the –SH groups. Sufficient structural change to cause complete loss of catalytic activity occurs well before complete reaction of the –SH groups. Exposure to 4.0 *M* urea allows reaction of all but approximately 3 of the –SH groups with *p*-mercuribenzoate, yet the effect on catalytic activity is entirely reversible. Thus the aldolase molecule in 4.0 *M* urea retains sufficient structure to allow the molecule to regain the original configuration or a comparably effective configuration of the active center. Likewise, aldolase inactivated by reaction with *p*-mercuribenzoate at 37° retains sufficient structure for regaining of catalytic activity (Table II). The urea concentration required for complete reaction of the –SH corresponds approximately to that for irreversible inactivation of the aldolase.

The activity of enzymes is variably affected by urea. Aldolase is more sensitive than trypsin to urea; the loss of trypsin activity in 8 *M* urea is completely recovered on dilution.[14] Ribonuclease maintains catalytic activity in 8 *M* urea solution,[15] pepsin in 4 *M* urea solution,[16] and carboxypeptidase in 6 *M* urea.[17] The pronounced effect of urea on aldolase catalytic activity is indicative of the importance of secondary and tertiary protein structure in the enzymic function of aldolase.

The ability of rabbit muscle aldolase to react with 10 *p*-mercuribenzoate molecules without loss of catalytic activity (Table I) was not an expected result. However, as mentioned earlier the most reactive groups of urease are not essential for catalytic activity.[3] The type of result obtained with aldolase and urease may prove to be a more general phenomenon. Desnuelle and Rovery noted that the loss of activity of urease occurred concomitantly with combination of the less reactive groups with phenyl isocyanate.[4] They argued cogently for the interpretation similar to that presented herein for aldolase, namely, that the inactivation resulted from reversible structural changes accompanying reaction of the –SH groups. Nygaard has suggested that some of the effects of *p*-mercuribenzoate on lactic dehydrogenase may result from structural alteration.[5] The results with aldolase are in contrast to the finding of Wallenfels and Sund[18] that the loss of activity of liver alcohol dehydrogenase is strictly proportional to the extent of reaction with *p*-mercuribenzoate.

The frequent interpretation that inactivation accompanied by blocking of –SH group implies a primary role of the –SH groups in enzyme catalysis is open to serious question. Enzymes showing such inactivation, particularly where the inactivation is

reversible, have been termed "sulfhydryl enzymes."[2] Such classification should not carry the implication of a primary function of the –SH groups in catalysis. The demonstration of a primary function for –SH groups is difficult. The probability of a primary function would follow from information as to how the –SH participates, as has been obtained for glyceraldehyde 3-phosphate dehydrogenase,[19] or the establishment that the inactivation is not accompanied by secondary structural changes. Such information is lacking for most "sulfhydryl enzymes."

Experimental

Special Reagents.—Aldolase was crystallized from rabbit muscle by the method of Taylor, *et al.*,[7,20] except that all solutions for extraction and crystallization contained 10^{-4} *M* ethylenediaminetetraacetate and were prepared in distilled water passed through a mixed ion-exchange resin bed (Rohm and Haas Amberlite Monobed 3) to remove ionic impurities. The enzyme used was crystallized 4 times to a constant specific activity. When stored as a suspension in the crystallizing medium at 5° the enzyme maintained full activity for at least three months. The molar concentration of aldolase was determined from its absorbance at 280 mμ (A_{280}/0.910 equal grams of aldolase per liter[20]) and its molecular weight of 147,000.[20] The more recent figure of 149,000[21] would not significantly change the values of –SH groups per mole reported herein.

Fructose 1,6-diphosphate solutions were prepared from the magnesium salt (Nutritional Biochemicals) by passing a 0.02 *M* solution through a Dowex 50-H column after which the *p*H was brought to 7.4 with 2 *M* NaOH.

Purification of urea was deemed advisable to minimize possible acceleration of –SH oxidation by any heavy metal contaminants present. For most of the studies urea was purified by passage of 8 *M* solutions through small beds of mixed ion-exchange resin. However, this procedure resulted in a prominent initial elution followed by a slower continuous elution from the column of material giving small absorption at 220–260 mμ. This material did not give a spectral shift with *p*-mercuribenzoate. Also, different batches of urea of the same grade and source differed in their content of ultraviolet absorbing impurities. These could be removed by recrystallization twice from hot 95% ethanol, and urea purified in this manner rather than by the ion exchange resins was used for some later studies.

Aldolase Catalytic Activity Assay.—The catalytic activity assay used is a modification[22] of that of Sibley and Lehninger.[23] One ml. of aldolase solution, recently brought to 30° and containing approximately 10 μg. of aldolase, was added to 0.5 ml. of 0.02 *M* fructose 1,6-diphosphate, *p*H 7.4, and 0.5 ml. of 0.5 *M* hydrazine sulfate, *p*H 7.4, at 30°. At the end of 10 minutes the reaction was stopped with 1 ml. of 0.005 *M* 2,4-dinitrophenylhydrazine in 2 *M* HCl. The development of chromogen proceeded for another 10 minutes at 30° at which time 7 ml. of 0.375 *M* NaOH was added and the system removed from the bath to stand at room temperature. After standing exactly 10 minutes at room temperature the absorbance of 525 mμ was read using a blank in which the sequence of addition of enzyme and 2,4-dinitrophenylhydrazine was reversed. The absorbance at 525 mμ divided by the calculated absorbance of the enzyme at 280 mμ in the assay system is defined herein as the specific activity of the enzyme. For values as measured on the Beckman DU spectrophotometer, using 1 cm. light paths, the 4 times crystallized enzyme had a specific activity of 46–50. Absorbance measurements in routine assays were made with a Bausch and Lomb Spectronic 20 colorimeter and converted to the equivalent Beckman readings by use of appropriate conversion factors.

Although the aldolase assay procedure used has only approximately 1/10 the sensitivity of Beck's modification[24] of the Sibley–Lehninger[23] method, it is considerably simpler, readily reproducible, and could be used because sensitivity was not a limitation of the experimental procedures. Removal of protein by trichloroacetic acid precipitation is not necessary when working with the purified enzyme; the acidic 2,4-dinitrophenylhydrazine solution serves to stop the enzyme action.

Urea caused a marked depression of color development in the aldolase assay. For example, the presence of 4 *M* urea in the assay mixture decreased the absorbance at 525 mμ by 79%. To accommodate this effect when assay samples contained urea, the procedure was altered to include the same concentration of urea in all of a given series of samples during color development. This was done as follows. At the end of the 10-minute incubation period of the enzyme and substrate, a 1-ml. aliquot was removed and added to a solution containing 1 ml. of the 2,4-dinitrophenylhydrazine reagent and 1 ml. of a urea solution of sufficient concentration to bring all samples to the urea level of that of the highest urea content of the series under investigation. Color development then proceeded as previously described.

Reactive Sulfhydryl Determinations.—The spectrophotometric method of Boyer[6] was used for measurement of the amount of *p*-mercuribenzoate reacting with –SH groups. The *p*-mercuribenzoate was reprecipitated four times,[6] and a sufficient amount dissolved in 0.05 *M* tetrasodium pyrophosphate to give stock solutions containing approximately 2×10^{-3} *M* *p*-mercuribenzoate. The concentration of solutions was accurately determined from the absorbance at 232 mμ[6] of appropriate dilutions. In all –SH determinations, requisite corrections were made for the absorbance of aldolase at 250 mμ.

Assays in the presence of urea were made by the same procedure, with consideration of the effect of the urea on the extent of the spectrophotometric shift accompanying mercaptide formation, as noted in the section on results. Assays in 8 *M* urea necessitated making all solutions to be used 8 *M* in urea.

Effect of Urea on Catalytic Activity of Aldolase.—For measurements of the catalytic activity of aldolase in the presence of urea, as reported in Fig. 5, the following conditions were used: 0.1 ml. of aliquots of an aldolase solution, 400 μg. per ml., were incubated 30° for 10 minutes with 0.9 ml. of 0 to 8 *M* urea solution and 0.5 ml. of 0.5 *M* hydrazine, *p*H 7.4. Then 0.5 ml. of 0.02 *M* fructose 1,6-diphosphate, *p*H 7.4, was added, with the resultant urea concentrations during the period of enzyme action as shown in Fig. 5. After 10 minutes a 1-ml. aliquot was removed from the reaction mixture and added to a mixture of 1.0 ml. of 0.005 *M* 2,4-dinitrophenylhydrazine in 2 *N* HCl, and 1.0 ml. of a urea solution of sufficient coucentration to bring the urea level of each mixture to that of the highest in the series under study. This was necessary to have all tubes at equal urea concentration for subsequent color development. This procedure was checked using glyceraldehyde in place of enzyme and substrate and was shown to be accurately reproducible.

The experiments on recovery of activity following dilution of urea (Fig. 5) were performed as follows: 2-mg. portions of crystalline aldolase, freshly centrifuged from ammonium sulfate suspension and well drained, were dissolved in 1 ml. of urea solution of the concentration indicated by Fig. 5. The small volume of the centrifuged aldolase suspension would decrease the molarity of the urea by considerably less than 5%. The solutions were allowed to stand at 30° for 10 minutes, and then diluted 100 times with water containing sufficient urea to bring all samples to 0.08 *M* urea; this concentration of urea was known from other studies to have no effect on catalytic activity. Catalytic activity measurements were made 10 minutes after dilution. Longer periods of standing after dilution did not result in increase in catalytic activity. One-ml. aliquots of the diluted solutions were added to the substrate and hydrazine and the assay carried out as previously described. The data reported in Fig. 5 are for solutions with no added buffer; the *p*H of these solutions was approximately 7.2. Closely similar results were obtained when the urea solutions contained 0.05 *M*

phosphate buffer *p*H 7.4 and 10^{-4} *M* ethylenediaminetetraacetate.

Correlation of Loss of Catalytic Activity with Extent of Reaction with *p*-Mercuribenzoate.—For these experiments, from 1 to 5 × 10^{-6} *M* aldolase was incubated with 3 × 10^{-5} *M* *p*-mercuribenzoate and 0.15 *M* phosphate buffer, *p*H 7.0. At room temperature, only approximately 8 –SH groups per mole of aldolase reacted within a 3-hour period. Exposure at 37° for 1 hour was necessary to obtain reaction with 12 –SH groups and exposure for 3 hours resulted in reaction of 14 groups. Longer exposure periods usually resulted in appearance of turbidity from protein precipitation. Subsequent to the desired incubation with the *p*-mercuribenzoate, samples were diluted with water to give solutions containing 20 μg. of aldolase per ml., and the activity was determined by the usual procedure. No compensation was necessary for differences in unreacted *p*-mercuribenzoate in the diluted samples because the low residual concentrations did not affect the catalytic assay. Aldolase samples incubated at 37° for three hours in the phosphate buffer without addition of *p*-mercuribenzoate showed little or no loss of catalytic activity. The loss observed in the presence of *p*-mercuribenzoate could thus be ascribed to reaction of the enzyme with the mercurial.

Reversal of the *p*-Mercuribenzoate Inactivation of Aldolase.—Samples of 1 ml. total volume containing 1 × 10^{-6} *M* aldolase and 0.12 *M* phosphate buffer *p*H 7.2 with or without 3 × 10^{-5} *M* *p*-mercuribenzoate were incubated at 0 or 37° as indicated in Table II. Then either 0.2 ml. of water or of 0.05 *M* glutathione, *p*H 7, was added, the samples allowed to stand 20 minutes at room temperature, and placed in an ice-bath. Catalytic activity assays were then made on appropriate aliquots as described previously.

The α-Chymotrypsin-catalyzed Hydrolysis of a Series of Hydrazides. I. Determination of *p*H Optima and their Dependence upon Temperature[1]

BY RALPH LUTWACK,[2] HOWARD F. MOWER[3] AND CARL NIEMANN[4]

RECEIVED JULY 31, 1956

It has been found that the α-chymotrypsin-catalyzed hydrolysis of L-tyrosinhydrazide and of six α-N-acylated-L-tyrosinhydrazides can be followed quantitatively by the spectrophotometric determination of the liberated hydrazine in the form of a protonated bis-*p*-dimethylaminobenzalazine. With this procedure it has been shown that for aqueous solutions at 25° the *p*H optimum for the α-chymotrypsin-catalyzed hydrolysis of L-tyrosinhydrazide is 7.05 ± 0.15 and that the *p*H optima for the comparable reactions involving the six α-N-acylated-L-tyrosinhydrazides lie in a more basic region, *i.e.*, *ca.* 7.7 to 8.0. It also has been observed that the *p*H optima for the α-chymotrypsin-catalyzed hydrolysis of three representative α-N-acylated-L-tyrosinhydrazides are strikingly temperature dependent in the region between 25 and 40° and that an increase in temperature from 25 to 40° causes the *p*H optima to be shifted to a more acidic region, *i.e.*, from *ca.* 7.8 to *ca.* 6.8.

The knowledge that α-N-nicotinyl-L-tyrosinhydrazide and presumably α-N-acetyl-L-phenylalaninhydrazide are hydrolyzed in the presence of α-chymotrypsin[5–7] led us to consider the usefulness of the hydrazides of certain α-amino acids and acylated α-amino acids as specific substrates in studies involving the above enzyme. While MacAllister and Niemann[5] had followed the α-chymotrypsin-catalyzed hydrolysis of α-N-nicotinyl-L-tyrosinhydrazide, in aqueous solutions at 25° and *p*H 7.9 and 0.02 *M* in the EDA[8] component of an EDA–HCl buffer, with the aid of a formol titration[9] and Goldenberg, Goldenberg and McLaren[6] had determined the extent of the α-chymotrypsin catalyzed hydrolysis of α-N-acetyl-DL-phenylalaninhydrazide, in aqueous solutions at 24.6° and *p*H 7.3 and 0.05 *M* in an unspecified phosphate buffer, with a Grassmann–Heyde titration[10] neither of these procedures was employed in the present study because it was anticipated that for many α-amino acid and α-N-acylated amino acid hydrazides any titrimetric procedure based upon the determination of liberated carboxyl groups would not be sufficiently sensitive to be used for determining their rates of hydrolysis by α-chymotrypsin.

Goldenberg, Goldenberg and McLaren[7] were aware of the limitations of the above titrimetric procedures when applied to the hydrazides and these investigators devised a colorimetric procedure for the qualitative recognition of the α-chymotrypsin-catalyzed hydrolysis of α-N-acetyl-DL-phenylalaninhydrazide, which was based upon the reduction of phosphomolybdate ion to the so-called molybdenum blue by the liberated hydrazine. While it was stated[7] that this latter procedure was capable of detecting an extent of hydrolysis of 1 to 2% at specific substrate concentrations of 0.03 to 0.05 *M* no attempt appears to have been made to develop the procedure to the point where it could be used for quantitative measurements.

An alternative colorimetric procedure for determining the extent of the α-chymotrypsin-catalyzed hydrolysis of α-amino acid and α-N-acylated α-amino acid hydrazides, and one that promised exceptional sensitivity, was suggested by the observation of Pesez and Pelit[11] that hydrazine reacts with *p*-dimethylaminobenzaldehyde in aqueous acidic media to give a protonated bis-*p*-dimethylaminobenzalazine with an absorption maximum

in the region of 455 mμ. Therefore, a procedure for the spectrophotometric determination of hydrazine which was based upon the above reaction was developed and although it was anticipated, and in a sense improved, by Watt and Crisp[12] and by Wood[13] it was employed in its original form in all of the studies described in this communication. With the availability of this latter procedure, which was capable of determining quantities of hydrazine of the order of 10^{-6} to 10^{-7} M in contrast to the lower limits of 10^{-3} to 10^{-4} M encountered in the determination of carboxylate groups with the formol titration,[9] it was possible to determine the extent of the α-chymotrypsin-catalyzed hydrolysis of seven α-amino acid and α-N-acylated α-amino acid hydrazides to carboxylate ion and hydrazine under conditions that involved only a limited extent of hydrolysis.

The seven specific substrates employed in the present investigation were, respectively, L-tyrosinhydrazide and the formyl-, acetyl-, trimethylacetyl-, dichloroacetyl-, benzoyl-, and nicotinyl-α-N-acyl derivatives of L-tyrosinhydrazide. All of these compounds were prepared from the corresponding esters and were found to be stable in the absence of α-chymotrypsin under the conditions employed in the enzymatic studies. In every instance it was found possible to establish conditions that would permit the demonstration of an enzyme-catalyzed hydrolysis. In view of the fact that α-N-benzoyl-L-tyrosinhydrazide, a compound which was previously reported[14] to be ineffective as a competitive inhibitor of the α-chymotrypsin-catalyzed hydrolysis of benzoyl-L-tyrosinamide, or of benzoyl-L-tyrosine ethyl ester, has now been shown to be a specific substrate of this enzyme it is clear that the inference that benzoyl-L-tyrosinhydrazide is incapable of interacting with the catalytically active site of α-chymotrypsin can no longer be maintained.

In view of the general dependence of enzyme-catalyzed reactions upon hydrogen ion concentration the *p*H optima of systems containing α-chymotrypsin and the seven specific substrates listed above were determined for each enzyme–substrate pair in aqueous solutions at 25° and 0.02 M in the THAM[15] component of a THAM–HCl buffer.[16] The results obtained in these studies are given in Table I along with comparable values for the corresponding amides and hydroxamides.[17]

It will be seen from the values summarized in Table I that the *p*H optima for the six α-N-acylated-L-tyrosinhydrazides, in aqueous solutions at 25°, are identical, within the limits of experimental error, with those of the four acylated-L-tyrosinamides, which were studied under comparable conditions, and that in general the optimum *p*H with respect to the attainment of the maximum extent of reaction in aqueous solutions at 25° in a given time interval is approximately 7.8 for both the acylated-L-tyrosinamides and the α-N-acylated-L-tyrosinhydrazides. The observation that the *p*H optimum for the reaction involving acetyl-L-tyrosinhydroxamide, *i.e.*, 7.60 ± 0.05, lies in a more acidic region than that observed for the comparable reaction involving either acetyl-L-tyrosinamide, *i.e.*, 7.90 ± 0.10, or acetyl-L-tyrosinhydrazide, *i.e.*, 7.95 ± 0.20, is not unexpected since of these three specific substrates only acetyl-L-tyrosinhydroxamide is capable of partial ionization in the region of the *p*H optimum and to thus cause a shift of the *p*H optimum in the direction noted.[18]

TABLE I

*p*H OPTIMA AT 25°[a]

β-(C₅H₄N)CONH–	.....	7.90 ± .05	7.80 ± .20

[a] With respect to the α-chymotrypsin-catalyzed hydrolysis of a series of derivatives of L-tyrosine in aqueous solutions 0.02 M in the THAM component of a THAM–HCl buffer unless otherwise noted. [b] 0.1 M THAM. [c] 0.3 M THAM.

From an argument[19] developed to explain the difference in *p*H optima for the α-chymotrypsin-catalyzed hydrolysis in aqueous solutions at 25° of acetyl-L-tyrosinhydroxamide, *i.e.*, 7.60 ± 0.05, and L-tyrosinhydroxamide, *i.e.*, 6.95 ± 0.05, it would be expected that the *p*H optimum for the α-chymotrypsin-catalyzed hydrolysis of acetyl-L-tyrosinhydrazide, *i.e.*, 7.95 ± 0.20, would lie in a more basic region than that observed for the comparable reaction with L-tyrosinhydrazide, *i.e.*, 7.05 ± 0.15. While this expectation has been realized it should be noted that Schwert[20] has suggested that the *p*H optimum reported[17,19] for the α-chymotrypsin-catalyzed hydrolysis of L-tyrosinhydroxamide, in aqueous solutions at 25°, *i.e.*, 6.95 ± 0.05, is to be associated with a transpeptidation reaction rather than with the assumed hydrolytic reaction. Since the absence of pertinent information does not permit us at this time to affirm or deny what appears to us to be an unlikely possibility we have undertaken a study of the importance of transpeptidation reactions under the conditions ordinarily employed for the evaluation of the kinetic constants of α-chymotrypsin-catalyzed hydrolyses of α-amino acid esters, hydroxamides, amides and hydrazides. These studies are now in progress.

The observation that the *p*H optima for the α-chymotrypsin catalyzed hydrolysis of L-tyrosinhydrazide and of L-tyrosinhydroxamide,[17,19] in aqueous solutions at 25°, are identical, within the limits of experimental error, *i.e.*, *ca.* 7.0, and that this latter value is greater than the value of 6.25

which has been reported[21,22] for the *p*H optimum for the equivalent reaction involving L-tyrosine ethyl ester raises the question as to whether the difference just noted is real or is the result of a variation in procedure.

We may assume that the ammonium group present in a monoprotonated α-amino acid ester, hydroxamide or hydrazide will have a pK'_A value of 7.4 ± 0.4.[19,23,24] Therefore, in aqueous solutions at 25° and between *p*H 6.0 and 9.0 one may expect to encounter significant amounts of the monoprotonated, *i.e.*, $H_3\overset{+}{N}CHRCOY$, and unprotonated, *i.e.*, $H_2NCHRCOY$, species of each of the above specific substrates[25] with the relative concentrations of the two species being dependent upon the *p*H of the particular system under investigation. Thus, with all three of the above specific substrates it is clear that the over-all dependence of relative activity upon *p*H is much more complicated than the case involving interaction of the enzyme with a single substrate species in systems of varying *p*H since in the former instance one is confronted not only with the added problem of multiple and competitive specific substrates[26] but also by the fact that their relative concentrations are varying with the *p*H of the systems. Consequently with situations of such complexity it is imperative that in the first instance significance be given only to those differences that can be observed through the use of comparable experimental procedures.

It will be noted that the *p*H optima for L-tyrosinhydrazide and L-tyrosinhydroxamide which are given above were evaluated under conditions where in each reaction system the extent of reaction arising from the interaction of the enzyme with all substrate species derived from either of the above added specific substrates was collectively determined. In contrast to these two cases the *p*H optimum for L-tyrosine ethyl ester which is given above was evaluated by a procedure which measured only the extent of reaction of the monoprotonated L-tyrosine ethyl ester in a given reaction system.

Balls and his co-workers[21,22,27] in their studies on α-chymotrypsin and modified α-chymotrypsin catalyzed hydrolyses of L-tyrosine ethyl ester employed an analytical procedure which was developed earlier[28] for following the enzyme-catalyzed hydrolysis of acylated α-amino acid esters. In this procedure, which may be represented by eq. 1 and 2, the reaction system was maintained at a constant, or nearly constant, *p*H by the frequent addition of standard alkali and the amount of the latter reagent added was taken to be proportional to the extent of reaction. However, in solutions

$$RCONHCHR'CO_2R'' + H_2O \longrightarrow RCONHCHR'CO_2^- + R''OH + H^+ \quad (1)$$

$$H^+ + OH^- \longrightarrow H_2O \quad (2)$$

containing added α-amino acid ester and in the *p*H region with which we are concerned one is confronted with a situation represented not only by eq. 3 and 2 but also by eq. 4. Therefore, when the

$$H_3{}^+NCHR'CO_2R'' + HOH^- \longrightarrow \overset{+}{H_3}NCHR'CO_2^- + R''OH + H^+ \quad (3)$$

$$H_2NCHR'CO_2R'' + HOH \longrightarrow \overset{+}{H_3}NCHR'CO_2^- + R''OH \quad (4)$$

procedure of Schwert, *et al.*,[28] is used with α-amino acid esters in the *p*H region where both monoprotonated and unprotonated species are present only the extent of reaction of the monoprotonated species can be determined.

Having established the fact that the procedure used by Balls and his co-workers[21,22,27] for the evaluation of the *p*H optimum of L-tyrosine ethyl ester differs in principle from those employed for the evaluation of the *p*H optima of L-tyrosinhydrazide and L-tyrosinhydroxamide the question that arises is whether the difference in *p*H optima noted above may or may not be due to the difference in procedures.

If it is assumed that the monoprotonated species derived from L-tyrosine ethyl ester is hydrolyzed at a faster rate than the corresponding unprotonated species[19] and that the pK'_A value of the monoprotonated L-tyrosine ethyl ester is *ca.* 7.3[29] it may be inferred that had Balls and his co-workers[21,22,27] employed a procedure that was comparable to those used for the evaluation of the *p*H optima of L-tyrosinhydrazide and L-tyrosinhydroxamide they would have observed with L-tyrosine ethyl ester that the relative activities in the region between *p*H 6.3 and 6.9 did not decrease, within the limits of experimental error, with increasing *p*H and thus would have obtained a *p*H activity relationship with a relatively flat maximum extending from *ca.* *p*H 6.3 to 6.9. Since the location of the *p*H optimum would be somewhat arbitrary in a case of this kind all that can be said with certainty is that the *p*H optimum evaluated by measurement of the cumulative extent of reaction embracing all reactive species would lie in a more basic region than the *p*H optimum evaluated by determining the extent of reaction of only the monoprotonated species. Thus, we may conclude that the difference in the *p*H optima of L-tyrosine ethyl ester and of L-tyrosinhydrazide and L-tyrosinhydroxamide which was noted earlier may not be real since the difference could arise either wholly or in part from a difference in procedures. In this connection it may be recalled that Goldenberg, Goldenberg and McLaren[7] have noted that the *p*H optimum for the α-chymotrypsin-catalyzed hydrolysis of L-leucine ethyl ester in aqueous solutions at 25° appears to

(25) With L-tyrosinhydroxamide the additional species $H_3\overset{+}{N}CHRCONHO^-$ and $H_2NCHRCONHO^-$ will be present in the more alkaline solutions. However, in systems more acid than *p*H 7.5 their contribution will be negligible.

be *ca.* 6.8 when determined by the procedure used by Balls and his co-workers[21,22,27] for L-tyrosine ethyl ester and to be *ca.* 7.2 when determined by a procedure which would be expected to reveal the cumulative extent of reaction of both the unprotonated and monoprotonated L-leucine ethyl ester. Although it has been suggested[30] that the difference in *p*H optima noted above may be a consequence of a transpeptidation reaction we believe that the argument given above provides a more likely explanation of the observation of Goldenberg, Goldenberg and McLaren[7] and it may be added that the shift in the *p*H optima noted by these authors[7] is in the direction anticipated on the basis of this argument.

The absence of information with respect to the dependency of the *p*H optima of α-chymotrypsin-catalyzed hydrolyses upon temperature led us to determine the *p*H optima for the α-chymotrypsin-catalyzed hydrolysis of α-N-acetyl-, α-N-benzoyl- and α-N-nicotinyl-L-tyrosinhydrazide in aqueous solutions at 10, 25 and 40° and those of L-tyrosinhydrazide in aqueous solutions at 25 and 40°. It will be seen from the data summarized in Table II that the *p*H optima for the α-chymotrypsin-catalyzed hydrolysis of the above three α-N-acylated-L-tyrosinhydrazides in aqueous solutions at 10° are identical, within the limits of experimental error, with those observed at 25°. However, when the values observed at 25° are compared with those observed at 40° it is seen that an increase in temperature from 25 to 40° causes a shift in the *p*H optima from *ca.* 7.9 at 25° to *ca.* 6.8 at 40° for all three of the above α-N-acylated-L-tyrosinhydrazides. In contrast to the behavior of the α-N-acylated-L-tyrosinhydrazides it was found, *cf.* Table II, that the *p*H optimum for the α-chymotrypsin-catalyzed hydrolysis of L-tyrosinhydrazide in aqueous solutions at 25°, *i.e.*, 7.05 ± 0.15, is identical, within the limits of experimental error, with that observed in aqueous solutions at 40°, *i.e.*, 6.85 ± 0.15. It is noteworthy that in aqueous solutions at 40° the *p*H optimum for the α-chymotrypsin catalyzed hydrolysis of L-tyrosinhydrazide is practically the same as that observed for any one of the three α-N-acylated-L-tyrosinhydrazides considered in this study.

TABLE II

VARIATION OF *p*H OPTIMA WITH TEMPERATURE[a]

$-CH(CH_2C_6H_4OH)-CONHNH_2$	10°	25°	40°
H_2N	.....	7.05 ± 0.15	6.85 ± 0.15
CH_3CONH-	7.85 ± 0.25	7.95 ± .20	6.75 ± .15
$(C_6H_5)CONH-$	7.80 ± .25	8.0 ± .20	6.75 ± .20
β-$(C_5H_4N)CONH-$	7.80 ± .25	7.80 ± .20	6.75 ± .20

[a] With respect to the α-chymotrypsin-catalyzed hydrolysis of L-tyrosinhydrazide and of three α-N-acylated-L-tyrosinhydrazides in aqueous solutions 0.02 *M* in the THAM component of a THAM–HCl buffer.

When it is realized that the *p*H optimum of an enzyme-catalyzed reaction is a reflection of the effect of *p*H upon a relatively large number of independent reaction parameters, that each of these dependencies may in turn possess different temperature dependencies and that one may also encounter temperature dependencies which are independent of the *p*H of the reaction system it is clear that in the absence of knowledge of the magnitude and direction of each of the above dependencies one must regard the *p*H optimum and its dependence upon temperature simply as the summation of all of the above effects. Therefore, in view of the nature of the information reflected in knowledge of the *p*H optimum and its dependence upon temperature in the case of the α-chymotrypsin-catalyzed hydrolysis of L-tyrosinhydrazide and of α-N-acetyl-, α-N-benzoyl-, and α-N-nicotinyl-L-tyrosinhydrazide in aqueous solutions at 10, 25 and 40° one can only note that the practice of evaluating the thermodynamic constants of similar α-chymotrypsin catalyzed reactions[14,31] by studying such reactions at a constant *p*H, *i.e.*, 7.8, appears to contain more elements of uncertainty than those already envisaged[14,31] even though such reactions were studied in the temperature range from *ca.* 10 to 30° but in solutions containing 30% aqueous methanol.

Experimental[32,33]

L-Tyrosinhydrazide.[34]—This compound was prepared by the reaction of L-tyrosine methyl ester in methanol solution with hydrazine hydrate essentially as described[34] for the equivalent reaction of the ethyl ester. The product which crystallized from the reaction mixture was twice recrystallized from ethanol and dried *in vacuo* over phosphorus pentoxide to give L-tyrosinhydrazide, m.p. 193–194°. Curtius[34] gives a m.p. of 195.5° for the same compound and a m.p. of 171° for DL-tyrosinhydrazide.

Anal. Calcd. for $C_9H_{12}O_2N_3$ (195): C, 55.4; H, 6.7; N, 21.5. Found: C, 55.4; H, 6.8; N, 21.4.

α-N-Formyl-L-tyrosinhydrazide.—To a well-stirred solution of 10.5 g. of L-tyrosine ethyl ester, m.p. 108.5–109.5°, in 250 ml. of 80% formic acid was added 43 ml. of acetic anhydride at a rate such that the temperature of the reaction mixture remained below 70°. After the reaction mixture had stood overnight at room temperature the solution was evaporated to dryness *in vacuo*, the sirupy residue taken up in 200 ml. of ethyl acetate, the ethyl acetate solution successively washed with 3 *N* aqueous sodium hydroxide, 6 *N* aqueous hydrochloric acid and with water, dried over anhydrous potassium carbonate, the solvent removed *in vacuo* and the 7.1 g. of sirupy residue taken up in 20 ml. of methanol. To the boiling methanol solution was added 2.25 g. of hydrazine hydrate, the reaction mixture allowed to stand overnight prior to concentration, the concentrate allowed to crystallize, the crystalline product recrystallized from aqueous methanol and dried *in vacuo* over phosphorus pentoxide to give 1.7 g. of α-N-formyl-L-tyrosinhydrazide, m.p. 218° with decomp., $[\alpha]^{25}D$ +21.4° (in 30% aqueous ethanol).

Anal. Calcd. for $C_{10}H_{14}O_3N_3$ (224): C, 53.8; H, 6.0; N, 18.9. Found: C, 53.7; H, 6.0; N, 18.8.

α-N-Acetyl-L-tyrosinhydrazide.—This compound was obtained from L-tyrosine by the same procedure used by Hogness and Niemann[18] for the preparation of the D-isomer for which a m.p. of 236–236.5° was erroneously reported instead of the correct value of 226–226.5°. The crude α-N-acetyl-L-tyrosinhydrazide recovered from the reaction mixture was recrystallized twice from methanol and dried *in vacuo* over phosphorus pentoxide to give α-N-acetyl-L-tyrosinhydrazide, m.p. 227–228°.

Anal. Calcd. for $C_{11}H_{16}O_3N_3$ (237): C, 55.7; H, 6.4; N, 17.7. Found: C, 55.7; H, 6.3; N, 17.8.

α-N-Trimethylacetyl-L-tyrosinhydrazide.—A vigorously agitated solution of 10.5 g. of L-tyrosine ethyl ester in 300 ml. of ethyl acetate was cooled to −5° prior to the addition of 2.75 g. of trimethylacetyl chloride, b.p. 104–105°, pre-

pared in 35% yield by the reaction of trimethylacetic acid with benzoyl chloride.[35] Two minutes after the addition of the above amount of acid chloride 50 ml. of 0.05 *N* aqueous potassium carbonate was added to the cold and vigorously agitated reaction mixture and the process repeated until four portions of acid chloride and of aqueous potassium carbonate solution had been introduced. The cold solution was then allowed to separate into two phases, the ethyl acetate phase collected, washed with 6 *N* aqueous hydrochloric acid and then twice with water prior to drying over anhydrous potassium carbonate. Removal of the solvent *in vacuo* gave 7.2 g. of a sirupy residue which was taken up in 20 ml. of methanol and allowed to react with 2 g. of hydrazine hydrate as described for the preparation of the α-N-formyl derivative, *vide ante*, to give 5.4 g. of the crude hydrazide which was recrystallized twice from aqueous methanol and dried *in vacuo* over phosphorus pentoxide to give 2.5 g. of α-N-trimethylacetyl-L-tyrosinhydrazide, m.p. 179–180°, $[\alpha]^{25}D$ +29° (in water).

Anal. Calcd. for $C_{14}H_{21}O_3N_3$ (247): C, 60.2; H, 7.5; N, 15.1. Found: C, 60.2; H, 7.5; N, 15.1.

α-N-Dichloroacetyl-L-tyrosinhydrazide.—L-Tyrosine ethyl ester, 10.5 g. in 300 ml. of ethyl acetate was acylated with 14.7 g. of dichloroacetyl chloride, b.p. 106–107.5°, and 200 ml. of 0.05 *N* aqueous potassium carbonate as described for the preparation of α-N-trimethylacetyl-L-tyrosine ethyl ester, *vide ante*, and the 7.7 g. of crude α-N-dichloroacetyl-L-tyrosine ethyl ester obtained as a gummy solid was taken up in 15 ml. of methanol and allowed to react with 1.8 g. of hydrazide hydrate to give 5.9 g. of the crude hydrazide which was recrystallized twice from aqueous methanol and dried *in vacuo* over phosphorus pentoxide to give 2.0 g. of α-N-dichloroacetyl-L-tyrosinhydrazide, m.p. 193–193.5°, $[\alpha]^{25}D$ +12.5° (in 40% aqueous ethanol).

Anal. Calcd. for $C_{11}H_{13}O_3N_3Cl_2$ (306): C, 43.2; H, 4.3; N, 13.7; Cl, 23.2. Found: C, 43.2; H, 4.2; N, 13.8; Cl, 23.3.

α-N-Benzoyl-L-tyrosinhydrazide.—This compound was prepared essentially as described by Bergmann and Fruton.[36] The crude hydrazide was recrystallized twice from methanol and dried *in vacuo* over phosphorus pentoxide to give α-N-benzoyl-L-tyrosinhydrazide, m.p. 247–248°. Bergmann and Fruton[36] report a m.p. of *ca.* 255°.

Anal. Calcd. for $C_{16}H_{19}O_3N_3$ (301): C, 64.2; H, 5.7; N, 14.0. Found: C, 64.2; H, 5.6; N, 14.1.

α-N-Nicotinyl-L-tyrosinhydrazide.—This compound was prepared as described by MacAllister and Niemann[5] from α-N-nicotinyl-L-tyrosine ethyl ester, m.p. 147–149°.[37] The crude hydrazide was recrystallized twice from methanol and dried *in vacuo* over phosphorus pentoxide to give α-N-nicotinyl-L-tyrosinhydrazide, m.p. 242–243°.[5]

Anal. Calcd. for $C_{15}H_{16}O_3N_4$ (300): C, 60.0; H, 5.4; N, 18.7. Found: C, 60.1; H, 5.4; N, 18.8.

Buffer Solutions.—Aqueous stock solutions were prepared from THAM, m.p. 169–169.5°, which had been recrystallized twice from aqueous methanol. These stock solutions were 0.20 *M* with respect to the THAM component and were adjusted to the desired *p*H by the dropwise addition of concd. hydrochloric acid at the temperature at which they were to be used and prior to adjustment to the final volume. In every case the *p*H was checked upon a 1:10 dilution of the above stock solutions and the *p*H readjusted if necessary. All reaction systems were 0.02 *M* with respect to the THAM component.

In a few cases a sodium cacodylate–cacodylic acid buffer, which was 0.02 *M* in cacodylic acid when present in the reaction system, was employed. Some evidence was obtained that a 0.02 *M* THAM–HCl buffer and a 0.02 *M* sodium cacodylate–cacodylic acid buffer of identical *p*H may not be exactly equivalent in the reaction systems considered in this communication. However, the differences observed with these two buffer systems were of minor significance.

***p*-Dimethylaminobenzaldehyde Reagent.**—The *p*-dimethylaminobenzaldehyde, m.p. 74.5–75°, was prepared from a reagent grade product by recrystallization from aqueous methanol or from a practical grade product by precipitation with aqueous sodium hydroxide from a hydrochloric acid solution followed by two recrystallizations from aqueous methanol. The reagent employed contained 1.0 g. of the aldehyde in 100 ml. of absolute ethanol. This solution was stable for periods up to 1 week when stored in sealed brown glass containers.

Enzyme Stock Solutions.—The aqueous enzyme stock solutions were prepared, usually in 5-ml. volumetric flasks, from crystalline bovine α-chymotrypsin, Armour preparations No. 10705 and 00592, but in no case was a stock solution used after it had stood at 25° for more than 1 hour. In every case the stock solutions were equilibrated for not less than 15 minutes at the temperature employed for the examination of a particular system.

A set of experiments were conducted to determine whether there was a significant change in activity when enzyme solutions were maintained at 40° for 1 hour by holding the enzyme in aqueous solutions at 40° and *p*H 7.8 and 0.02 *M* in the THAM component of a THAM–HCl buffer for periods up to 1 hour and then determining the activity at 25° and *p*H 7.8 using α-N-nicotinyl-L-tyrosinhydrazide as the specific substrate and comparing it with the activity of an equivalent enzyme solution that had been kept at 25° and *p*H 7.8 for the same period. The results obtained from these experiments gave no indication that there was a significant change in activity when the enzyme was maintained at 40° for 1 hour under the conditions specified.

Specific Substrate Stock Solutions.—Aqueous stock solutions of the various specific substrates were prepared at concentrations such as to permit the addition of the desired amount of specific substrate to the reaction system in the form of an 8.0-ml. aliquot.

Reaction System.—To a 10-ml. volumetric flask was added, at 25°, 8.0 ml. of the specific substrate stock solution and 1.0 ml. of the 0.2 *M* buffer stock solution and the mixture equilibrated for 30 minutes in a constant temperature bath maintained within ±0.1° of the selected temperature. At zero time a 1.0-ml. aliquot of the enzyme stock solution was added to the flask containing the buffered specific substrate solution and the solution mixed by gentle inversion six or seven times. Aliquots were then withdrawn from the reaction system at selected time intervals and analyzed as described below. A summary of representative reaction systems employed in this study is given in Table III.

TABLE III

REPRESENTATIVE REACTION CONDITIONS USED IN *p*H OPTIMUM STUDIES[a]

Hydrazide	*T*, °C.	[E], mg. P.N/ml.	$[S]_0 \times 10^2$, *M*	*t*, min.
L-Tyrosin-	25	0.104[b]	1.65	60

hyde reagent, 1.0 ml. of 1.72 *N* aqueous hydrochloric acid and *ca.* 5 ml. of water. The above solution was then made up to 10.0 ml. with water and allowed to stand for a period of 15–45 minutes before the optical density of the solution, contained in a 1-cm. quartz cell, was determined at 455 mμ using a Beckman Model B spectrophotometer equipped with a thermostated cell compartment maintained at 25°. It was found that the absorption at this wave length, *i.e.*, 455 mμ, followed Beer's law when the concentration of hydrazine was between 1 and 50 × 10^{-5} *M*. The size of the aliquot withdrawn from the reaction mixture was adjusted so the amount of hydrazine determined was between these limits.

With regard to blank corrections it should be noted that none of the specific substrates considered in this study were hydrolyzed in the absence of the enzyme under the conditions employed. However, a small blank correction was frequently made because of the presence of trace quantities of hydrazine in the specific substrates and because of a turbidity arising from the presence of a small amount of denatured enzyme in the solution of the azine.

Results.—The primary data obtained from analysis of the various reaction systems were recorded in terms of optical density, *i.e.*, extent of reaction, observed after a constant time interval for systems of varying hydrogen ion concentration with all other factors, *i.e.*, enzyme concentration, specific substrate concentration, time and temperature being maintained constant for any one specific substrate. Because the rather large variability in the susceptibility to hydrolysis of the various specific substrates resulted in a lack of uniformity, particularly with respect to enzyme and specific substrate concentrations, which had to be separately established for almost each specific substrate in order to obtain a significant extent of hydrolysis in a reasonable time interval, all of the primary data were normalized in order to facilitate presentation of the principal results of this study. In the normalization process the maximum optical density observed with any one specific substrate was assigned a value of unity and all other optical densities observed with the same specific substrate, where the only variable was the hydrogen ion concentration, were assigned values between zero and unity which were proportional to the respective observed optical densities relative to the observed maximum optical density. The plots given in Figs. 1 and 2 are representative examples of the derived data used for estimating the *p*H optima which are summarized in Tables I and II.

Acknowledgment.—The authors wish to express their indebtedness to Drs. R. M. Bock, J. T. Braunholtz, R. Kerr and W. E. M. Lands for their assistance during various stages of this study.

Synthesis of Potential Anticancer Agents. III. Hydrazino Analogs of Biologically Active Purines[2]

BY JOHN A. MONTGOMERY AND LEE B. HOLUM

RECEIVED JUNE 11, 1956

Several hydrazinopurines have been prepared from the appropriate chloropurines. One compound, 2-amino-6-hydrazinopurine, could not be prepared from 2-chloro-6-hydrazinopurine, but was obtained from 2-amino-6-methylmercaptopurine.

There are several purines of biological importance which contain primary amino groups. Among them are adenine, guanine and 2,6-diaminopurine. Adenine and guanine occur naturally in cell nuclei, whereas 2,6-diaminopurine is, curiously enough, incorporated into nucleic acid guanine better than guanine itself[3] and has shown some anticancer activity.[4]

In view of the striking activity produced when the amino group of certain amino acids is replaced by a hydrazino group,[5] it is reasonable to assume that some interesting anticancer agents might result if the amino groups of the above-mentioned compounds are replaced by hydrazino groups (II, III, VI, X and XIV).

Of these compounds, 6-hydrazinopurine (II) has been reported previously,[6] but the method of preparation is inconvenient since it involves heating a sealed tube for 16 hours. In addition to these compounds, 2-hydrazinopurine (V) seemed worthy of synthesis for biological testing.

Two methods of introducing a hydrazino group into the desired positions of the purine ring appeared feasible: the replacement of a methylmercapto group and the replacement of a chlorine atom.

This replacement might be done either before or after ring closure of the appropriate 4,5-diaminopyrimidines to purines, since a new ring closure[7] has made the necessary chloropurines readily available.

The introduction of the hydrazino group prior to ring closure is undesirable for two reasons: the hydrazino group in the 6 position presents the possibility of closure involving the hydrazino group rather than the 4-amino group giving rise to 9-aminopurines, since 6-alkylamino-4,5-diaminopyrimidines give 9-alkylpurines[8]; the intermediate purines such as 2-chloro-6-hydrazinopurine would be more interesting for screening than the intermediate 4,5-diaminopyrimidines such as 2-chloro-4,5-diamino-6-hydrazinopyrimidine.[9]

Although the mercapto group in the 6-position of the purine ring cannot be replaced by amines or hydrazine, the 6-methylmercapto group can be replaced under rather strenuous conditions.[6] Since the chlorine atom is generally more susceptible to nucleophilic attack than the methylmercapto group,[10] it seemed probable that the replacement of the chlorine atom constituted a more desirable method of preparation of 6-hydrazinopurine. Therefore, the preparation of 6-hydrazinopurine *via* 6-chloropurine was attempted; it was found that replacement of the chlorine atom in anhydrous hydrazine took place smoothly at room temperature giving a 92% yield of pure 6-hydrazinopurine, showing that indeed the chlorine atom is more reactive.

It is well known that the substituents in the 2-position of purine are less reactive than substituents in the 6-position. Because of this the chlorine atom in this position, rather than the methylmercapto group, is an even more logical choice for replacement by the hydrazino group. Indeed Todd, *et al.*,[11] found that it was not possible to prepare 2,6-diaminopurine from 2-methylthioadenine under any conditions tried. Hydrazine, while more reactive than ammonia, is still not apt to replace the 2-thio or 2-methylthio group readily, unless an activating group is present in the 6-position.[12] Therefore, 2-chloropurine was chosen as the precursor to 2-hydrazinopurine, and the replacement with hydrazine carried out; although, as predicted, more strenuous conditions than those employed with 6-chloropurine were necessary.

The difference in reactivity of the chloro group in the 2- and 6-position of purine shows up distinctly in the reactions of 2,6-dichloropurine (VIII). This difference is much more pronounced than in the case of the chlorine atoms of 2,4-dichloropyrimidine[14]; it follows closely the comparison of 2-chloropurine and 6-chloropurine. When allowed to react with anhydrous hydrazine, the chlorine atoms of 2,6-dichloropurine are replaced stepwise.

(12) Since this work was begun Elion, Lange and Hitchings[13] have reported that, in contrast to the behavior of 2-methylmercapto-6-aminopurine, the methylmercapto group of 2-methylmercapto-6-hydroxypurine can be replaced by amines. We have found that this is also true for hydrazine, although a better yield of 2-hydrazino-6-hydroxypyrine was obtained from 2-chloro-6-hydroxypurine under milder conditions.

2-Chloro-6-hydrazinopurine (VII)[15] is obtained at room temperature and it is necessary to heat the solution of 2,6-dichloropurine in anhydrous hydrazine to 80° for 12 hours to obtain 2,6-dihydrazinopurine (III).

Attempts to prepare 2-amino-6-hydrazinopurine (VI) by the reaction of 2-chloro-6-hydrazinopurine (VII) with ammonia failed; only starting material was recovered. These findings agree with those of Adams and Whitmore[16] concerning the reactivity of the 2-chloro group of 6-N-substituted-amino-2-chloro-7-methylpurines. This compound (VI) was successfully prepared from 6-thioguanine (XII) *via* 2-amino-6-methylmercaptopurine (XI). The methylation of thioguanine with dimethyl sulfate worked well, but replacement of the 6-methylmercapto group was slow and the yield was low compared to the replacement of the 6-chloro group.

The synthesis of 6-amino-2-hydrazinopurine (X) was accomplished more readily. 2-Chloroadenine (IX) was prepared by the amination of 2,6-dichloropurine[17]; replacement of the 2-chloro group was accomplished by use of the same reaction conditions employed for the preparation of 2-hydrazinopurine and 2,6-dihydrazinopurine.

The preparation of the hydrazino analog of guanine (XIV) involved the selective hydrolysis of the 6-chlorine of 2,6-dichloropurine followed by reaction of the 2-chloro group with anhydrous hydrazine, as described for the other 2-hydrazinopurines.

The hydrolysis of 2,6-dichloropurine in 0.1 *N* acid or base is much slower than that of 6-chloropurine,[18] but proceeds readily in 1 *N* acid or base. Acid hydrolysis yields xanthine, while basic hydrolysis gives 2-chloro-6-hydroxypurine (XIII). Since XIII, when treated with hydrazine, yields the same compound (XIV) as does 6-hydroxy-2-methylmercaptopurine, this constitutes a chemical proof of structure of XIII. The ultraviolet and infrared spectra of this compound are quite similar to those of hypoxanthine and different from those of 2-hydroxypurine.

Absorption Spectra.—The effect of the hydrazino group on the ultraviolet spectrum of purine is about the same as that of the amino group. The only two comparisons available of the effect of the hydrazino group and the methylamino group (6-methylaminopurine: 6-hydrazinopurine and 6-hydroxy-2-methylaminopurine: 2-hydrazino-6-hydroxypurine) show that these two groups are also similar, as might be expected.

The hydrazino or amino group in the 6-position of the purine nucleus has only a slight effect on the position of the peak, but both groups do exert a pronounced hyperchromic effect.

In the 2-position they produce a large bathochromic effect and a slight hypsochromic effect, although in most cases the bathochromic effect of the 2-hydrazino group is less than that of the 2-amino group. Table I shows these comparisons plainly.

The extreme insolubility of the hydrazino purines in water or the common organic solvents makes the accurate determinations of molar absorbancies difficult; their instability in basic solution precludes entirely the accurate determination of their spectra at the higher *p*H.

As in the case of the ultraviolet absorption spectra, the hydrazino group and the amino group have a very similar effect on the infrared spectrum of purine. The spectra of these hydrazino and amino purines typically exhibit strong broad absorption between 3400–2900 cm.$^{-1}$ due primarily to NH vibrations and to a small extent to CH vibrations.

(15) The assignment of the structure of VII as 2-chloro-6-hydrazinopurine instead of 6-chloro-2-hydrazinopurine was made indirectly on the basis of the compound's ultraviolet and infrared spectra (see Table I and Experimental section), and on the chemical behavior of 2,6-dichloropurine in other instances, *i.e.*, the formation of 2-chloroadenine and 2-chloro-6-hydroxypurine (see Experimental).

The characteristic purine absorption between 2900–2400 cm.$^{-1}$ (due to acidic NH) is present in all cases. The most useful region of the spectrum is between 1700–1500 cm.$^{-1}$. In this region absorption due to NH deformation and C=C and C=N vibrations occurs, and differentiation between 2-substituted, 6-substituted, and 2,6-disubstituted (amino or hydrazino) purines is possibly due to the different modes in which the amino (or hydrazino) group interacts with the ring vibrations when in the 2- and in the 6-position. In the 6-position either group causes splitting of the strong absorption band and two distinct peaks occur, one at 1670–1640 cm.$^{-1}$ and the other at 1605–1590 cm.$^{-1}$. In the 2-position either group interacts to give one broad band about 1650 cm.$^{-1}$. The spectra of the 2,6-disubstituted compounds resemble more closely those of the 2-substituted purines, but the peak of the one broad band in this case is found at 1600–1590 cm.$^{-1}$. All these compounds show a weak to medium absorption peak about 1460–1430 cm.$^{-1}$ and one or two weak to medium peaks 960–900 cm.$^{-1}$, the absorption in both regions being due to CH. They also show a medium to strong band at 1340–1300 cm.$^{-1}$ from C–N deformation. The principal absorption maximum of each compound is listed in the Experimental section under the preparation of the compound.

Acknowledgment.—The authors are indebted to Mr. J. P. Holmquist for the microanalytical results reported, to Mr. J. W. Murphy and Mr. J. B. McBrayer for the ultraviolet and infrared spectral determinations, and in particular to Dr. B. R. Baker for his helpful suggestions and encouragement in this work. Some of the Dumas nitrogen determinations were carried out by the Galbraith Microanalytical Laboratories, Knoxville, Tennessee.

Experimental

Spectral Data.—The ultraviolet spectra were first determined with a Beckman Model DK-2 spectrophotometer, but the optical densities at the maxima were determined with a Beckman DU. The infrared spectra were run in pressed potassium bromide pellets with a Perkin–Elmer Model 21 spectrophotometer.

6-Hydrazinopurine (II).—6-Chloropurine[7,18] (5 g., 32.2 m*M*) was added in small portions with stirring to 25 ml. of anhydrous hydrazine over a period of 15–20 minutes. The solution became warm and turned purple so that it was necessary to moderate the reaction with an ice-bath. After standing for half an hour the solution deposited a large amount of fine crystals of 6-hydrazinopurine. The solid was removed by filtration and washed thoroughly with cold *n*-propyl alcohol. The yield of crude material was 4.76 g., m.p. 206–208° dec. (uncor.). Recrystallization of this material from 250 ml. of water gave 4.25 g. of white crystals, m.p. 246–247.5° dec. (cor.) (lit. 244–245°).[6] On standing the reaction mixture deposited more 6-hydrazinopurine. Purification gave 0.22 g. of additional material making the total yield 4.47 g. (92%); γ_{max} 3328 cm.$^{-1}$ (secondary NH), 3230 and 3175 cm.$^{-1}$ (NH_2), 2960 cm.$^{-1}$ (CH), 2800–2400 cm.$^{-1}$ (acidic NH), 1640 cm.$^{-1}$ (NH), 1605 cm.$^{-1}$ (C=C, C=N), 1455 cm.$^{-1}$ (CH), 1322 cm.$^{-1}$ (C–N), 942 cm.$^{-1}$ (CH).

2-Hydrazinopurine (V).—A solution of 2-chloropurine[7] (500 mg.) in 10 ml. of hydrazine was heated for 12 hours at 80°. The excess hydrazine was removed *in vacuo*. The cream-colored residue was triturated with water, removed by filtration, and dried *in vacuo* over P_2O_5 at 80°; yield 280 mg. (57.7%), m.p. >300°; γ_{max} 3265 cm.$^{-1}$ (secondary NH), 3160 cm.$^{-1}$ (NH_2), 2930 cm.$^{-1}$ (CH), 2800–2500 cm.$^{-1}$ (acidic NH), 1655, 1626 (sh) cm.$^{-1}$ (NH), 1585 and 1538 cm.$^{-1}$ (C=C, C=N), 1432 cm.$^{-1}$ (CH), 1328 cm.$^{-1}$ (C–N), 930 cm.$^{-1}$ (CH).

The ultraviolet and infrared absorption spectra of a sample recrystallized from water for analysis were essentially the same as those of the unrecrystallized material.

Anal. Calcd. for $C_5H_6N_6$: C, 40.0; H, 4.00; N, 56.0. Found: C, 40.1; H, 4.05; N, 56.4.

2,6-Dihydrazinopurine (III) (A).—A solution of 2-chloro-6-hydrazinopurine (500 mg.) in 10 ml. of anhydrous hydrazine upon heating at 80° for four hours deposited a white solid which was removed by filtration, washed with water, and dried *in vacuo* over P_2O_5; yield 175 mg., m.p. > 300°; γ_{max} 3215 cm.$^{-1}$ (secondary NH), 3140 and 3000 cm.$^{-1}$ (NH), 2920 cm.$^{-1}$ (CH), 2800–2400 cm.$^{-1}$ (acidic NH), 1650 (sh) and 1625 (sh) cm.$^{-1}$ (NH), 1600 cm.$^{-1}$ (NH and C=C, C=N), 1550 cm.$^{-1}$ (C=C, C=N), 1435 cm.$^{-1}$ (CH), 1325 cm.$^{-1}$ (C–N), 923 cm.$^{-1}$ (C–H).

Anal. Calcd. for $C_5H_8N_8$: C, 33.3; H, 4.45; N, 62.2. Found: C, 33.1; H, 4.42; N, 62.1.

The hydrazine filtrate from above was taken to dryness *in vacuo* and the residue triturated with water, filtered and dried. The yield was 25 mg., λ_{max}^{pH1} 276 mμ ($a_M \times 10^{-3}$ 7), λ_{max}^{pH7} 275 mμ ($a_M \times 10^{-3}$ 6.08). The total yield of 2,6-dihydrazinopurine was 200 mg. (41%).

(B).—2,6-Dichloropurine[7] (1 g.) was added slowly to 11 ml. of anhydrous hydrazine with intermittent cooling. After standing overnight at room temperature, the solution was heated at 80° for 12 hours. The precipitate which formed during the reaction was removed by filtration, washed with cold water, and dried *in vacuo* over P_2O_5; yield 760 mg. Another 20 mg. of product was obtained by concentration of the hydrazine filtrate from above making the total yield 780 mg. (82%). The ultraviolet and infrared spectra of this material were identical with that of the material prepared by A.

6-Amino-2-hydrazinopurine (X).—A solution of 2-chloroadenine[17] (440 mg.) in 15 ml. of anhydrous hydrazine was heated at 80° for 12 hours. The excess hydrazine was removed under reduced pressure and the resultant gray solid triturated with warm water, removed by filtration, and dried *in vacuo* over P_2O_5; yield 200 mg. (47%), m.p. >300°; γ_{max} 3300 cm.$^{-1}$ (secondary NH), 3100 cm.$^{-1}$ (NH_2), 2980 cm.$^{-1}$ (CH), 2800–2500 cm.$^{-1}$ (acidic NH), 1655 cm.$^{-1}$ (NH), 1600 and 1545 cm.$^{-1}$ (C=C, C=N), 1450 cm.$^{-1}$ (CH), 1331 cm.$^{-1}$ (C–N), 934 cm.$^{-1}$ (CH).

A small sample was recrystallized from water for analysis.

Anal. Calcd. for $C_5H_7N_7$: C, 36.40; H, 4.25; N, 59.5. Found: C, 36.2; H, 4.55; N, 60.34.

2-Chloro-6-hydrazinopurine (VII).—2,6-Dichloropurine (2.5 g.) was added to 15 ml. of anhydrous hydrazine with stirring and intermittent cooling. After standing overnight at room temperature the mixture was evaporated under reduced pressure and the solid residue boiled with 25 ml. of distilled water. The suspension was then cooled and the solid removed by filtration and dried *in vacuo* over P_2O_5; yield 1.98 g. (81%), m.p. >300°; γ_{max} 3340 cm.$^{-1}$ (secondary NH), 3250, 3100 cm.$^{-1}$ (NH), 2800–2400 cm.$^{-1}$ (acidic NH), 1665 and 1655 (sh) cm.$^{-1}$ (NH), 1605 cm.$^{-1}$ (C=C, C=N), 1450 cm.$^{-1}$ (CH), 1305 cm.$^{-1}$ (CN), 925 cm.$^{-1}$ (CH).

The ultraviolet and infrared spectra of a small sample recrystallized from water for analysis were practically unchanged.

Anal. Calcd. for $C_5H_5ClN_6$: C, 32.50; H, 2.75; Cl, 19.25. Found: C, 32.6; H, 2.87; Cl, 19.4.

2-Chloro-6-hydroxypurine (XIII).—A solution of 2,6-dichloropurine (500 mg.) in 25 ml. of 1 *N* sodium hydroxide was refluxed for one hour, cooled, neutralized with acetic acid, and allowed to stand in a refrigerator overnight. The light yellow crystals were removed by filtration, washed with ice water, and dried *in vacuo* over P_2O_5; yield of almost pure material, 300 mg. (66%), m.p. >300°.

A small sample was recrystallized from water for analysis; λ_{max}^{pH1} 250 mμ ($a_M \times 10^{-3}$ 11.2), λ_{max}^{pH7} 259 mμ ($a_M \times 10^{-3}$ 10.1), λ_{max}^{pH13} 265 mμ ($a_M \times 10^{-3}$ 11.6); γ_{max} 3020 cm.$^{-1}$ (NH), 2900 cm.$^{-1}$ (CH), 2800–2300 cm.$^{-1}$ (acidic H), 1680 cm.$^{-1}$ (C=O), 1562, 1530 (sh) cm.$^{-1}$ (C=C, C=N), 950 cm.$^{-1}$ (CH).

Anal. Calcd. for $C_5H_3ClN_4O$: C, 35.20; H, 1.76; N, 32.82. Found: C, 35.4; H, 1.93; N, 32.65.

2-Hydrazino-6-hydroxypurine (XIV) (A).—A solution of 6-hydroxy-2-methylmercaptopurine[18] (720 mg.) in 10 ml. of anhydrous hydrazine was refluxed for 20 hours, cooled, and the excess hydrazine removed at reduced pressure. The gray residue was triturated with water, removed by filtration, and dried *in vacuo* over P_2O_5; yield of almost pure material, 200 mg. (30%). A small sample of this material was recrystallized from water for analysis, m.p. >300°; γ_{max} 3305 cm.$^{-1}$ (secondary NH), 3160 cm.$^{-1}$ (NH), 3000 cm.$^{-1}$ (CH), 2800–2300 cm.$^{-1}$ (acidic NH), 1665 cm.$^{-1}$ (NH and C=O), 1600, 1590 (sh), 1537 (sh) cm.$^{-1}$ (C=C, C=N), 1455 cm.$^{-1}$ (CH), 1308 cm.$^{-1}$ (CN), 942 cm.$^{-1}$ (CH).

Anal. Calcd. for $C_5H_6N_6O$: C, 36.2; H, 3.62. Found: C, 36.4; H, 4.17.

(B).—A solution of 2-chloro-6-hydroxypurine (3.5 g.) in 25 ml. of anhydrous hydrazine was heated at 80° for 14 hours, cooled, and the product isolated as described in Method A above; yield of almost pure material, 3.1 g. (91%); the ultraviolet and infrared spectra were identical with that of the material obtained by Method A above.

A 100-mg. sample was recrystallized from 200 ml. of water and dried over P_2O_5 *in vacuo* at 110°; yield 65 mg.

Anal. Calcd. for $C_5H_6N_6O$: C, 36.2; H, 3.62; N, 50.60. Found: C, 36.25; H, 4.13; N, 50.05.

2-Amino-6-methylmercaptopurine (XI).—Thioguanine[19] (5 g., 30 m*M*) was dissolved with heating in 253 ml. of 0.115 *N* sodium hydroxide (30 m*M*). This solution was cooled to 30–40° and dimethyl sulfate (3.79 g., 2.8 ml., 30 m*M*) added dropwise with stirring. After stirring the mixture for another hour, the material which had precipitated was removed by filtration and dried. The yield of almost pure material was 3.5 g., m.p. 239–239.5°; λ_{max}^{pH1} 241, 272, 318 mμ ($a_M \times 10^{-3}$ 6.72, 9.6, 12.4), λ_{max}^{pH7} 242, 310 mμ ($a_M \times 10^{-3}$ 12.1, 10.6), λ_{max}^{pH13} 227, 314 mμ ($a_M \times 10^{-3}$ 19.9, 10.3). An additional gram of material, m.p. 239–240°, was obtained by concentration of the mother liquor.

A small sample of the material was recrystallized from water and dried *in vacuo* at 80–100° for about 6 hours, m.p. 239.5–240°; λ_{max}^{pH1} 241, 273, 317 mμ ($a_M \times 10^{-3}$ 7.0, 10, 13), λ_{max}^{pH7} 242, 309 mμ ($a_M \times 10^{-3}$ 12.7, 11.0), λ_{max}^{pH13} 228, 313 mμ ($a_M \times 10^{-3}$ 20.2, 10.6); γ_{max} 3350–3050 cm.$^{-1}$ (NH), 2960 cm.$^{-1}$ (CH_3), 2800–2400 cm.$^{-1}$ (acidic NH), 1635 (sh) cm.$^{-1}$ (NH), 1600 and 1556 cm.$^{-1}$ (C=C, C=N), 1450 cm.$^{-1}$ (CH), 1308 cm.$^{-1}$ (C–N), 911 cm.$^{-1}$ (CH).

Anal. Calcd. for $C_6H_7N_5S$: C, 39.8; H, 3.86. Found: C, 39.8; H, 3.91.

2-Amino-6-hydrazinopurine (X).—A solution of 2-amino-6-methylmercaptopurine (505 mg.) in 10 ml. of anhydrous hydrazine was refluxed for 12 hours. Most of the excess hydrazine was removed under reduced pressure and 10 ml. of *n*-propanol added to the residue. The resultant gray solid was removed by filtration, triturated with boiling water, again collected by filtration and dried *in vacuo* over P_2O_5 at 100° for 3 hours; yield of almost pure material, 310 mg. (67%). A small amount of this material was recrystallized from water for analysis and dried *in vacuo* over P_2O_5 for 3 hours at 100°, m.p. >300°; γ_{max} 3345 cm.$^{-1}$ (secondary NH), 3250 and 3140 cm.$^{-1}$ (NH), 2930 cm.$^{-1}$ (CH), 2800–2500 cm.$^{-1}$ (acidic NH), 1645 (sh) and 1625 (sh) cm.$^{-1}$ (NH and C=C, C=N), 1590 cm.$^{-1}$ (C=C, C=N), 1436 cm.$^{-1}$ (CH), 1332 cm.$^{-1}$ (C–N), 930 cm.$^{-1}$ (CH).

Anal. Calcd. for $C_5H_7N_7$: C, 36.38; H, 4.23; N, 59.5. Found: C, 36.05; H, 4.29; N, 59.2.

Synthesis of Potential Anticancer Agents. IV. 4-Nitro- and 4-Amino-5-imidazole Sulfones

BY L. L. BENNETT, JR., AND HARRY T. BAKER

RECEIVED NOVEMBER 19, 1956

A number of 4-nitro- and 4-amino-5-imidazole sulfones have been prepared as potential antagonists of 4-amino-5-imidazolecarboxamide. Attempts to prepare 4-amino-5-imidazolesulfonamide by several methods were unsuccessful. A convenient preparation of 4-acetamidoimidazole is described.

The synthesis of compounds designed to interfere with purine metabolism has been the subject of considerable recent literature.[2] Most of the com-

pounds prepared for this purpose have been analogs or derivatives of purines and their ribosides. Although imidazole ribotides have been implicated for some time as intermediates in the biosynthesis of purines,[3–5] there have been no reports of attempts to prepare imidazoles as antagonists of 4-aminoimidazole or 4-amino-5-imidazolecarboxamide which, as their ribotides, occur as intermediates in *de novo* synthesis of purines.[3–5] This paper is concerned with the synthesis of certain 4-amino-5-imidazole sulfones and related compounds as potential antagonists of 4-amino-5-imidazolecarboxamide.

A number of 2-mercaptoimidazoles are known, but only a few 4-mercaptoimidazoles are recorded in the literature.[6] A series of sulfones derived from 2-mercaptoimidazole has been reported recently,[7] but there have been no reports of sulfones derived from 4-mercaptoimidazoles.

In the present work, two series of imidazole sulfides and sulfones were prepared: one derived from 4-nitro-5-mercaptoimidazole and one from 1-methyl-4-nitro-5-mercaptoimidazole. 1-Methyl-4-nitro-5-chloroimidazole[8] and 4-nitro-5-bromoimidazole[9] were converted to the ammonium salts of 1-methyl-4-nitro-5-mercaptoimidazole and 4-nitro-5-mercaptoimidazole, respectively, by reaction with hydrogen sulfide in ammoniacal methanol, a method used by Bhagwat and Pyman[10] for the synthesis of 2-methyl-4-nitro-5-mercaptoimidazole. The nitroimidazole mercaptans were then alkylated in methanolic sodium methoxide, and the resulting sulfides were oxidized to the sulfones with hydrogen peroxide in glacial acetic acid. The nitroimidazole sulfones finally were reduced to 4-amino-5-imidazole sulfones by Raney nickel in absolute ethanol. In the 1-methyl series the sulfides also were prepared easily from the reaction of 1-methyl-4-nitro-5-chloroimidazole with mercaptans in ammoniacal ethanol, but 4-nitro-5-bromoimidazole failed to react with a variety of mercaptans under these conditions. 1-Methyl-4-nitro-5-(*p*-acetamidophenylsulfonyl)-imidazole was prepared by reaction of 1-methyl-4-nitro-5-chloroimidazole with *p*-acetamidobenzenesulfinic acid[11] under the conditions used by Baker, *et al.*,[12] for the preparation of 2,4-dinitro-4′-acetamidodiphenyl sulfone. The sulfides and sulfones prepared are listed in Tables I and II.

In the course of this work, a number of attempts were made to prepare 4-amino-5-imidazolesulfonamides. 1-Methyl-4-nitro-5-imidazolesulfonic acid[13] failed to react with phosphorus pentachloride, phosphorus pentachloride–phosphorus oxychloride mixtures, thionyl chloride, or chlorosulfonic acid under a variety of conditions; this failure was anticipated from the unsuccessful attempts of Pyman and co-workers[14,15] to prepare sulfonyl chlorides from other imidazolesulfonic acids. Chlorosulfonic acid at 190–200° converted 4-bromoimidazole[9] to 4-bromo-5-imidazolesulfonyl chloride which was converted readily to the corresponding sulfonamide. However, the bromine atom in this sulfonamide and in its derivative, 4-bromoimidazole-5-N,N-dibenzylsulfonamide, was inert toward ammonia and amines under a variety of conditions. Considerable inertness to replacement by hydroxyl groups has been observed by Eliel and Nelson[16] in studies with *p*-chlorobenzenesulfonamides.

Attempted chlorosulfonation of 4-acetamidoimidazole[17] led only to decomposition products from which no sulfonyl chloride could be isolated. Unsuccessful attempts were also made to convert 1-methyl-4-nitro-5-mercaptoimidazole to the sulfonamide *via* the sulfenamide, a method recently used with success by Greenbaum[18] for the conversion of 6-mercaptouracil to uracil-6-sulfonamide.

4-Acetamidoimidazole, used for the attempted chlorosulfonation mentioned above, was prepared by reduction of 4-nitroimidazole[19] with Raney nickel in a mixture of acetic anhydride and acetic acid, a method considerably more convenient for the preparation of this compound in quantity than the stannous chloride reduction method of Hunter and Nelson.[17] Under the conditions of the Raney nickel reduction, 4-aminoimidazole was isolated as a diacetyl derivative, which on the basis of a comparison of its infrared spectrum with that of an authentic sample of 1-acetylimidazole,[20] was assigned the structure of 1(or 3)-acetyl-4-acetamidoimidazole. Boiling water readily removed the ring acetyl group, giving 4-acetamidoimidazole in 88% yield from the diacetyl compound.

Acknowledgments.—The authors are indebted to Dr. B. R. Baker, Dr. J. A. Montgomery and Miss K. Hewson for helpful discussions; to Mr. J. P. Holmquist for elemental analyses; and to Dr. W. C. Coburn and Mr. J. W. Murphy for infrared spectra determinations.

Experimental

All melting points are uncorrected. The infrared spectra were run in pressed potassium bromide pellets with a Perkin-Elmer model 21 spectrophotometer.

4-Nitro-5-mercaptoimidazole.—This compound was prepared by the same method used by Bhagwat and Pyman[10] for 2-methyl-4-nitro-5-mercaptoimidazole.

4-Nitro-5-bromoimidazole[9] (2.0 g.) was dissolved in 20 ml. of warm 5 *N* ammonium hydroxide and hydrogen sulfide was bubbled through the solution for 15 min. The ammonium salt of the mercaptoimidazole separated as bright orange needles, m.p. >300°, yield 1.9 g. (82%). The crude product was crystallized from methanol.

Anal. Calcd. for $C_3H_6N_4O_2S$: C, 22.20; H, 3.73; N, 34.52; S, 19.75. Found: C, 22.11; H, 3.54; N, 34.37; S, 19.58.

The ammonium salt of 1-methyl-4-nitro-5-mercaptoimidazole, m.p. 197–198°, was prepared similarly in 58% yield and purified by crystallization from methanol by the addition of ether.

Anal. Calcd. for $C_4H_8N_4O_2S$: C, 27.27; H, 4.58; N, 31.78; S, 18.19. Found: C, 27.70; H, 4.46; N, 31.79; S, 18.14.

4-Nitro-5-imidazole Sulfides.—The imidazole sulfides were prepared either by alkylation of the mercaptoimidazole or by reaction between the 4-nitro-5-haloimidazole and mercaptans.

Alkylation of Mercaptoimidazoles.—The ammonium salt (2.0 g.) of the 4-nitro-5-mercaptoimidazole was dissolved in 50 ml. of methanol containing about 1 g. of sodium methoxide. The alkyl halide (5–10% excess) was added and the mixture was refluxed for two hours. After the solvent had been removed by evaporation in a stream of nitrogen, the residue was crystallized from water or aqueous ethanol.

Reaction of 4-Nitro-5-haloimidazoles with Mercaptans.—This reaction, which was used only in the 1-methyl series, was carried out under the conditions reported by Overberger, *et al.*,[21] for the synthesis of *p*-nitrobenzyl sulfide.

To a solution of 1-methyl-4-nitro-5-chloroimidazole[8] (10.0 g.) in 200 ml. of warm ethanol there was added an equimolar amount of the mercaptan, and ammonia was bubbled through the solution for two hours. The reaction mixture was allowed to stand overnight after which the solution was evaporated to dryness and the residue was crystallized from aqueous ethanol.

4-Nitro-5-imidazole Sulfones.—The imidazole sulfide was dissolved in a small volume (about 10 ml./g. sulfide) of glacial acetic acid at 60°, and oxidized by the dropwise addition of 30% hydrogen peroxide[21] (10 ml./g. sulfide). After the yellow color of the original solution had disappeared, the solution was warmed at 80° for 30 min. The sulfone usually crystallized at this point or upon standing overnight; in some cases it was necessary to concentrate the solution or to add water or ethanol to cause precipitation. The sulfones were purified by crystallization from water or ethanol.

1-Methyl-4-nitro-5-(*p*-acetamidophenylsulfonyl)-imidazole.—A solution of 1-methyl-4-nitro-5-chloroimidazole (5.0 g.) and 6.2 g. of *p*-acetamidobenzenesulfinic acid in 25 ml. of ethanol and 5 ml. of 6 *N* NaOH was refluxed for 30 min. After the mixture had been cooled to room temperature, 200 ml. of water was added. The precipitated yellow solid was washed with water and alcohol and dried; wt. 5.4 g., m.p. 120–125°. Recrystallization of the sulfone

from alcohol with charcoal treatment gave white needles, m.p. 125–127°, which analyzed as a monohydrate (Table II).

4-Amino-5-imidazole Sulfones.—The 4-nitroimidazole sulfone was suspended in dry ethanol (100 ml./g. sulfone) containing Raney nickel which had been washed repeatedly with dry ethanol. The suspension was reduced in a Parr hydrogenation apparatus at atmospheric pressure until the theoretical amount of hydrogen was taken up (about 15 min. required). While air was excluded by a nitrogen atmosphere, the catalyst was removed, four volumes of anhydrous ether were added, and dry hydrogen chloride was bubbled through the solution for 30 min. After the solvents had been removed by evaporation at 40–60° in a stream of nitrogen, the residue was taken up in 2–3 ml. of dry ethanol, decolorized with charcoal, and the amine hydrochloride was precipitated by addition of a large volume of dry ether. When 1-methyl-4-nitro-5-(*p*-acetamidophenylsulfonyl)-imidazole was reduced, the free base began to precipitate from the reaction mixture, and was obtained in a pure state by removing the catalyst and evaporating the ethanol *in vacuo*.

The 4-amino-5-imidazole sulfides reported (Table I) were prepared similarly by reduction of the nitro compounds.

Infrared Spectra.—All of the reaction products described above were characterized by infrared spectra which were compared with the spectra of known imidazoles. Reduction of 4-nitro-5-imidazole sulfones caused the disappearance of bands in the ranges 1460–1550 and 1360–1380 cm.$^{-1}$; these ranges correspond fairly well to those in which the aromatic nitro group is known to absorb.[22] Concurrent with the disappearance of the nitro group there appeared a strong amino band at 1630–1650 cm.$^{-1}$ and increased NH absorption in the range 3100–3400 cm.$^{-1}$. Oxidation of 4-nitro-5-imidazole sulfides to sulfones caused the appearance of new bands in the ranges 1120–1170 cm.$^{-1}$ and 1300–1330 cm.$^{-1}$, regions in which sulfones are known to absorb.[22] When these compounds were reduced, strong bands were retained in the ranges 1120–1170 and 1300–1330 cm.$^{-1}$. It was difficult, however, to make a definite assignment of the sulfone absorption, since the 4-nitro-5-imidazole sulfides showed some absorption in the same regions, and since there was apparently some interaction between the sulfone and nitro groups.

4-Bromo-5-imidazolesulfonamide.—To 10 ml. of chlorosulfonic acid in a small flask was added 2.0 g. of 4-bromoimidazole.[9] With exclusion of moisture, the mixture was heated slowly to 190–200° and kept at this temperature for 2 hr. The mixture was then poured onto 50 g. of crushed ice, and the colorless sulfonyl chloride, which precipitated, was removed and dried in air; m.p. 186–188° (dec.), wt. 1.7 g. (51%). For preparation of the amide, the crude acid chloride was dissolved in 20 ml. of concd. NH_4OH at room temperature. After 10 min., excess ammonium was removed by gentle warming in a stream of nitrogen and the solution was acidified with HCl. The precipitate weighed 0.76 g. (55%), m.p. 243–244°. After crystallization from water, the m.p. was 246–247°.

Anal. Calcd. for $C_3H_4BrN_3O_2S$: C, 15.92; H, 1.77; N, 18.60; Br, 35.40; S, 14.18. Found: C, 15.99; H, 1.79; N, 18.47; Br, 35.34; S, 14.25.

The anilide and the N,N-dibenzylamide were prepared by the Schotten–Baumann method. *Anal.* Calcd. for anilide: $C_9H_8BrN_3O_2S$: C, 35.79; H, 2.65; N, 13.90; Br, 26.94; S, 10.60. Found: C, 35.37; H, 2.62; N, 13.99; Br, 26.37; S, 10.69. Calcd. for dibenzylamide: $C_{17}H_{16}BrN_3O_2S$: C, 50.20; H, 3.94. Found: C, 50.14; H, 4.12.

Treatment of the amide with nitrous acid[23] gave the sulfonic acid, m.p. 265–267°. *Anal.* Calcd. for $C_3H_3BrN_2O_3S$: C, 15.88; H, 1.32; N, 12.32. Found: C, 15.72; H, 1.40; N, 12.40.

A sample of 4-bromo-5-imidazolesulfonic acid, prepared by sulfonation of 4-bromoimidazole according to Balaban and Pyman,[9] melted at 270–271°; a mixed melting point of this sample with that prepared above was 265–267°. The infrared spectra of the two samples were identical in the fingerprint region.

1(or 3)-Acetyl-4-acetamidoimidazole and 4-Acetamidoimidazole.—4-Nitroimidazole[19] (2.3 g.) was suspended in 50 ml. of acetic anhydride to which was added 20 ml. of glacial acetic acid and 1 teaspoonful of Raney nickel slurry. The mixture was shaken in a Parr hydrogenation apparatus at 31 p.s.i. initial pressure until the theoretical pressure drop occurred (about 2 hr. required). Raney nickel was removed and, while air was excluded by blowing dry nitrogen on the surface, the clear solution was evaporated to dryness on a steam-bath. The black residue was treated with cold water; a gray insoluble residue, which was removed by filtration, weighed 1.2 g. and melted at 225–227°. After crystallization from dioxane with charcoal treatment, the product was obtained colorless and melted at 227.5–228.5°. The infrared spectrum showed a strong band at 1680 cm.$^{-1}$, characteristic of the amide carbonyl group, and an additional band at 1720 cm.$^{-1}$. Since 1-acetylimidazole[20] was found to have a strong band at 1725 cm.$^{-1}$, the compound was assigned the structure of 1(or 3)-acetyl-4-acetamidoimidazole. The infrared spectrum of N-acetylimidazole has also been determined recently by Otting[24] who reported a peak at 1747 cm.$^{-1}$ for the N-acetyl group.

Anal. Calcd. for $C_7H_9N_3O_2$: C, 50.30; H, 5.38; N, 25.12. Found: C, 50.37; H, 5.36; N, 25.06.

When the above compound was treated with a solution of picric acid in aqueous ethanol, a picrate was formed which analyzed as the picrate of 4-acetamidoimidazole, m.p. 202°, reported[17] 208°.

Anal. Calcd. for $C_{11}H_{10}N_6O_8$: C, 37.29; H, 2.82; N, 23.73. Found: C, 37.12; H, 3.08; N, 23.25.

For conversion to 4-acetamidoimidazole, a sample of the diacetyl compound was boiled in water for 30 min., after which the solution was evaporated to dryness *in vacuo* on a steam-bath. The residue was crystallized from dioxane to yield white crystals which were dried *in vacuo* at 140° and 1 mm. pressure; m.p. 220°, reported m.p. 226°[17]; yield 88% from the diacetyl derivative.

Anal. Calcd. for $C_5H_7N_3O$: C, 48.00; H, 5.60; N, 33.59. Found: C, 47.77; H, 5.36; N, 33.28.

Alkaloids of the Amaryllidaceae. X. The Structure of Caranine[1]

BY E. W. WARNHOFF AND W. C. WILDMAN

RECEIVED NOVEMBER 12, 1956

A combination of degradative experiments substantiates the structure I for the alkaloid caranine.

In previous papers[2,3] of this series the alkaloid caranine, isolated from *Amaryllis belladonna* L., was characterized as a base, $C_{16}H_{17}NO_3$. One of the two simplest Amaryllidaceae alkaloids, it contained a methylenedioxyphenyl group, a hydroxyl group, a tertiary nitrogen atom and one double bond.

Preliminary tests on caranine have now shown it to be unaffected by hot 10% hydrochloric acid, hot 90% formic acid, hot 10% ethanolic potassium hydroxide and lithium aluminum hydride. The alkaloid was not oxidized to an α,β-unsaturated ketone by active manganese dioxide although part of the base was destroyed by the reagent. Caranine contained no N-methyl or methoxyl groups, and a Rast molecular weight determination showed the molecular formula to be $C_{16}H_{17}NO_3$.

Hydrogenation of caranine in acetic acid over platinum gave α-dihydrocaranine (IV), m.p. 170.5–172°, $[\alpha]D$ −126°, which proved to be different from β-dihydrocaranine (V), m.p. 166.5–168°, $[\alpha]D$ −191°, obtained from the reduction of caranine in ethanol over palladium.[2]

On the basis of an unusual, but reproducible, modified Oppenauer oxidation of caranine to the phenanthridinium compound II,[3] the base I was postulated to have the lycorine[4] carbon skeleton with a hydroxyl group in the 1-position. The unprecedented nature of the above oxidation does not exclude the possibility of a molecular rearrangement or the possibility that the hydroxyl present in II is not that originally present in caranine but may have been introduced by the air oxidation occurring during the reaction work-up. Hence it was felt desirable to provide additional evidence for each structural feature and in particular for the size of each ring of caranine.

Potassium permanganate oxidation of caranine (I) gave hydrastic acid isolated as its anhydride III, m.p. 179–180.5°, to establish the nature and position of the substituents on ring A.

The size of the B-ring of caranine was determined in the same way as for lycorine.[5] Acetylation of α-dihydrocaranine or hydrogenation of acetylcaranine in acetic acid over platinum gave the same α-dihydroacetylcaranine (VI). This was oxidized with permanganate to the lactam VII whose infrared spectrum in chloroform showed a peak at 6.10 μ characteristic of a 6-membered lactam ring.[5] The lactam was reduced with lithium aluminum hydride to α-dihydrocaranine (IV) to prove that no rearrangement had taken place.

Ring C was investigated through the ketone α-dihydrocaranone (VIII). When a benzene solution of α-dihydrocaranine was stirred for 1.5 hours at room temperature with potassium *t*-butoxide and fluorenone, a 65% yield of pure α-dihydrocaranone was isolated. Its chloroform infrared spectrum had a carbonyl peak at 5.87 μ characteristic of a ketone in a six-membered ring. From the oxidation, in addition to the ketone VIII, there was obtained, in 3% yield, a neutral keto-lactam, $C_{16}H_{13}NO_4$, m.p. 251.5–253°, which must have the structure IX since its complex ultraviolet spectrum is almost identical with the model compound X prepared previously.[3,6]

The isolation of the keto-lactam IX provides additional evidence for the placement of the caranine hydroxyl group in the 1-position. Unequivocal evidence for this point was obtained when the treatment of α-dihydrocaranone with acetic anhydride gave an enol acetate conjugated with the aromatic ring, λ_{max} 264 mμ (ϵ 12,000), possible only with a 1-keto structure. The enol acetate proved too sensitive to oxidation and hydrolysis to be separated from a second product of the reaction, the neutral keto-amide XII, which could have been formed either by direct attack of the anhydride on the nitrogen atom of VIII or by acetylation of the nitrogen after its β-elimination from the C-ring.

The results of the Hofmann degradation of caranine are consistent with the above findings Caranine, like lycorine,[7] gives an α- and a β-methiodide XIII but in the proportion of 2:1. The β-methiodide, m.p. 312–314°, $[\alpha]D$ +62°, crystallized from ethanol–water while the α-methiodide, m.p. 254–255°, $[\alpha]D$ −111°, could be obtained from the filtrates by evaporation to dryness and trituration with ethanol. The Hofmann reaction on the mixture of methiodides was carried out at 120°. The optically inactive caranine anhydromethine, $C_{17}H_{17}NO_2$, m.p. 92–92.5°, obtained by chromatography of the crude product contained no hydroxyl group and did not absorb hydrogen in the presence of palladium. The oxidation of the anhydromethine to 4,5-methylenedioxy-2,3′-biphenyldicarboxylic acid (XVa), m.p. 262.5–263.5°, together with the fact that the nitrogen atom is benzylic to the methylenedioxyphenyl ring

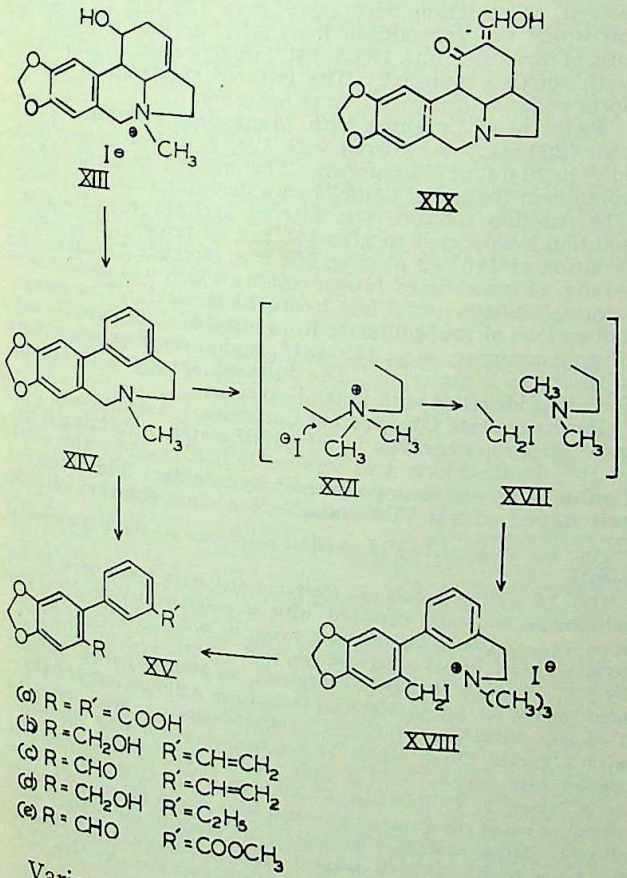
(as shown by formation of lactam VII) proves the structure to be XIV.



Various attempts to prepare the methiodide of caranine anhydromethine failed until its sensitive nature was realized.[8] The best procedure was to allow a methyl iodide solution of the methine to stand at room temperature until a crystalline precipitate slowly settled. This proved to be the product XVIII of reaction of two molecules of methyl iodide with the anhydromethine. Undoubtedly the first reaction was the formation of the normal methiodide XVI which then underwent nucleophilic attack by the iodide ion at the benzylic carbon.[9] The resulting iodo-tertiary amine XVII was quaternized by another molecule of methyl iodide to give XVIII. When this methiodide was subjected to the Hofmann reaction with two equivalents of silver oxide, the vinyl benzyl alcohol XVb was formed.[10] The other product of the reaction, trimethylamine, was isolated as its picrate when the quaternary salt XVIII was heated with aqueous base.

The presence of a vinyl group in XVb was shown by the strong infrared absorption at 10.98 μ[11] which disappeared on hydrogenation with the absorption of one equivalent of hydrogen. The

(8) The strain introduced into the biphenyl system of XIV by the four-atom bridge renders the anhydromethine extremely sensitive to nucleophilic attack at the benzylic carbon bonded to the nitrogen atom when this nitrogen is quaternized by a proton or an alkyl group. This will be elaborated in a later publication.

(9) *Cf.* the formation of 6-phenylpiperonyl iodide from tazettine methine (6-phenylpiperonyl dimethylglycinate) on heating in acetone with methyl iodide at 100°. *Cf.* (a) G. R. Clemo and M. Hoggarth, *Chemistry & Industry*, 1046 (1954); (b) G. R. Clemo and R. Robinson, *ibid.*, 1086 (1955); (c) W. I. Taylor, S. Uyeo and H. Yajima, *J. Chem. Soc.*, 2962 (1955).

(10) A second, crystalline compound, $C_{31}H_{36}O_5$, was isolated from the Hofmann reaction on oily anhydromethine methiodide prepared in acetone at 95°. This was apparently the ether of two molecules of XVb.

hydroxyl of XVb was shown to be benzylic by its oxidation to an aldehyde XVc with active manganese dioxide. Finally, the isolation of 4,5-methylenedioxy-2,3′-biphenyldicarboxylic acid from the permanganate oxidation of the vinyl aldehyde XVc excludes the possibility of a rearrangement in the second Hofmann reaction.

An authentic sample of 3,4-methylenedioxy-2,3′-biphenyldicarboxylic acid was prepared by an Ullmann reaction. Methyl *m*-iodobenzoate and 6-bromopiperonal were condensed in the presence of copper powder to give 14% of methyl 2-formyl-4,5-methylenedioxy-3′-biphenylcarboxylate (XVe) which was saponified and oxidized to the diacid XVa by heating with hydrogen peroxide in basic ethanol solution. In addition to the desired Ullmann product, there were isolated two fluorenones, formed by dehydrogenative coupling of the formyl group of XVe with the unsubstituted *o*-positions of the aromatic ring containing the carbomethoxyl group.[12] The isolation of two fluorenones is possible only if the carbomethoxyl group of XVe is in the 3′-position.

The degradation of the Hofmann product to XVa means that the remaining two carbon atoms forming the D-ring of caranine are joined to the nitrogen atom and either C_2 or C_{3a} (formula I). Attachment at C_2 was eliminated both by (a) the preparation of a hydroxymethylene α-dihydrocaranone (XIX) which had the same ultraviolet absorption peak at 275 mμ, after subtraction of the methylenedioxyphenyl contribution, as a simple α-hydroxymethylene ketone[13] and by (b) Takeda and Kotera's conversion of dihydrolycorine to α-dihydrocaranine.[14,14a]

The position of the double bond in caranine is as yet fixed only by negative evidence. The double bond is not conjugated with the aromatic ring. The failure of caranine to yield an α,β-unsaturated ketone on stirring with manganese dioxide[15] and, more important, the formation of two dihydrocaranines preclude the 2,3-position for the double bond. Nor is the double bond α,β to the nitrogen atom since (a) caranine is not reduced by lithium aluminum hydride, (b) neither the perchlorate of caranine nor of acetylcaranine shows strong infrared absorption in the 6 μ region[16] and (c) the pK_a of α-dihydrocaranine is higher than that of caranine.[17] The double bond must be at least trisubstituted since two isomers were obtained on hydrogenation of caranine. Of the two possible positions 3,3a or 3a,4 for the double bond, the 3,3a-isomer more readily accommodates the oxidation of caranine to II.

(12) For other examples of this reaction see S. Uyeo, *Ber.*, **73**, 661 (1940).

(13) For example, hydroxymethylene taraxerone, λ_{max} 275 mμ, E. Koller, A. Hiestand, P. Dietrich and O. Jeger, *Helv. Chim. Acta*, **33**, 1050 (1950).

(14) K. Takeda and K. Kotera, *Chemistry & Industry*, 347 (1956).

(14a) ADDED IN PROOF.—A third and most convincing argument for the lycorine ring system in caranine is the conversion of lycorine to caranine with sodium and amyl alcohol (W. C. Wildman and H. M. Fales, unpublished observation).

(15) (a) B. C. L. Weedon, *Ann. Repts.*, **49**, 142 (1952); **50**, 169 (1953); (b) F. Sondheimer, E. Amendolla and G. Rosenkranz, THIS JOURNAL, **75**, 5932 (1953).

(16) N. J. Leonard and V. W. Gash, *ibid.*, **76**, 2781 (1954).

(17) R. Adams and J. E. Mahan, *ibid.*, **64**, 2588 (1942).

The stereochemistry of caranine, α-dihydrocaranine and β-dihydrocaranine as indicated in I, IV and V, respectively, follows from the work of Takeda and Kotera[14] who have produced convincing evidence that monodesoxydihydrolycorine, identical with α-dihydrocaranine,[18] has the stereochemistry shown in IV. If no double bond migration has taken place during any of the hydrogenations, β-dihydrocaranine must be the C_{3a} epimer of α-dihydrocaranine.

Experimental[19]

Preliminary Tests.—Caranine was recovered unchanged after (a) 2-hour reflux in 10% hydrochloric acid, (b) 1-hour reflux in 10% ethanolic potassium hydroxide and (c) 4-hour reflux with 90% formic acid.

Anal. Calcd. for $C_{16}H_{17}NO_3$: (1) OCH_3, 11.43; (1) (N)–CH_3, 5.54; (1) (C)–CH_3, 5.54; mol. wt., 271. Found: OCH_3, none; (N)–CH_3, 0.53; (C)–CH_3, none; mol. wt. (Rast), 277.

In dimethylformamide-water (3:7) these pK_a's were obtained: caranine, 7.60; α-dihydrocaranine, 9.00; lycorine, 6.90; dihydrolycorine, 8.67.

The addition of a few drops of 70% perchloric acid to a solution of 100 mg. of acetylcaranine in 5 ml. of ether gave 123 mg. (93%) of **acetylcaranine perchlorate** which was recrystallized three times from 99% ethanol to give colorless prisms, m.p. 259.5–261.5°, λ_{max}^{Nujol} 2.91, 5.77, 9.72 and 10.80 μ with no strong absorption in the 6 μ region.

Anal. Calcd. for $C_{18}H_{19}NO_4 \cdot HClO_4$: C, 52.24; H, 4.87; N, 3.38. Found: C, 52.58; H, 4.98; N, 3.50.

Action of Lithium Aluminum Hydride on Caranine.—A solution of 150 mg. of caranine in 10 ml. of dry tetrahydrofuran was refluxed with 150 mg. of lithium aluminum hydride for 25 hours. The excess hydride was destroyed with ethyl acetate and concentrated aqueous sodium hydroxide was added until the precipitated aluminum hydroxide dissolved. Extraction with ether gave 138 mg. of colorless oil which was crystallized from ethyl acetate to yield 111 mg. of caranine, m.p. 178.5–181°, undepressed on admixture with starting material. The infrared spectrum in chloroform was identical with that of caranine.

Reaction of Caranine with Manganese Dioxide.—Caranine (200 mg.) was stirred with 1.00 g. of manganese dioxide[20] in 10 ml. of chloroform. The infrared spectrum of the solution at the end of 1 and 2 hours showed no carbonyl band. The reaction mixture was filtered and the emerald-green solution evaporated to give 146 mg. of brown glass. Sublimation at 145° (2 μ) gave 106 mg. of crude caranine and 40 mg. of unsublimed brown residue which was insoluble in organic solvents and dilute hydrochloric acid. Two recrystallizations of the sublimate from ethyl acetate gave 62 mg. of pure caranine, m.p. 179–181°, undepressed on admixture with starting material. The infrared spectrum in chloroform was identical with that of caranine.

Permanganate Oxidation of Caranine.—A solution of 1.00 g. of caranine dissolved in 50 ml. of water containing 6 ml. of 10% hydrochloric acid was made just basic by the addition of 10% aqueous potassium hydroxide. This solution was stirred with a Vibro-mischer[21] while a solution of 5.00

(18) For a comparison of physical properties see the Experimental section.

(19) All melting points are corrected and were taken on a Kofler microscope hot-stage equipped with a polarizer unless otherwise specified. Optical rotations were taken in a 2-dm. tube on chloroform solutions unless otherwise specified. Analyses were performed by J. F. Alicino, Metuchen, New Jersey; W. Manser, Zurich, Switzerland; and W. C. Alford, National Institute of Arthritis and Metabolic Diseases, Bethesda, Maryland. Infrared spectra were recorded with a Perkin-Elmer Model 21 spectrophotometer and ultraviolet spectra were recorded with a Cary Model 11MS spectrophotometer by F. Byers, F. C. Bateman, C. Monaghan and C. Smith. Unless otherwise noted the ultraviolet spectra were run in Pharmco absolute ethanol. Molar extinction coefficients are given in parentheses after the wave length. Merck reagent grade chromatographic alumina (*p*H 10) was used. The pK_a measurements were made by Mrs. L. E. Giuffrida.

g. of potassium permanganate in 250 ml. of water was added dropwise during 45 minutes. After an additional 15-minute stirring period the reaction mixture was treated with sulfur dioxide until solution of the manganese dioxide was effected. A few milliliters of dilute sulfuric acid was added and the yellow solution was extracted with ethyl acetate to give 413 mg. of yellow solid. The solid was triturated with 10% potassium bicarbonate solution and filtered. Acidification of the filtrate followed by ethyl acetate extraction gave 178 mg. of solid which was refluxed with 8 ml. of 20% aqueous sodium hydroxide under nitrogen for 3.5 hours. A yellow gum (84 mg.) was obtained on acidification and extraction with ethyl acetate. This was sublimed at 160° (0.3 mm.) to give 12.5 mg. of crude hydrastic anhydride (III), m.p. 168–175°.

Continuous ether extraction of the original aqueous layer from the oxidation gave 83 mg. of brown oil which was sublimed at 160° (0.3 mm.) to give 8.5 mg. more of crude hydrastic anhydride, m.p. 140–155°, bringing the total yield to 3%.

A sample of the sublimate (4.5 mg.) was recrystallized from cyclohexane–acetone to give 3.0 mg. of pure **hydrastic anhydride**, m.p. 179–180.5°, undepressed on admixture with an authentic specimen[22] of m.p. 179.5–180.5°. The infrared spectra of the two samples in chloroform were identical, $\lambda_{max}^{CHCl_3}$ 5.40, 5.49, 5.65, 6.28, 9.70 and 10.69 μ.

Another sample of the crude anhydride (8.0 mg.) was triturated in a sublimation tube with 2 drops of 30% aqueous ethylamine. The tube was heated to drive off the water and the residue was sublimed at 160° (0.3 mm.) to give 8.0 mg. of **N-ethylhydrastimide**, m.p. 150–164°. Recrystallization from ethanol gave 5 mg. of colorless blades, m.p. 168.5–169.5°, undepressed on admixture with an authentic specimen[23] of m.p. 169–170°. The ultraviolet and infrared spectra of the two specimens were identical, λ_{max} 245 (41,100), 302 (1860), 313 (1810) and 341 mμ (1010); $\lambda_{max}^{CHCl_3}$ 5.64, 5.85, 6.23, 9.66 and 10.66 μ.

Hydrogenation of Caranine in Acetic Acid with Platinum.—A solution of 5.000 g. of caranine in 30 ml. of glacial acetic acid was added to a suspension of 400 mg. of reduced platinum oxide in 5 ml. of glacial acetic acid. The reduction stopped in two hours after 0.96 equivalent of hydrogen was absorbed at atmospheric pressure and room temperature. Most of the acetic acid was evaporated from the solution after filtration and the residue was basified with 10% aqueous potassium hydroxide before extraction with ethyl acetate. Concentration of the dried solution gave 3.626 g. (72%) of **α-dihydrocaranine** (IV), m.p. 169–172°. A second crop of 0.300 g. (6%), m.p. 168–172°, brought the total yield to 78%. Three recrystallizations from ethyl acetate gave colorless prisms, m.p. 170.5–172°, $[\alpha]^{26}D$ −126° (*c* 0.441), λ_{inf} 233 mμ (4400) and λ_{max} 291 mμ (4700); $\lambda_{max}^{CHCl_3}$ 2.77, 9.65 and 10.70 μ.

Anal. Calcd. for $C_{16}H_{19}NO_3$: C, 70.31; H, 7.01; N, 5.13. Found: C, 70.44; H, 6.95; H, 5.27.

The picrate was prepared with ethanolic picric acid and recrystallized three times from acetone–ethanol to give clusters of yellow needles, m.p. 149–150° and 172–173° dec.

Anal. Calcd. for $C_{16}H_{19}NO_3 \cdot C_6H_3N_3O_7$: C, 52.59; H, 4.41; N, 11.15. Found: C, 52.65; H, 4.60; N, 11.23.

A sample of **monodesoxydihydrolycorine** kindly supplied by Dr. Takeda[14] had m.p. 170.5–172.5°, $[\alpha]^{24}D$ −126° (*c* 0.610). The mixture melting point with α-dihydrocaranine was 170.5–172.5°. The infrared spectra of the two compounds in chloroform were identical. The mixture melting point of the monodesoxydihydrolycorine and β-dihydrocaranine was depressed to 141–160°.

Hydrogenation of Caranine in Ethanol with Palladium.—A solution of 300 mg. of caranine in 9 ml. of ethanol in the presence of 100 mg. of 10% palladium-on-carbon catalyst took up one mole of hydrogen at room temperature and atmospheric pressure. Filtration of the solution and evaporation of the solvent gave 290 mg. of colorless glass. This was crystallized from ethyl acetate to give 96 mg. (32%) of β-dihydrocaranine (V), m.p. 157–163°. A second crop of 41 mg. (14%), m.p. 156–162°, brought the total yield to 46%. Five recrystallizations from ethyl acetate–cyclohexane gave colorless prisms, m.p. 166.5–168° (depressed to 142–164° on admixture with α-dihydrocaranine), $[\alpha]^{25}D$ −191° (*c* 0.520), λ_{inf} 233 mμ (3720), λ_{max} 292 mμ (4650); $\lambda_{max}^{CHCl_3}$ 2.75, 9.65 and 10.69 μ.

Anal. Calcd. for $C_{16}H_{19}NO_3$: C, 70.31; H, 7.01; N, 5.13. Found: C, 70.64; H, 7.00; N, 5.08.

The picrate was prepared with ethanolic picric acid and recrystallized twice from chloroform–ethanol to give yellow spherulites, m.p. 174–175° dec., depressed to 163–171° on admixture with α-dihydrocaranine picrate.

Anal. Calcd. for $C_{16}H_{19}NO_3 \cdot C_6H_3N_3O_7$: C, 52.59; H, 4.41. Found: C, 52.65; H, 4.35.

Hydrogenation of Acetylcaranine.—A solution of 230 mg. of acetylcaranine in 8 ml. of glacial acetic acid was stirred under hydrogen with 72 mg. of platinum oxide catalyst. The reduction stopped in 20 minutes after the absorption of 20 ml. (108% of one equivalent) of hydrogen. The catalyst was removed by filtration and most of the acetic acid evaporated at reduced pressure. The residue was dissolved in 2% hydrochloric acid, washed with ethyl acetate, basified and extracted with ethyl acetate to give 220 mg. (95%) of colorless oil which crystallized. Five recrystallizations from ethyl acetate–cyclohexane gave colorless felted needles of **α-dihydroacetylcaranine** (VI), m.p. 193.5–195°, $[\alpha]^{23.5}D$ −121° (*c* 0.332), λ_{max} 235 (3950) and 293 mμ (4770); $\lambda_{max}^{CHCl_3}$ 5.77, 9.64 and 10.67 μ.

Anal. Calcd. for $C_{18}H_{21}NO_4$: C, 68.55; H, 6.71; N, 4.44. Found: C, 68.65; H, 6.81; N, 4.46.

The picrate was prepared in ethanol solution and when crystallized rapidly from chloroform–ethanol gave feathery needles, m.p. 182–184°, but when crystallized slowly from the same solvent gave micaceous yellow plates, m.p. 188–189°.

Acetylation of α-Dihydrocaranine (IV).—A solution of 200 mg. of α-dihydrocaranine in 3 ml. of dry pyridine and 1 ml. of acetic anhydride was refluxed for 3 hours. Most of the acetylation mixture was removed at reduced pressure. The residue was taken up in chloroform, washed with aqueous potassium carbonate solution, dried and evaporated to give 225 mg. of yellow oil which was chromatographed on 7 g. of alumina. Benzene and benzene–ethyl acetate (49:1) eluted 183 mg. (80%) of α-dihydroacetylcaranine (VI) which crystallized.

A solution of 50 mg. of the acetate in ethanol gave 79 mg. (92%) of **picrate**, m.p. 183–192°, on treatment with ethanolic picric acid. Four recrystallizations from chloroform–ethanol gave yellow micaceous plates, m.p. 188–189°, λ_{max} 237 (15,200), 292.5 (6450) and 359 mμ (15,700).

Anal. Calcd. for $C_{18}H_{21}NO_4 \cdot C_6H_3N_3O_7$: C, 52.94; H, 4.44; N, 10.29. Found: C, 52.73; H, 4.51; N, 10.15.

This picrate exhibited the same polymorphic behavior as the picrate in the preceding experiment and the mixture melting point of the two was undepressed. The infrared spectra of the two picrates in chloroform were identical.

Oxidation of α-Dihydroacetylcaranine.—A solution of 290 mg. (0.92 mmole) of α-dihydroacetylcaranine in 8 ml. of reagent-grade acetone was cooled to 1–2° in an ice–salt bath. A solution of 194 mg. (1.23 mmoles) of potassium permanganate in 19 ml. of water was cooled to 5° and added dropwise over a period of 20 minutes to the stirred acetone solution. At the end of the addition period all permanganate had been reduced. The reaction mixture was filtered through Celite and the manganese dioxide washed with acetone. The filtrates were evaporated to dryness and taken up in ether–chloroform before washing with dilute hydrochloric acid. Concentration of the dried organic layer gave 135 mg. (44% crude yield) of oily **α-dihydroacetylcaranine lactam** (VII) which crystallized on trituration with ethyl acetate, m.p. 180°. Four recrystallizations from ethyl acetate–cyclohexane gave irregular prisms, m.p. 192–194°; $[\alpha]^{23}D$ −171° (*c* 0.595); λ_{max} 222 (29,900), 251 (5150), 265 (4600) and 305 mμ (6940); $\lambda_{max}^{CHCl_3}$ 5.80, 6.11, 6.25, 9.67 and 10.70 μ.

Anal. Calcd. for $C_{18}H_{19}NO_5$: C, 65.64; H, 5.82; N, 4.25. Found: C, 65.39; H, 5.63; N, 4.21.

Reduction of α-Dihydroacetylcaranine Lactam.—A solution of 30 mg. of the lactam VII, m.p. 189–193°, in 10 ml. of ether was refluxed with lithium aluminum hydride for 22 hours. The excess hydride was decomposed with dilute hydrochloric acid and the aqueous solution was washed with ether. Basification of the acid solution followed by extrac-

tion with ether gave 19 mg. of crystals, m.p. 168°. Recrystallization from ethyl acetate gave 5 mg. of **α-dihydrocaranine** (IV), m.p. 170–172.5°, undepressed on admixture with an authentic sample of m.p. 170.5–172°. The infrared spectra of the two samples in chloroform were identical.

Modified Oppenauer Oxidation of α-Dihydrocaranine (IV).—Potassium *t*-butoxide was prepared from 2.30 g. of potassium and 75 ml. of dry *t*-butyl alcohol. The excess alcohol was evaporated at reduced pressure. To the dry alkoxide were added a magnetic stirring bar, 65 ml. of benzene, 5.00 g. of fluorenone and 3.000 g. (11.0 mmoles) of α-dihydrocaranine, m.p. 169–172°. The reaction mixture was put under nitrogen and stirred at room temperature. The color changed from orange to a dark brown within the first few seconds after mixing. At the end of 1.5 hours water was added to the brown mixture whereupon the color lightened to an orange-yellow. The aqueous layer was separated and washed twice with ether. The combined organic layers were washed once with water and extracted with three portions of 5% hydrochloric acid. The combined acid layers were washed with ether and basified with concentrated sodium hydroxide solution. The oil which precipitated was extracted with ether to give 2.873 g. (96% crude yield) of crystalline α-dihydrocaranone (VIII). Recrystallization from methanol gave 1.945 g. (65%) of long colorless prisms, m.p. 140–149°. The analytical sample after three more recrystallizations from methanol had m.p. 141–148°, unchanged when taken in a nitrogen atmosphere, $[\alpha]^{25}D$ 0°, $[\alpha]^{25}_{436}$ +24° (*c* 0.849); λ_{inf} 226 mμ (5660), λ_{max} 289 mμ (4600); $\lambda_{max}^{CHCl_3}$ 5.87, 9.68 and 10.70 μ.

Anal. Calcd. for $C_{16}H_{17}NO_3$: C, 70.83; H, 6.32; N, 5.16. Found: C, 70.97; H, 6.44; N, 5.25.

A solution of 40 mg. of the ketone and 50 mg. of 2,4-dinitrophenylhydrazine in 4 ml. of glacial acetic acid was warmed on a steam-bath and allowed to stand at room temperature overnight. Dilution of the solution with water and neutralization of the acid precipitated 71 mg. of 2,4-dinitrophenylhydrazone which was recrystallized twice from chloroform–ethanol to give felted orange needles which decomposed with a yellow flash at *ca.* 270° on a Kofler Heizbank, $\lambda_{max}^{CHCl_3}$ 3.01, 6.19, 6.28, 9.67 and 10.70 μ.

Anal. Calcd. for $C_{22}H_{21}N_5O_6$: C, 58.53; H, 4.69; N, 15.52. Found: C, 58.90; H, 4.46; N, 16.04.

The material in the mother liquor from recrystallization of the ketone was taken up in ether–ethyl acetate and washed with three portions of 5% hydrochloric acid, dried and evaporated to give 100 mg. (3%) of neutral keto-lactam (IX), m.p. 220–250°, which was recrystallized three times from chloroform–methanol to give small felted needles, m.p. 251.5–253°, $[\alpha]^{26}D$ −21.5° $[\alpha]^{26}_{436}$ −92° (*c* 1.01), λ_{max} 214 (12,600), 247 (30,900), 265 (28,000), 303 (7140), 330 (9480) and 344 mμ (9480); $\lambda_{max}^{CHCl_3}$ 6.09, 6.18, 6.30, 9.65 and 10.65 μ. The model compound X[3] had λ_{max} 216 (11,700), 246 (30,500), 265, (27,400), 316 (8380), 331 (9600) and 345 mμ (8200).

Anal. Calcd. for $C_{16}H_{13}NO_4$: C, 67.84; H, 4.63; N, 4.95. Found: C, 67.84; H, 4.70; N, 4.88.

The 2,4-dinitrophenylhydrazone was prepared and recrystallized twice from dimethylformamide as felted red needles, m.p. 299–302° dec.

Anal. Calcd. for $C_{22}H_{17}N_5O_7$: C, 57.02; H, 3.70; N, 15.11. Found: C, 56.89; H, 3.77; N, 15.34.

Reaction of Acetic Anhydride with α-Dihydrocaranone.—A solution of 400 mg. of α-dihydrocaranone (VIII) and three drops of triethylamine in 2 ml. of acetic anhydride was kept under nitrogen at 90° for 2 hours. The clear brown solution was evaporated to dryness *in vacuo*. The infrared spectrum of the crude material in chloroform showed carbonyl absorption at 5.73, 5.99, and 6.10 μ which indicated a mixture of enol acetate XI and keto amide XII. The brown glass was dissolved in ethyl acetate, washed with 5% hydrochloric acid and 5% potassium hydroxide solution, dried and evaporated to give 252 mg. (55%) of oily keto-amide XII which crystallized on trituration with ethyl acetate. Three recrystallizations from ethyl acetate–cyclohexane gave colorless prisms, m.p. 182.5–184.5°, $[\alpha]^{27}D$ +242° (*c* 0.565); λ_{max} 245 mμ (10,300), λ_{inf} 260 (7350) and 292 mμ (3910); $\lambda_{max}^{CHCl_3}$ 5.99, 6.12, 9.66 and 10.72 μ.

Anal. Calcd. for $C_{18}H_{19}NO_4$: C, 68.99; H, 6.11; N, 4.47; (N)-$COCH_3$, 13.73. Found: C, 68.89; H, 6.22; N, 4.44; (N)-$COCH_3$, 14.52.

The 2,4-dinitrophenylhydrazone was prepared and recrystallized twice from dimethylformamide to give small red needles, m.p. 300–301° dec., in amount insufficient for analysis.

Attempts to isolate the pure enol acetate XI from acetylations under milder conditions by fractional sublimation, crystallization and rapid chromatography failed because of the sensitivity of the compound to oxidation and hydrolysis. A sample of the crude enol acetate containing very little XII had λ_{max} 263 (12,000) and λ_{max} 304 mμ (5720) compared to λ_{max} 260 (11,800) and 305 mμ (5200) for isosafrole. The infrared spectrum in chloroform had λ_{max} 5.72, 9.65 and 10.70 μ with weaker peaks at 6.00 and 6.11 μ.

Caranine α- and β-Methiodides (XIII).—To a refluxing solution of 6.00 g. (22.1 mmoles) of caranine, m.p. 178.5–180.5°, in 130 ml. of benzene was added 20 ml. of redistilled methyl iodide. A white precipitate formed immediately. The reaction mixture was cooled and filtered to give 9.15 g. (100%) of crude methiodide, m.p. 270–275° dec., $[\alpha]^{28}D$ −60° (*c* 0.34, 1:1 water–dimethylformamide).

A 200-mg. sample was recrystallized from water–ethanol to give 76 mg. (38%) of colorless blades, m.p. 305–308° dec. Two more recrystallizations from water–ethanol gave pure **caranine β-methiodide**, m.p. 312–314° dec. (reported[2] 316–318° dec.), $[\alpha]^{28}D$ +62° (*c* 0.28, 1:1 water–dimethylformamide); λ_{max} 291 mμ (4740); λ_{max}^{KBr} 2.90, 9.69 and 10.75 μ.

The filtrates from the first recrystallization of the methiodide were evaporated to dryness and the resulting glass triturated with ethanol whereupon it crystallized. Recrystallization from 99% ethanol gave 98 mg. (49%) of **caranine α-methiodide**, m.p. 255–256° dec. Three more recrystallizations from 99% ethanol gave colorless felted needles, m.p. 254–255° dec., $[\alpha]^{25}D$ −111° (*c* 0.459, 1:1 water–dimethylformamide); λ_{max} 293 mμ (4600); λ_{max}^{KBr} 2.92, 9.70 and 10.72 μ.

Anal. Calcd. for $C_{17}H_{20}NO_3I$: C, 49.40; H, 4.88; N, 3.39. Found: C, 49.68; H, 5.17; N, 3.49.

The proportion of α- to β-methiodide calculated from rotation data is 70:30 whereas that calculated from the fractional crystallization is 62:38.

The Hofmann Reaction on Caranine Methiodide.—To a suspension of 8.95 g. (21.6 mmoles) of a mixture of caranine α- and β-methiodides in 80 ml. of water was added neutral silver oxide prepared from 3.900 g. (22.9 mmoles) of silver nitrate. The formation of the methohydroxide was shown to be complete within a few minutes when a centrifuged sample of the mixture gave no precipitate with silver nitrate–nitric acid solution. The silver salts were removed by filtration through Celite. The clear filtrate was evaporated under reduced pressure at 50°. The flask containing the greenish residual oil was put under nitrogen and immersed in an oil-bath at 120° for 40 minutes. The water given off was removed at reduced pressure, and the brown glass dried in a desiccator to give 5.76 g. (99%).

The product was partitioned between ether and 5% hydrochloric acid. The acid solution was washed with ether, cooled in an ice-bath and basified with concentrated sodium hydroxide solution. Ether extraction gave 4.80 g. of brown oil which was dissolved in cyclohexane and chromatographed on a column of 120 g. of alumina. Elution with cyclohexane:benzene (49:1) gave 2.22 g. of colorless oil which solidified. Recrystallization from methanol gave 1.95 g. (33%) of **caranine anhydromethine** (XIV), m.p. 91–92.5°.

The material eluted with cyclohexane:benzene (3:1) was rechromatographed to give an additional 208 mg., m.p. 91–92.5° after recrystallization from methanol, bringing the total yield to 37%.

Three additional recrystallizations from methanol gave white flakes, m.p. 92–92.5°, $[\alpha]^{24}D$ 0°, $[\alpha]^{24}_{436}$ 0° (*c* 0.835); λ_{max} 255 (8460) and 302 mμ (7080); $\lambda_{max}^{CHCl_3}$ 6.25, 6.37, 9.67 and 10.76 μ.

Anal. Calcd. for $C_{17}H_{17}NO_2$: C, 76.38; H, 6.41; N, 5.24; (N)-CH_3, 5.62. Found: C, 76.25; H, 6.36; N, 5.11; (N)-CH_3, 4.07; (C)-CH_3, none.

The anhydromethine (42 mg.) gave 75 mg. (96%) of picrate, m.p. 124–148° when treated with ethanolic picric acid. The derivative was recrystallized twice by solution

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

in a small volume of acetone at room temperature followed by addition of ethanol and chilling to −20° to give the pure picrate, m.p. 130–152°, λ_{max} 304 (10,200) and 358 mμ (16,100).

Anal. Calcd. for $C_{17}H_{17}NO_2 \cdot C_6H_3N_3O_7$: C, 55.64; H, 4.06; N, 11.29. Found: C, 55.68; H, 4.02; N, 11.20.

When the salt was warmed above *ca.* 50° in aqueous or alcoholic solution, an acid-catalyzed rearrangement occurred. Presumably the low and wide melting point of the picrate is also due to this rearrangement taking place.

A solution of 100 mg. of the anhydromethine in 8 ml. of 99% ethanol with 100 mg. of 10% palladium-on-carbon did not absorb any hydrogen in two hours. The anhydromethine was recovered unchanged on evaporation of the alcohol.

Oxidation of Caranine Anhydromethine.—To a solution of 400 mg. (1.50 mmoles) of caranine anhydromethine (XIV) in 50 ml. of water containing 3 ml. of 10% hydrochloric acid was added 10% aqueous potassium hydroxide until the solution was neutral and there was only a faint turbidity. This solution was warmed to 70°, and a solution of 1.895 g. (12.0 mmoles) of potassium permanganate in 100 ml. of water was added dropwise during 0.5 hour with stirring by a Vibro-mischer.[21] A few minutes after addition was over all the permanganate had been reduced. The reaction mixture was cooled and sulfur dioxide bubbled in until solution of the manganese dioxide was effected. The solution was extracted continuously with ethyl acetate after the addition of 5 ml. of 10% sulfuric acid. Evaporation of the ethyl acetate gave 233 mg. of brown gum which after trituration with chloroform left 53 mg. of insoluble acid. The chloroform solution containing 180 mg. was chromatographed on 15 g. of Mallinckrodt silicic acid. Chloroform–methanol (99:1) eluted 69 mg. of the same crude acid which had not dissolved in chloroform. This material could not be completely purified by recrystallization from ethyl acetate. Some of the purer crops of crystals were combined (44 mg.) in ethyl acetate and converted to the methyl ester with ethereal diazomethane. Evaporation of the solvent and chromatography of the residue on 2.5 g. of alumina gave 24 mg. of crystalline ester eluted with benzene. The ester was dissolved in 3 ml. of methanol and refluxed for 1 hour with 2 ml. of water containing 0.8 g. of sodium hydroxide. The methanol was boiled off and the cooled aqueous solution acidified with dilute sulfuric acid. The resulting white precipitate was filtered, washed and dried to give 19 mg. of **4,5-methylenedioxy-2,3′-biphenyldicarboxylic acid** (XVa) which was recrystallized from ethyl acetate–benzene to give 17 mg. (4%) of small white prisms, m.p. 262.5–263.5°. The mixture melting point with an authentic specimen, m.p. 262.5–263.5°, prepared as described below, was 261–263.5°. The infrared and ultraviolet spectra of the two compounds were identical, λ_{max} 226 (37,200), 267.5 (6750) and 295 mμ (5950); λ_{max}^{KBr} 3.70–3.95, 5.92, 6.20, 9.72 and 10.81 μ.

Anal. Calcd. for $C_{15}H_{10}O_6$: C, 62.94; H, 3.52. Found: C, 62.84; H, 3.61.

Caranine Anhydromethine Bis-methiodide (XVIII).—Caranine anhydromethine (1.000 g., 3.74 mmoles) was dissolved in 13 ml. of redistilled methyl iodide and allowed to stand at room temperature protected from light. After 17 hours 600 mg. (29%) of tan solid was removed by filtration. After another 8 hours 157 mg. (7.6%) of almost colorless matted needles separated. Further crops collected over a period of several days gave 1.181 g. (57%) more bis-methiodide for a total yield of 93% of XVIII. The salt decomposed on warming with solvents. A sample prepared for analysis by washing a colorless crop of the matted needles several times with benzene before drying at room temperature *in vacuo* had m.p. 199–201° dec., λ_{max} 295 mμ (6700).

Anal. Calcd. for $C_{19}H_{23}NO_2I_2$: C, 41.39; H, 4.20; N, 2.54; I, 46.05; (3) (N)–CH_3, 8.18. Found: C, 41.01; H, 4.12; N, 2.67; I, 44.83; (N)–CH_3, 8.18.

Isolation of Trimethylamine from Caranine Anhydromethine Bis-methiodide.—A mixture of 135 mg. of the bis-methiodide XVIII and 10 ml. of 10% potassium hydroxide solution was heated to reflux in an oil-bath. Nitrogen was passed through the solution and the effluent gas bubbled through an ethanolic solution of picric acid. A slow precipitation of trimethylamine picrate occurred. The picrate was recrystallized twice from ethanol to give long yellow prisms, m.p. 213–216° (sealed capillary), undepressed on admixture with an authentic specimen of trimethylamine picrate, m.p. 214–217° (sealed capillary). The infrared spectra of the two picrates in chloroform were identical. The organic material in the potassium hydroxide solution was an intractable brown gum.

The Hofmann Reaction on Caranine Anhydromethine Bis-methiodide.—To a suspension of 1.246 g. (2.26 mmoles) of the crystalline bis-methiodide XVIII in 15 ml. of water was added the neutral silver oxide from 800 mg. (4.71 mmoles) of silver nitrate. The mixture was stirred until a sample of the supernatant liquid gave no precipitate with silver nitrate–nitric acid solution. The silver salts were separated by centrifugation and the opalescent solution of quaternary amine hydroxide decanted and evaporated to dryness *in vacuo* at 60°. An aspirator was attached to the flask which was immersed in an oil-bath at 120° for 30 minutes. The dark brown residue was taken up in benzene, washed twice with dilute hydrochloric acid, dried and evaporated to give 280 mg. (48%) of neutral yellow oil. This was combined with 47 mg. of oil from a smaller scale reaction, dissolved in benzene and chromatographed on 10 g. of alumina. Elution with benzene–ethyl acetate (1:1) gave 270 mg. of colorless **2-hydroxymethyl-4,5-methylenedioxy-3′-vinylbiphenyl** (XVb) which did not crystallize on trituration with various solvents. A sample was evaporatively distilled at 140° (0.025 mm.); λ_{max} 251 (22,100) and 293 mμ (5900); $\lambda_{max}^{CHCl_3}$ 2.76, 2.90, 6.19, 6.26, 6.31, 9.66, 10.73 and 10.98 μ.

Anal. Calcd. for $C_{16}H_{14}O_3$: C, 75.57; H, 5.55. Found: C, 75.69; H, 5.52.

From a Hofmann reaction on the crude bis-methiodide prepared by heating crude, non-crystalline caranine anhydromethine with methyl iodide in acetone at 95° was obtained by chromatography on alumina a neutral, nitrogen-free compound which was apparently the ether derived from two molecules of XVb, m.p. 111–113° after three recrystallizations from 99% ethanol, λ_{max} 252 (41,400) and 293 mμ (11,400); $\lambda_{max}^{CHCl_3}$ 6.18; 6.25; 6.35, 9.65, 10.72 and 11.00 μ.

Anal. Calcd. for $C_{32}H_{26}O_5$: C, 78.35; H, 5.34. Found: C, 78.27; H, 5.44; N, 0.0.

Hydrogenation of 2-Hydroxymethyl-4,5-methylenedioxy-3′-vinylbiphenyl.—A solution of 71 mg. of XVb in 5 ml. of 99% ethanol absorbed 7.0 ml. (92% of one equivalent) of hydrogen over 40 mg. of 10% palladium-on-carbon catalyst in 8 minutes at room temperature and atmospheric pressure. Filtration of the solution and evaporation of the solvent gave 62 mg. of **2-hydroxymethyl-4,5-methylenedioxy-3′-ethylbiphenyl** (XVd), a colorless liquid, which was evaporatively distilled at 140° (0.03 mm.); λ_{max} 257 (7210) and 293 mμ (5400); $\lambda_{max}^{CHCl_3}$ 2.76, 2.90, 6.19, 6.25, 6.33, 9.65 and 10.72 μ.

Anal. Calcd. for $C_{16}H_{16}O_3$: C, 74.98; H, 6.29. Found: C, 74.53; H, 6.25.

The ultraviolet spectrum of 6-phenylpiperonyl alcohol has λ_{max} 257.5 (7150) and 293 mμ (5410) for comparison.

An attempt to prepare a 3,5-dinitrobenzoate of the alcohol by allowing the alcohol in pyridine to react with 3,5-dinitrobenzoyl chloride at room temperature for 4 days gave recovered starting material.

2-Formyl-4,5-methylenedioxy-3′-vinylbiphenyl (XVc).—Manganese dioxide[20] (700 mg.) was added to a solution of 146 mg. of the benzyl alcohol XVb in 10 ml. of chloroform. The mixture was stirred for three hours at the end of which time the solution showed strong carbonyl absorption at 5.95 μ and no hydroxyl absorption. The solution was filtered and evaporated to give 137 mg. of colorless oil. Chromatography over 4 g. of alumina gave 116 mg. (80%) of XVc in the benzene eluate. The aldehyde crystallized from ethanol at −78° but after separation from solvent liquefied at room temperature. Evaporative distillation at 140° (0.025 mm.) gave a colorless glass, λ_{max} 247 (40,000) and 325 mμ (6630); $\lambda_{max}^{CHCl_3}$ 5.97, 6.20, 9.66, 10.70 and 10.96 μ.

Anal. Calcd. for $C_{16}H_{12}O_3$: C, 76.18; H, 4.80. Found: C, 76.38; H, 5.04.

The 2,4-dinitrophenylhydrazone was prepared and recrystallized four times from chloroform–ethanol to give small felted orange needles, m.p. 215.5–216.5°, $\lambda_{max}^{CHCl_3}$ 396 mμ (30,400); $\lambda_{max}^{CHCl_3}$ 3.04, 6.21, 6.28, 9.67, and 10.72 μ.

Anal. Calcd. for $C_{22}H_{16}N_4O_6$: C, 61.11; H, 3.73; N, 12.96. Found: C, 60.95; H, 3.94; N, 12.95.

Oxidation of 2-Formyl-4,5-methylenedioxy-3′-vinylbiphenyl.—To a solution of 48 mg. of the aldehyde XVc in 6 ml. of reagent-grade acetone stirred with a magnetic stirring bar was added a solution of 90 mg. of potassium permanganate in 3 ml. of water. After the 2-minute addition period the brown reaction mixture was allowed to stir for 30 minutes. Sulfur dioxide was added until solution of the manganese dioxide. Most of the acetone was blown off in an air jet and the residual aqueous solution was extracted continuously with ethyl acetate. The ethyl acetate was evaporated and to the residue was added 3 ml. of ethanol, 3 ml. of water and 1 g. of sodium hydroxide. This mixture was warmed for 45 minutes on the steam-bath during the dropwise addition of 12 ml. of 30% hydrogen peroxide. Acidification of the cooled solution gave 33 mg. of white precipitate, m.p. 240–252°. This acid was converted to the methyl ester with ethereal diazomethane and chromatographed on 2 g. of alumina. The benzene eluate (24.5 mg.) was saponified with methanolic sodium hydroxide. Acidification of the solution and recrystallization of the white precipitate from ethyl acetate–benzene gave 12.5 mg. (23%) of **4,5-methylenedioxy-2,3′-biphenyldicarboxylic acid** XVa, m.p. 262.5–263.5°, undepressed on admixture with an authentic specimen of m.p. 262.5–263.5°, prepared as described below. The infrared spectra of the two acids were identical, λ_{max}^{KBr} 3.70–3.95, 5.93, 6.22, 9.73 and 10.83 μ.

2-Hydroxymethylene-α-dihydrocaranone (XIX).—A solution of 654 mg. of α-dihydrocaranone in 6 ml. of benzene and 3 ml. of redistilled ethyl formate was refluxed under nitrogen with 335 mg. of sodium methoxide for 3 hours. The reaction mixture was diluted with water and benzene. The benzene solution was separated and washed with two portions of 10% aqueous potassium hydroxide. The combined basic aqueous solutions were washed with benzene, acidified to *p*H 7 with dilute hydrochloric acid and extracted with three portions of ethyl acetate. Evaporation of the dried ethyl acetate solution gave 461 mg. (64%) of hydroxymethylene ketone (XIX). A portion was recrystallized thrice from absolute ethanol to give almost colorless prisms, m.p. 131–133°, $\lambda_{max}^{CHCl_3}$ 5.98, 6.24, 9.60 and 10.70 μ, which gave a deep violet ferric chloride test.

Anal. Calcd. for $C_{17}H_{17}NO_4$: C, 68.21; H, 5.73. Found: C, 68.59; H, 5.95.

In absolute ethanol containing 2 drops of 10% hydrochloric acid per 10 ml. the derivative had λ_{max} 280 mμ (16,600). Subtraction of the spectrum of α-dihydrocaranone gave λ_{max} 275 mμ (13,700). The absorption peak of XIX was shifted to 304 mμ (24,700) in absolute ethanol containing 2 drops of 10% aqueous potassium hydroxide per 10 ml.

Methyl 2-Formyl-4,5-methylenedioxy-3′-biphenylcarboxylate (XVe).—In a 50-ml. pear-shaped flask equipped with a stirrer and nitrogen inlet were placed 26.2 g. (0.10 mole) of methyl *m*-iodobenzoate, m.p. 45.5–48.5°, and 22.9 g. (0.10 mole) of 6-bromopiperonal,[24] m.p. 122–128°. A small flask containing 50 g. of copper powder was attached to the third neck of the flask by a piece of rubber tubing and the whole apparatus was flushed with nitrogen. The flask was heated to 230–250° in a Woods metal-bath while the copper powder was added in small portions to the stirred liquid during one-half hour. The reaction was kept at 230–250° for another hour. The contents of the cooled flask were dissolved in benzene and filtered. Benzene was removed by distillation and 5.5 g. of recovered methyl *m*-iodobenzoate was distilled at 150° (0.8 mm.). The 22.1 g. of residue in the flask was taken up in benzene and chromatographed on 500 g. of alumina. Benzene eluted 4.0 g. of methyl *m*-iodobenzoate and 1.0 g. of impure 6-bromopiperonal. Benzene–ethyl acetate (49:1) eluted 3.62 g. of yellow oil which crystallized on trituration with ether. Further elution with the same solvent gave 1.04 g. of an orange fluorenone (a) while elution with pure ethyl acetate gave a different orange fluorenone (b).

The 3.62 g. of partially crystalline material was triturated with benzene and filtered to remove some insoluble fluorenone. The benzene of the filtrate was replaced by methanol and the solution concentrated to give 1.66 g. of **methyl 2-formyl-4,5-methylenedioxy-3′-carboxylate** (XVe), m.p., 129.5–131°. A second crop of 0.93 g., m.p. 126–131°, brought the yield to 14% based on recovered methyl *m*-iodobenzoate. A sample was recrystallized twice more from methanol to give colorless prisms, m.p. 130–131°, λ_{max} 242.5 (30,900), 281 (6580) and 324 mμ (6670); $\lambda_{max}^{CHCl_3}$ 5.82, 5.98, 6.21, 9.66 and 10.71 μ.

Anal. for $C_{16}H_{12}O_5$: C, 67.60; H, 4.26. Found: C, 67.42; H, 4.39.

A sample of the orange fluorenone (a) was recrystallized three times from dimethylformamide and sublimed at 200° (0.05 mm.) to give bright orange prisms of **2,3-methylenedioxy-6(or 8)-carbomethoxyfluorenone**, m.p. 287–288° with sublimation, $\lambda_{max}^{CHCl_3}$ 277 (46,100), 331 (2780) and 437 mμ (610); $\lambda_{inf}^{CHCl_3}$ 316 (3960) and 344 mμ (1180); λ_{max}^{Nujol} 5.82, 5.86, 6.26, 9.70 and 10.88 μ.

Anal. Calcd. for $C_{16}H_{10}O_5$: C, 68.08; H, 3.57. Found: C, 67.90; H, 3.81.

A specimen of the orange fluorenone (b) was recrystallized three times from chloroform–ethanol to give pale orange felted needles of **2,3-methylenedioxy-8(or 6)-carbomethoxyfluorenone**, m.p. 247–249° and 272.5–275° with sublimation, $\lambda_{max}^{CHCl_3}$ 282 (64,500), 340 (4550), 356 (3550) and 448 mμ (590); $\lambda_{inf}^{CHCl_3}$ 275 (45,500) and 313 mμ (8970); λ_{max}^{Nujol} 5.80, 5.85, 6.25, 9.63 and 10.80 μ.

Anal. Calcd. for $C_{16}H_{10}O_5$: C, 68.08; H, 3.57. Found: C, 67.89; H, 3.52.

4,5-Methylenedioxy-2,3′-biphenyldicarboxylic Acid (XVa).—A solution of 91 mg. of the Ullmann product XVe, m.p. 129–131°, from the above reaction in 10 ml. of ethanol and 2 ml. of water containing five potassium hydroxide pellets was warmed on a steam-bath. The addition of 5 ml. of 30% hydrogen peroxide caused a vigorous reaction. After subsidence of gas evolution another 5 ml. of peroxide was added. The solution was heated for another 30 minutes, concentrated to one-third its original volume, cooled and acidified with 10% hydrochloric acid. The white precipitate was collected on a filter, washed with water and dried to give 78 mg. (85%) of 4,5-methylenedioxy-2,3′-biphenyldicarboxylic acid (XVa), m.p. 248–263°. Three recrystallizations from ethyl acetate–benzene gave small colorless prisms, m.p. 262.5–263.5°, λ_{max} 226 (36,800), 268 (6750) and 295 mμ (5970); λ_{max}^{KBr} 3.70–3.95, 5.92, 6.20, 9.70 and 10.81 μ.

Anal. Calcd. for $C_{15}H_{10}O_6$: C, 62.94; H, 3.52. Found: C, 62.97; H, 3.46.

The Preparation of Some Merimine Derivatives[1]

BY WILLIAM B. WRIGHT, JR., JOHN S. WEBB AND JAMES M. SMITH, JR.

RECEIVED OCTOBER 17, 1956

The preparation and properties of a number of derivatives of 6-methylmerimine have been described.

The compound 2,3-dihydro-1H-pyrrolo[3,4-c]-pyridine was prepared by Gabriel and Colman,[2] in 1902, by the hydrogen iodide and phosphorus reduction of the γ-lactam of 3-aminomethylisonicotinic acid and was named merimine. The only other compounds of this bicyclic ring structure known in the literature are the imides and lactams derived from substituted pyridinecarboxylic acids.

7-Amino-6-methylmerimine (I) was prepared by the lithium aluminum hydride reduction of the γ-lactam of 3-amino-5-aminomethyl-2-methylisonicotinic acid (II).[3] Compound I was used as the basic raw material in the preparation of the series of compounds outlined in Chart I.

When compound I was treated with nitrous acid, dark tars were obtained. When the 2-position was blocked by a carbethoxy (III) or a benzoyl (IV) group, the primary amino group was easily diazotized and a variety of 2,7-disubstituted derivatives (V-X) could be obtained by standard procedures. Hydrolysis with either acid or alkali resulted in the 7-substituted-6-methylmerimines (XI-XV). These merimines, unsubstituted in the 2-position, are strong bases which absorb carbon dioxide on standing. They are best stored as the high melting dihydrochlorides.

When 7-methoxy-6-methylmerimine (XI) was heated with 48% hydrobromic acid, 7-hydroxy-6-methylmerimine (XII) dihydrobromide was obtained. Catalytic reduction converted 7-bromo-6-methylmerimine dihydrochloride (XIV) to 6-methylmerimine dihydrochloride (XV). 2-Benzoyl-7-iodo-6-methylmerimine (XVI) and 2-benzoyl-7-bromo-6-methylmerimine (XVII) were not prepared easily by diazotization of IV, but were obtained in excellent yield by the Schotten–Baumann reaction on XIII and XIV.

Typical reactions of merimines unsubstituted in the 2-position are illustrated with 7-methoxy-6-methylmerimine (XI) in Chart II. The 2-guanyl (XVIII) and 2-imidazolinyl (XIX) derivatives were prepared by reaction with thiuronium salts, 2-carbamyl derivatives (XXI) by reaction with potassium cyanate, and 2-dialkylsulfamyl derivatives (XX) by reaction with dialkylsulfamyl chlorides. When XI was treated with acetic anhydride, the 2-acetyl derivative XXII was formed and this was converted easily to the methiodide XXIII. The 2-*p*-acetylsulfanilyl derivative XXIV was prepared and was hydrolyzed to the unacetylated derivative XXV.

Similar derivatives were prepared from other 2-unsubstituted merimines and additional examples are described in the Experimental section.

Experimental

7-Amino-6-methylmerimine Dihydrochloride (I).—A solution of 2.0 g. of lithium aluminum hydride in 100 ml. of tetrahydrofuran was stirred under nitrogen at a temperature of 45–50° while a solution of 1.0 g. of the γ-lactam of 3-amino-5-aminomethyl-2-methylisonicotinic acid (II) in 200 ml. of tetrahydrofuran was added. The reaction mixture was heated at 60–65° for seven hours and then allowed to stand at room temperature overnight. A solution of 4 ml. of water in 50 ml. of tetrahydrofuran was added and the insoluble portion was filtered off and washed with ethanol. The filtrate was acidified with concentrated hydrochloric acid and the precipitate which separated was filtered and oven-dried. The yield was 0.77 g. of brown powder. This powder was dissolved in 10 ml. of water and treated with activated charcoal. The solution was concentrated to dryness and then diluted with 1 ml. of concentrated hydrochloric acid and 10 ml. of ethanol. The precipitate was filtered and washed with ethanol. The product was dissolved once more in 1.5 ml. of water and then diluted with 0.4 ml. of concentrated hydrochloric acid. The precipitate which separated was filtered, washed with ethanol and dried. The yield of 7-amino-6-methylmerimine dihydrochloride was 0.21 g. (15%).

Anal. Calcd. for $C_8H_{13}Cl_2N_3$: C, 43.3; H, 5.90; Cl, 32.0; N, 18.9. Found: C, 43.1; H, 5.86; Cl, 31.7; N, 18.9.

7-Amino-6-methylmerimine.—A mixture of 4.55 g. of the dihydrochloride, 2.16 g. of sodium methylate and 20 ml. of absolute ethanol was stirred under nitrogen for 2 hours at room temperature. The mixture was heated to the boil and filtered. The filtrate was concentrated *in vacuo* until heavy precipitation occurred and then diluted with ether. The mixture was filtered and the cake was washed with ether and dried. Two grams of 7-amino-6-methylmerimine (67%), m.p. 167–169°, was obtained.

Anal. Calcd. for $C_8H_{11}N_3$: C, 64.4; H, 7.43; N, 28.2. Found: C, 64.3; H, 7.47; N, 28.1.

7-Amino-2-carbethoxy-6-methylmerimine (III).—A solution of 448 g. of 7-amino-6-methylmerimine dihydrochloride in 2,500 ml. of water and 800 ml. of 5 *N* sodium hydroxide was cooled to 10° and 194 ml. of ethyl chloroformate and 400 ml. of 5 *N* sodium hydroxide were added simultaneously over a 15-minute period while allowing the temperature to rise to 20°. The reaction mixture was stirred for 1.5 hours longer and then filtered. The cake was washed with ice-water and then recrystallized from ethanol. A 65% yield of 7-amino-2-carbethoxy-6-methylmerimine monohydrate, m.p. 182–183°, was obtained.

Anal. Calcd. for $C_{11}H_{17}N_3O_3$: C, 55.2; H, 7.16; N, 17.6. Found: C, 55.2; H, 6.85; N, 17.9.

7-Amino-2-benzoyl-6-methylmerimine (IV).—A solution of 280 g. of 7-amino-6-methylmerimine dihydrochloride and 150 g. of sodium hydroxide in 2,400 ml. of water was adjusted to 33° and 165 g. of benzoyl chloride was added over a 40-minute period at 30–35°. The mixture was stirred for two hours longer at this temperature and the insoluble product was filtered, washed with water and dried at 50°. Recrystallization from ethanol resulted in a 61% yield of 7-amino-2-benzoyl-6-methylmerimine, m.p. 202–203°.

Anal. Calcd. for $C_{15}H_{15}N_3O$: C, 71.1; H, 5.97; N, 16.6. Found: C, 71.0; H, 5.98; N, 16.5.

2-Carbethoxy-7-hydroxy-6-methylmerimine Hydrochloride (V).—A mixture of 95.5 g. of 7-amino-2-carbethoxy-6-methylmerimine monohydrate, 320 ml. of 5 *N* hydrochloric

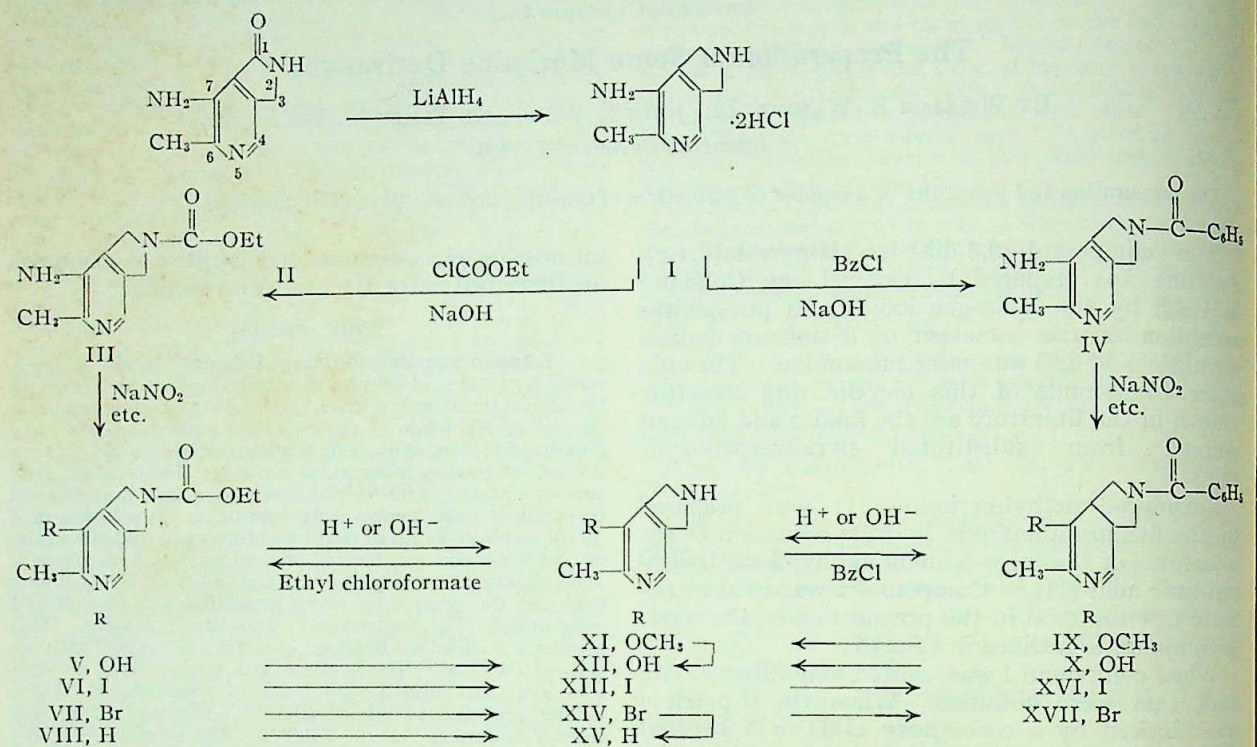

CHART II

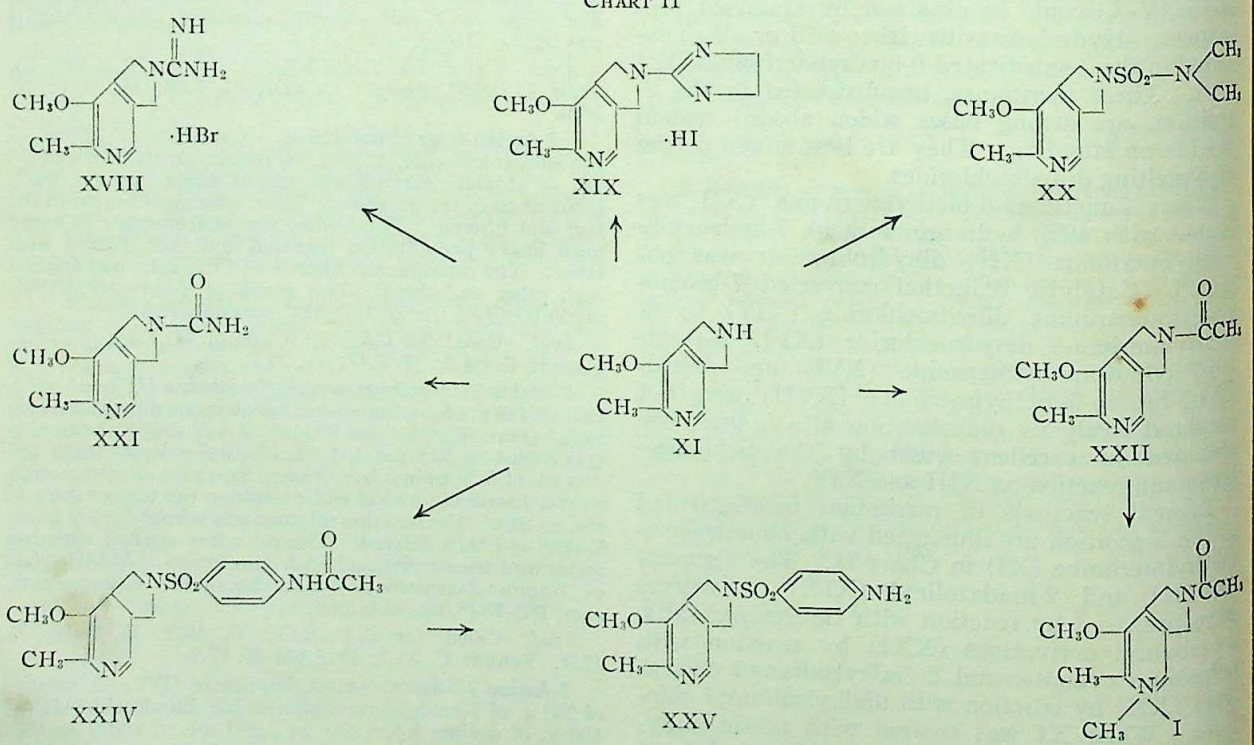

acid and 4 liters of ice and water was cooled to 0° and a solution of 29 g. of sodium nitrite in 150 ml. of water was added over ten minutes. The reaction mixture was allowed to warm to 25° over a 3-hour period and was then adjusted with sodium hydroxide to a *p*H of 3. The mixture was concentrated to dryness *in vacuo* and then boiled with 400 ml. of ethanol and filtered hot to remove the salt. On cooling the filtrate, 71.5 g. (69%) of product was obtained. Recrystallization from ethanol yielded pure 2-carbethoxy-7-hydroxy-6-methylmerimine hydrochloride, m.p. 246° dec.

Anal. Calcd. for $C_{11}H_{15}ClN_2O_3$: C, 51.1; H, 5.85; Cl, 13.7; N, 10.8. Found: C, 51.2; H, 5.87; Cl, 13.6; N, 11.1.

2-Carbethoxy-7-iodo-6-methylmerimine (VI).—A solution of 72 g. of sodium nitrite in 300 ml. of water was added over 5 minutes at −2 to −5° to a mixture of 239 g. of 7-amino-2-carbethoxy-6-methylmerimine monohydrate, 1,200 ml. of 5 *N* sulfuric acid and 6,200 ml. of water. The reaction mixture was stirred at this temperature for 20 minutes longer and then poured into a solution of 176 g. of po-

tassium iodide in 500 ml. of water. The mixture was warmed over a 4-hour period to 25–30° and then filtered to remove some brown insoluble material. The filtrate was treated with sodium bicarbonate and filtered to remove the precipitate. This was washed with water, dried and recrystallized twice from ethanol. The yield of 2-carbethoxy-7-iodo-6-methylmerimine, m.p. 130–131°, was 34%.

Anal. Calcd. for $C_{11}H_{13}IN_2O_2$: C, 39.8; H, 3.95; I, 38.2. Found: C, 39.8; H, 3.86; I, 38.0.

7-Bromo-2-carbethoxy-6-methylmerimine (VII).—A solution of 2.9 g. of sodium nitrite in 30 ml. of water was added over a 5-minute period at −1 to −4° to a mixture of 9.56 g. of 7-amino-2-carbethoxy-6-methylmerimine monohydrate, 15 ml. of 48% HBr and 150 ml. of water. The reaction mixture was held at this temperature for 20 minutes and then poured into a solution of 7 g. of cuprous bromide in 25 ml. of 48% HBr and 15 ml. of water. The dark brown foamy mixture was left at room temperature overnight and then warmed to 60° and filtered. The filtrate was treated with activated carbon and then with hydrogen sulfide gas. After filtration, the light colored filtrate was treated with sodium bicarbonate. An oil separated and gradually solidified. The precipitate was filtered off and washed with water. The yield of 7-bromo-2-carbethoxy-6-methylmerimine was 3.2 g. (28%). After recrystallization from ether the melting point was 93–94°.

Anal. Calcd. for $C_{11}H_{13}BrN_2O_2$: C, 46.4; H, 4.60; Br, 28.0. Found: C, 46.4; H, 4.02; Br, 27.7.

A purer product, m.p. 99–101°, was prepared by treating 7-bromo-6-methylmerimine (XIV) with ethyl chloroformate in aqueous alkali; yield 78%. Found: C, 46.6; H, 4.62; Br, 27.9.

2-Carbethoxy-6-methylmerimine Hydrochloride (VIII).—A solution of 2.17 g. of sodium nitrite in 10 ml. of water was added over a 10-minute period to a solution of 7.17 g. of 7-amino-2-carbethoxy-6-methylmerimine monohydrate and 24 ml. of 5 *N* hydrochloric acid in 200 ml. of water while holding the temperature at 0 to −5°. The reaction mixture was stirred for 5 minutes longer and 19.8 g. of 50% hypophosphorous acid was then added. The temperature was allowed to rise to 22° over a 7-hour period and sodium bicarbonate was then added until foaming no longer occurred. The solution was concentrated to a low volume, extracted with ether, and the ether layer was dried over sodium sulfate. On addition of hydrogen chloride 2-carbethoxy-6-methylmerimine hydrochloride separated. On recrystallization from alcohol and ether, 3.3 g. (45%), m.p. 219–220° dec., was obtained.

The same compound, m.p. 221–223° dec., was obtained in 67% yield by treating 6-methylmerimine dihydrochloride with ethyl chloroformate in aqueous alkali.

Anal. Calcd. for $C_{11}H_{15}ClN_2O_2$: C, 54.4; H, 6.25; N, 11.5. Found: C, 54.3; H, 6.40; N, 11.7.

2-Benzoyl-7-methoxy-6-methylmerimine (IX).—A mixture of 101 g. of 7-amino-2-benzoyl-6-methylmerimine, 4 liters of methanol and 166 ml. of concentrated hydrochloric acid was heated to 48° and a solution of 56 g. of sodium nitrite in 160 ml. of water was added over a 1-hour period at 48–59°. The reaction mixture was held for one hour longer at this temperature and then partially concentrated. The mixture was diluted with water, neutralized with sodium carbonate to a *p*H of about 8, and then concentrated further to remove all methanol. The precipitate which separated was filtered off and then dissolved in water adjusted to *p*H 3 with hydrochloric acid. The solution was treated with activated carbon and clarified and the filtrate was adjusted with sodium carbonate to *p*H 5.2. The product was filtered off and recrystallized first from ethanol and then from a mixture of ethanol and isopropyl acetate. The yield of 2-benzoyl-7-methoxy-6-methylmerimine, m.p. 149–151°, was 38%.

Anal. Calcd. for $C_{16}H_{16}N_2O_2$: C, 71.6; H, 6.01; N, 10.4. Found: C, 71.6; H, 5.95; N, 10.6.

2-Benzoyl-7-hydroxy-6-methylmerimine Hydrochloride (X).—A mixture of 76 g. of 7-amino-2-benzoyl-6-methylmerimine, 3,500 ml. of water and 240 ml. of 5 *N* hydrochloric acid was cooled to 0 to −5° and a solution of 21 g. of sodium nitrite in 100 ml. of water was added over a 30-minute period at this temperature. The reaction mixture was allowed to gradually warm over a two hour period to 28°. The mixture was adjusted with 5 *N* sodium hydroxide to a *p*H of about 3 and then concentrated *in vacuo* until heavy precipitation occurred. The precipitate was filtered off and washed with acetone. On recrystallization from ethanol, 2-benzoyl-7-hydroxy-6-methylmerimine hydrochloride, m.p. 228–230°, was obtained in 59% yield.

Anal. Calcd. for $C_{15}H_{15}ClN_2O_2$: C, 62.0; H, 5.20; Cl, 12.2; N, 9.64. Found: C, 61.7; H, 5.26; Cl, 12.4; N, 9.93.

7-Methoxy-6-methylmerimine Dihydrochloride (XI).—A mixture of 295 g. of 2-benzoyl-7-methoxy-6-methylmerimine, 1,100 ml. of 5 *N* sodium hydroxide and 1,800 ml. of ethanol was heated on the steam-bath for three hours, cooled, neutralized with 475 ml. of concentrated hydrochloric acid, concentrated to remove the ethanol and then further acidified with a mixture of 200 ml. of concentrated HCl and 400 ml. of water. The precipitated benzoic acid was filtered off and the filtrate was then treated with 530 ml. of 5 *N* sodium hydroxide and concentrated to remove as much water as possible. The residue was boiled with 400 ml. of ethanol, filtered hot and the salt cake washed with 300 ml. of ethanol. The filtrate was concentrated to a thick mush. This was dissolved in 500 ml. of water and the solution was treated with activated carbon and then acidified with 210 ml. of concentrated hydrochloric acid and further diluted with 500 ml. of ethanol. The crystalline product was filtered, washed with ethanol and dried. The yield of 7-methoxy-6-methylmerimine dihydrochloride, m.p. about 290° dec., was 65%. On concentration of the filtrate, an additional 25% was obtained.

Anal. Calcd. for $C_9H_{14}Cl_2N_2O$: C, 45.6; H, 5.95; Cl, 29.9; N, 11.8. Found: C, 45.5; H, 5.73; Cl, 29.7; N, 11.9.

7-Methoxy-6-methylmerimine Base.—A mixture of 166 g. of the dihydrochloride, 75.5 g. of sodium methylate and 1,500 ml. of ethanol was refluxed under nitrogen for three hours. The reaction mixture was filtered hot to remove the salt and the filtrate was concentrated to an oil. The 7-methoxy-6-methylmerimine was distilled at 125–130° (2 mm.), yield 76%. On cooling, it solidified as white crystals which melted at 57–59°.

Anal. Calcd. for $C_9H_{12}N_2O$: C, 65.8; H, 7.37; N, 17.1. Found: C, 65.6; H, 7.23; N, 17.2.

7-Hydroxy-6-methylmerimine Dihydrochloride (XII).

A. By Acid Hydrolysis.—A mixture of 10 g. of 2-benzoyl-7-hydroxy-6-methylmerimine hydrochloride and 80 ml. of 5 *N* hydrochloric acid was heated on the steam-bath for five hours. The reaction mixture was cooled and the benzoic acid was filtered off. The filtrate was treated with activated carbon and then concentrated until solidification occurred. The product was filtered, washed with alcohol and dried at 60°. The yield of 7-hydroxy-6-methylmerimine dihydrochloride, m.p. above 290°, was 91%.

Anal. Calcd. for $C_8H_{12}Cl_2N_2O$: C, 43.1; H, 5.42; Cl, 31.8; N, 12.6. Found: C, 42.9; H, 5.49; Cl, 31.8; N, 12.8.

B. By Alkaline Hydrolysis.—The same product was isolated in 68% yield by the alkaline hydrolysis of 2-carbethoxy-7-hydroxy-6-methylmerimine monohydrochloride.

C. From 7-Methoxy-6-methylmerimine.—When 7-methoxy-6-methylmerimine was heated on the steam-bath with 48% hydrobromic acid for 16 hours a 70% yield of 7-hydroxy-6-methylmerimine dihydrobromide, m.p. above 290°, was isolated.

Anal. Calcd. for $C_8H_{12}Br_2N_2O$: Br, 51.2; N, 8.98. Found: Br, 51.8; N, 8.89; CH_3O, 0.0.

7-Bromo-6-methylmerimine Dihydrochloride (XIV). A. Alkaline Hydrolysis of 7-Bromo-2-carbethoxy-6-methylmerimine.—A mixture of 86 g. of 7-bromo-2-carbethoxy-6-methylmerimine, 267 ml. of 4.5 *N* sodium hydroxide and 333 ml. of ethanol was heated on the steam-bath for 2.5 hours. The reaction mixture was cooled and the precipitate was filtered off. The filtrate was acidified with 125 ml. of concentrated hydrochloric acid and clarified with activated charcoal. The solution was concentrated to dryness and the solid residue was washed into a filter with ethanol. The cake was mixed with 26.4 g. of sodium methylate and 500 ml. of ethanol and the mixture was stirred at room temperature for one hour and heated at reflux for 30 min. and then filtered to remove the salt. The filtrate was cooled and HCl gas was passed through to precipitate 7-bromo-6-methylmerimine dihydrochloride as a light tan powder;

yield 72 g. (84%). Recrystallization from 85% ethanol resulted in an almost white powder which decomposed about 275°.

Anal. Calcd. for $C_8H_{11}BrCl_2N_2$: C, 33.6; H, 3.88; Br, 27.9; Cl, 24.8; N, 9.80. Found: C, 33.6; H, 3.88; Br, 27.7; Cl, 24.6; N, 9.90.

B. Acid Hydrolysis of 7-Bromo-2-carbethoxy-6-methylmerimine.—A mixture of 113 g. of 7-bromo-2-carbethoxy-6-methylmerimine and 500 ml. of concentrated hydrochloric acid was heated on the steam-bath for 30 hours and then concentrated to dryness *in vacuo*. The light brown residue was washed onto a filter with ethanol and then recrystallized from 85% ethanol. A 67% yield of 7-bromo-6-methylmerimine dihydrochloride was obtained as almost white crystals which decomposed about 275°.

7-Iodo-6-methylmerimine Dihydrochloride (XIII).—Alkaline hydrolysis of 2-carbethoxy-7-iodo-6-methylmerimine as described above resulted in a 28% yield of 7-iodo-6-methylmerimine dihydrochloride, m.p. 257° dec. Recrystallization was from aqueous acetone.

Anal. Calcd. for $C_8H_{11}Cl_2IN_2$: C, 28.9; H, 3.33; Cl, 21.3. Found: C, 29.2; H, 3.52; Cl, 21.0.

6-Methylmerimine Dihydrochloride (XV). A. From 2-Carbethoxy-6-methylmerimine Hydrochloride.—A 76% yield of 6-methylmerimine dihydrochloride, m.p. 280° dec., was obtained by the acid hydrolysis of 2-carbethoxy-6-methylmerimine. A 30% yield of pure product was obtained by alkaline hydrolysis of the same compound.

Anal. Calcd. for $C_8H_{12}Cl_2N_2$: C, 46.4; H, 5.84; Cl, 34.3; N, 13.5. Found: C, 46.2; H, 5.96; Cl, 34.1; N, 13.6.

B. From 7-Bromo-6-methylmerimine Dihydrochloride.—A mixture of 5.72 g. of 7-bromo-6-methylmerimine dihydrochloride, 50 ml. of water and 1.0 g. of palladium-on-carbon catalyst was reduced in a Parr shaker. One molar equivalent of hydrogen was absorbed in 15 min. The reaction mixture was filtered and concentrated to dryness. Alcoholic HCl was added and the mixture was again concentrated to dryness. The white crystals were washed into a filter with alcohol and dried at 60°; crude yield 92%. Analysis indicated a mixed hydrochloride hydrobromide salt of 6-methylmerimine.

The above product was dissolved in 5 *N* NaOH and the base was extracted with ether. The extract was treated with HCl gas and the 6-methylmerimine dihydrochloride so obtained did not depress the melting point of the product prepared by method A.

2-Benzoyl-7-iodo-6-methylmerimine (XVI).—The Schotten–Baumann reaction of benzoyl chloride and 7-iodo-6-methylmerimine dihydrochloride yielded 2-benzoyl-7-iodo-5-methylmerimine as white crystals which melted at 193–195° dec.

Anal. Calcd. for $C_{15}H_{13}IN_2O$: C, 49.5; H, 3.60; I, 34.9; N, 7.70. Found: C, 49.9; H, 3.58; I, 34.8; N, 7.62.

2-Benzoyl-7-bromo-6-methylmerimine (XVII).—The Schotten–Baumann reaction of benzoyl chloride and 7-bromo-6-methylmerimine dihydrochloride yielded 2-benzoyl-7-bromo-6-methylmerimine as white crystals which melted at 174–176°.

Anal. Calcd. for $C_{15}H_{13}BrN_2O$: C, 56.8; H, 4.13; Br, 25.2; N, 8.84. Found: C, 56.9; H, 3.65; Br, 25.6; N, 8.91.

2-Guanyl-7-methoxy-6-methylmerimine Hydrobromide (XVIII).—A solution of 1.7 g. of 7-methoxy-6-methylmerimine and 1.85 g. of S-ethylthiuronium bromide in 10 ml. of ethanol was allowed to stand at room temperature for 2 hours and then heated on the steam-bath for 1 hour. The mixture was cooled and filtered and then recrystallized from dilute ethanol. An 87% yield of 2-guanyl-7-methoxy-6-methylmerimine hydrobromide was obtained. This material darkened about 260° but was of indefinite melting point.

Anal. Calcd. for $C_{10}H_{15}BrN_4O$: C, 41.9; H, 5.27; Br, 27.8; N, 19.5. Found: C, 41.8; H, 5.10; Br, 27.9; N, 19.7.

7-Amino-2-guanyl-6-methylmerimine Hydrobromide.—This compound was prepared as above from 7-amino-6-methylmerimine and S-ethylthiuronium bromide. A white product of indefinite melting point was obtained after two recrystallizations from water.

Anal. Calcd. for $C_9H_{14}BrN_5$: C, 39.7; H, 5.18; Br, 29.4; N, 25.7. Found: C, 39.4; H, 4.74; Br, 28.9; N, 25.5.

2-(2-Imidazolinyl)-7-methoxy-6-methylmerimine Hydroiodide (XIX).—This compound was prepared as above from 7-methoxy-6-methylmerimine and 2-methylmercaptoimidazoline hydroiodide. The yield of 2-(2-imidazolinyl)-7-methoxy-6-methylmerimine hydroiodide was 89%.

Anal. Calcd. for $C_{12}H_{17}IN_4O$: C, 40.0; H, 4.76; I, 35.2; N, 15.5. Found: C, 39.7; H, 4.70; I, 34.9; N, 15.7.

2-Dimethylsulfamyl-7-methoxy-6-methylmerimine (XX).—A solution of 2.37 g. of 7-methoxy-6-methylmerimine dihydrochloride in 20 ml. of 1 *N* sodium hydroxide was treated with 1.08 ml. of dimethylsulfamyl chloride. After one hour, 10 ml. of 1 *N* sodium hydroxide was added and the precipitate which separated was filtered and recrystallized from aqueous ethanol. The yield of 2-dimethylsulfamyl-7-methoxy-6-methylmerimine, m.p. 100–103°, was 33%.

Anal. Calcd. for $C_{11}H_{17}N_3O_3S$: C, 48.7; H, 6.32; N, 15.5; S, 11.8. Found: C, 48.6; H, 6.23; N, 15.3; S, 12.1.

2-Dimethylsulfamyl-7-hydroxy-6-methylmerimine.—This compound was prepared as above from 7-hydroxy-6-methylmerimine dihydrochloride and dimethylsulfamyl chloride. Recrystallization from ethanol resulted in a 33% yield of white powder of indefinite melting point.

Anal. Calcd. for $C_{10}H_{15}N_3O_3S$: C, 46.7; H, 5.88; N, 16.3; S, 12.4. Found: C, 46.4; H, 5.80; N, 16.4; S, 12.4.

2-Diethylsulfamyl-7-hydroxy-6-methylmerimine.—A 22% yield of 2-diethylsulfamyl-7-hydroxy-6-methylmerimine, m.p. 195–197°, was obtained when 7-hydroxy-6-methylmerimine dihydrochloride and diethylsulfamyl chloride were allowed to react as above.

Anal. Calcd. for $C_{12}H_{19}N_3O_3S$: C, 50.5; H, 6.71; N, 14.7; S, 11.2. Found: C, 50.2; H, 6.78; N, 14.8; S, 10.9.

2-Carbamyl-7-methoxy-6-methylmerimine (XXI).—A mixture of 32.8 g. of 7-methoxy-6-methylmerimine, 200 ml. of 1 *N* hydrochloric acid and 16.2 g. of potassium cyanate was allowed to stand overnight at room temperature and was then heated on the steam-bath for 30 minutes. The solution was treated with activated carbon and cooled. The precipitate was filtered, washed with water, and then dried at 100°. The yield of 2-carbamyl-7-methoxy-6-methylmerimine, m.p. 233° dec., was 40 g. (97%).

Anal. Calcd. for $C_{10}H_{13}N_3O_2$: C, 58.0; H, 6.32; N, 20.3. Found: C, 58.1; H, 6.18; N, 20.4.

The following compounds were prepared by essentially the same procedure:

7-Amino-2-carbamyl-6-methylmerimine: yield 95%, m.p. 275° dec. *Anal.* Calcd. for $C_9H_{12}N_4O$: C, 56.2; H, 6.29; N, 29.2. Found: C, 56.3; H, 6.30; N, 29.0.

2-Carbamyl-7-hydroxy-6-methylmerimine: yield 82%, m.p. above 275°. *Anal.* Calcd. for $C_9H_{11}N_3O_2$: C, 56.0; H, 5.74; N, 21.8. Found: C, 56.0; H, 5.74; N, 21.8.

7-Bromo-2-carbamyl-6-methylmerimine: yield 58%, m.p. 243–244°. *Anal.* Calcd. for $C_9H_{10}BrN_3O$: C, 42.2; H, 3.94; Br, 31.2; N, 16.4. Found: C, 42.0; H, 3.57; Br, 31.2; N, 16.3.

2-Carbamyl-7-iodo-6-methylmerimine: yield 56%, m.p. 232–234° dec. *Anal.* Calcd. for $C_9H_{10}IN_3O$: C, 35.7; H, 3.34; I, 41.9; N, 13.9. Found: C, 35.6; H, 3.18; I, 41.9; N, 13.7.

2-Acetyl-7-methoxy-6-methylmerimine (XXII).—A mixture of 49.3 g. of 7-methoxy-6-methylmerimine and 150 ml. of acetic anhydride was heated on the steam-bath for 90 min. and then concentrated to a dark oil. Ether was added and a precipitate separated and was filtered off. After recrystallization from ethanol, the yield of 2-acetyl-7-methoxy-6-methylmerimine, m.p. 115–116°, was 35 g. (70%).

Anal. Calcd. for $C_{11}H_{14}N_2O_2$: C, 64.1; H, 6.84; N, 13.6. Found: C, 64.0; H, 6.89; N, 13.7.

The following were prepared by the same general procedure:

7-Acetoxy-2-acetyl-6-methylmerimine: yield 26%, m.p. 143–144°. *Anal.* Calcd. for $C_{12}H_{14}N_2O_3$: C, 61.5; H, 6.02; N, 12.0. Found: C, 61.3; H, 5.74; N, 12.3.

7-Acetamido-2-acetyl-6-methylmerimine: yield 71%, m.p. 226–228°. *Anal.* Calcd. for $C_{12}H_{15}N_3O_2$: C, 61.8; H, 6.48; N, 18.0. Found: C, 61.5; H, 6.48; N, 17.9.

2-Acetyl-7-methoxy-6-methylmerimine Methiodide (XXIII).—A mixture of 2.06 g. of 2-acetyl-7-methoxy-6-

methylmerimine, 1.87 ml. of methyl iodide and 15 ml. of ethanol was allowed to stand at room temperature for 5 days and was then heated at reflux for 90 min. The solution was concentrated and then diluted with ether. The precipitate which separated was filtered off and recrystallized from ethanol. The yield of 2-acetyl-7-methoxy-6-methylmerimine methiodide, m.p. 175–177°, was 89%.

Anal. Calcd. for $C_{12}H_{17}IN_2O_2$: C, 41.4; H, 4.92; I, 36.5; N, 8.05. Found: C, 41.4; H, 4.71; I, 36.5; N, 8.27.

The following were prepared by the same general procedure:

7-Acetoxy-2-acetyl-6-methylmerimine methiodide: yield 61%, m.p. 222–224°. *Anal.* Calcd. for $C_{13}H_{17}IN_2O_3$: C, 41.5; H, 4.56; I, 33.8; N, 7.45. Found: C, 41.4; H, 4.53; I, 33.6; N, 7.55.

7-Acetamido-2-acetyl-6-methylmerimine methiodide: yield 41%, m.p. 198–199°. *Anal.* Calcd. for $C_{13}H_{18}IN_3O_2$: C, 41.6; H, 4.84; I, 33.8; N, 11.2. Found: C, 41.7; H, 4.88; I, 32.9; N, 11.0.

2-Carbethoxy-6-methylmerimine methiodide: yield 54%, m.p. 183–185°. *Anal.* Calcd. for $C_{12}H_{17}IN_2O_2$: C, 41.4; H, 4.92; I, 36.5; N, 8.05. Found: C, 41.1; H, 4.62; I, 36.4; N, 7.78.

2-(*p*-Acetylsulfanilyl)-7-methoxy-6-methylmerimine (XXIV).—A mixture of 1.18 g. of 7-methoxy-6-methylmerimine dihydrochloride, 1.23 g. of *p*-acetylsulfanilyl chloride and 30 ml. of 1 *N* sodium hydroxide was allowed to react at 30–35° for one hour and then heated on the steam-bath for two hours. The precipitate was filtered hot, washed with water, dried and then recrystallized from ethanol. The yield of 2-(*p*-acetylsulfanilyl)-7-methoxy-6-methylmerimine, m.p. 212–213°, was 0.7 g. (44%).

Anal. Calcd. for $C_{17}H_{19}N_3O_4S$: C, 56.5; H, 5.30; N, 11.6; S, 8.85. Found: C, 56.7; H, 5.14; N, 11.4; S, 8.85.

The following compounds were prepared by the same general procedure:

2-(*p*-Acetylsulfanilyl)-7-hydroxy-6-methylmerimine: yield 35%, m.p. above 250°. *Anal.* Calcd. for $C_{16}H_{17}N_3O_4S$: C, 55.3; H, 4.93; N, 12.1; S, 9.23. Found: C, 55.2; H, 4.93; N, 11.9; S, 9.03.

2-(*p*-Acetylsulfanilyl)-7-amino-6-methylmerimine hemihydrate: yield 75%, m.p. above 280°. *Anal.* Calcd. for $C_{16}H_{18}N_4O_3S \cdot 0.5H_2O$: C, 54.1; H, 5.38; N, 15.8; S, 9.02. Found: C, 54.4; H, 5.05; N, 15.7; S, 8.85.

7-Methoxy-6-methyl-2-(*p*-sulfanilyl)-merimine (XXV).—A mixture of 1.08 g. of the above acetyl derivative, 20 ml. of ethanol and 5 ml. of 5 *N* sodium hydroxide was heated on the steam-bath for one hour. The reaction mixture was concentrated and diluted with water and the precipitate was filtered. On recrystallization from ethanol, 0.55 g. (58%) of 7-methoxy-6-methyl-2-(*p*-sulfanilyl)-merimine, m.p. 204–205°, was obtained.

Anal. Calcd. for $C_{15}H_{17}N_3O_3S$: C, 56.4; H, 5.37; N, 13.2; S, 10.0. Found: C, 56.4; H, 5.11; N, 13.5; S, 9.60.

7-Amino-6-methyl-2-(*p*-sulfanilyl)-merimine.—This compound was prepared as above from 2-(*p*-acetylsulfanilyl)-7-amino-6-methylmerimine. The yield was 80%, m.p. 217° dec.

Anal. Calcd. for $C_{14}H_{16}N_4O_2S$: C, 55.2; H, 5.30; N, 18.4; S, 10.5. Found: C, 55.0; H, 5.32; N, 18.6; S, 10.9.

Acknowledgment.—We are indebted to Mr. O. Sundberg and co-workers for the microanalyses.

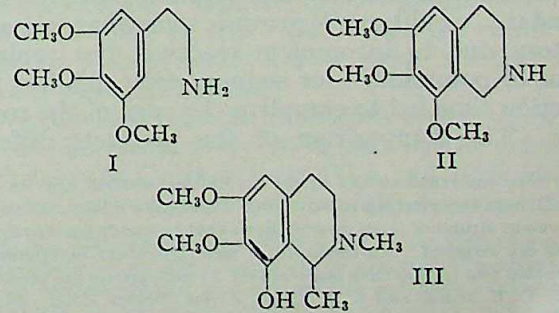
Alkaloid Studies. XVII.[1] The Structure of the Cactus Alkaloid Pilocereine[2]

BY CARL DJERASSI, S. K. FIGDOR,[3a] J. M. BOBBITT[3b] AND F. X. MARKLEY[3c]

RECEIVED OCTOBER 11, 1956

In contrast to the hitherto known cactus alkaloids which are based on a β-phenylethylamine or tetrahydroisoquinoline skeleton, pilocereine consists of two tetrahydroisoquinoline nuclei fused by an ether linkage. Its exact structure (XIIIa) was elucidated by diaryl ether cleavage of pilocereine methyl and ethyl ether with potassium in liquid ammonia and identification of all of the cleavage products. Attention is called to the presence of the 1-isobutyl substituent, which appears to be unique in alkaloid chemistry, and to certain side reactions in the potassium–ammonia cleavage of diaryl ethers.

The most remarkable chemical feature of the hitherto studied cactus alkaloids[4] is the simplicity of the various structures which are all based on β-phenylethylamine or 1,2,3,4-tetrahydroisoquinoline. Mescaline (I) and anhalinine (II) can be offered as two examples which also illustrate their close biogenetic origin[5] and even the most complicated cactus alkaloid, pellotine (III) contains only thirteen carbon atoms and one nitrogen atom.



Consequently, it was of particular interest to elucidate the structure of pilocereine, an alkaloid found[6–8] in various giant cacti and possessing the unusually high (at least for a cactus alkaloid)

empirical formula $C_{30}H_{44}N_2O_4$.[9] The pharmacology of this alkaloid already has been reported,[10] and we should now like to describe the relevant experiments[11] which lead us to propose structure XIIIa as a complete expression for pilocereine.

Of the four oxygen atoms in pilocereine, two are present as methoxyl groups, one as a kryptophenol and the remaining one was believed[7] to be involved in an ether linkage since no infrared hydroxyl or carbonyl bands were noted in pilocereine methyl ether. Further support could now be provided by the observation that while pilocereine contains one active hydrogen atom (kryptophenol), none is present in its methyl ether. The alkaloid remained unchanged after catalytic hydrogenation in ethanol solution using either platinum oxide or palladium–charcoal. Various oxidations led to no conclusive results except for a permanganate oxidation of its methyl ether which furnished as the only recognizable products[12] isobutyric and isovaleric acids, thus implying that pilocereine must contain at least an isobutyl fragment attached to carbon.

The most promising point of attack seemed to be the still uncharacterized ether linkage involving the fourth oxygen atom. On the supposition that this might be a diaryl ether type, we resorted to the sodium–liquid ammonia procedure[13] which has proved to be so fruitful in the field of the bisbenzyl isoquinoline alkaloids and related bases.[14] The standard conditions[13] proved somewhat unsatisfactory due to incomplete reaction, but replacement of potassium[14] for sodium and extending the reaction time led to complete cleavage of the molecule. The composition of the products differed depending upon the reaction temperature (−60° as compared to −30°), but in each case separation into phenolic and non-phenolic (including kryptophenolic) material could be accomplished by taking advantage of the differing solubility in alkali.

Irrespective of the temperature at which the potassium–ammonia cleavage of pilocereine was conducted, the principal, phenolic, basic component proved to be an oil which could not be converted into a crystalline derivative. However, after methylation with diazomethane in ether–methanol solution,[15] the oil could be characterized as a crystalline picrate and styphnate. The analytical results were consistent with the formulation $C_{16}H_{25}NO_2$, and since functional group analysis indicated the presence of two methoxyl[16] and one N-methyl group, it was clear that one-half of the cleaved pilocereine molecule had now been isolated.

The structure elucidation of the methylated, phenolic cleavage fragment (IVb) of pilocereine proceeded in a straightforward manner along the following lines. Hofmann degradation of IVb led to a methine (V) which furnished formaldehyde upon ozonolysis. Hydrogenation of the methine (V) and repeated Hofmann degradation of VI gave trimethylamine and a neutral substance (VII); ozonolysis of the latter produced isobutyraldehyde. Potassium permanganate oxidation of the original methyl ether IVb yielded a mixture of volatile stench acids (isobutyric and isovaleric acids) and a crystalline acid which was identified as *m*-hemipinic acid (VIII). This sequence of reactions is only compatible with structure IVb, and this was confirmed by direct comparison with a synthetic specimen of 1-isobutyl-2-methyl-6,7-dimethoxytetrahydroisoquinoline (IVb).[17] In order to define the exact position (C-6 or C-7) of the free phenolic group in the original cleavage product, the substance was ethylated with diazoethane and com-

(9) The analytical results of the crystalline alkaloid and its salts (ref. 7) were in better agreement with a $C_{30}H_{42}N_2O_4$ formulation, but the present structure proof clearly shows that two additional hydrogen atoms are required. Furthermore, a new N-methyl determination shows that two (rather than one—see ref. 7) such groups are present.

(15) It was reported earlier (ref. 7) that pilocereine was not methylated in ethereal solution by diazomethane (24 hr.) and that the Rodionow methylation procedure had to be used. Subsequently, it was found (see Experimental portion of this paper) that methylation could be achieved in ether–*methanol* in 3–7 days and all of the methylations were conducted in this manner even though the phenolic cleavage product IVa could also be methylated in ether without added methanol.

(16) Only one of the two methoxyl groups originated from the alkaloid while the second one was introduced by methylation of the newly formed phenolic function.

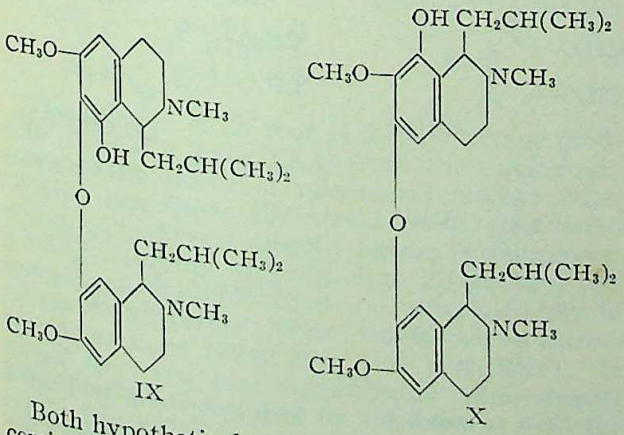
pared with the two possible isomers which had recently been synthesized.[18] The product was shown to be identical with 1-isobutyl-2-methyl-6-methoxy-7-ethoxy-1,2,3,4-tetrahydroisoquinoline (IVc) thus proving unequivocally that the free phenolic group was located at C-7 (IVa).

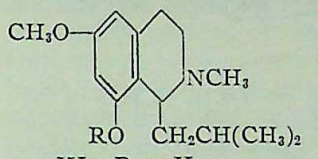
The composition of the alkali-insoluble portion from the pilocereine cleavage was affected by the temperature at which the reaction was conducted. At *ca.* −60°, two substances were isolated; the minor constituent, characterized as a crystalline picrate, corresponded to the empirical formula $C_{15}H_{23}NO$ (one methoxyl group). If this fragment had arisen from the same portion of the pilocereine molecule as the phenolic fragment IVa, it would have to be 1-isobutyl-2-methyl-6-methoxy-1,2,3,4-tetrahydroisoquinoline (IVd). This assumption was confirmed by direct comparison with a synthetic specimen.[18]

The second and major base-insoluble component formed a picrate, the analysis of which indicated the empirical formula $C_{15}H_{23}NO_2$ for the base. Since the substance possessed only one methoxyl group, it was presumably kryptophenolic (infrared hydroxyl band), and this was established by prolonged methylation with diazomethane[15] to a new ether lacking free hydroxyl absorption in the infrared. When this methylated, kryptophenolic fragment was subjected to the same reactions (Hofmann degradations and permanganate oxidations) as described above (IVb → VIII) for its phenolic counterpart IVa, the same results were observed (isolation of, respectively, formaldehyde, isobutyraldehyde, isobutyric acid and isovaleric acid) except that no substituted phthalic acid could be obtained. At this stage of the investigation it was simply assumed that the inability to isolate in this case a substituted phthalic acid may have been due to destruction of the aromatic ring activated by methoxyl substituents. Since the phenolic (IVa) and kryptophenolic cleavage products each corresponded to $C_{15}H_{23}NO_2$, it appeared that both fragments of the pilocereine molecule ($C_{30}H_{44}N_2O_4$) had been secured and that only two structures—IX and X—needed to be considered for the alkaloid.

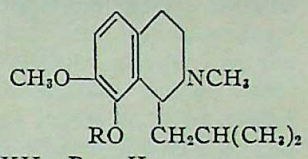


IX X

Both hypothetical structures IX and X for pilocereine appeared to be consistent with the cleavage results and with the general properties of the alkaloid. Thus ether cleavage would yield the two fragments IVa and IVd,[19] already identified by degradation and synthesis, while the kryptophenolic portion would then be represented by either XIa or XIIa. The kryptophenolic character of such a cleavage product and of pilocereine itself could be ascribed to steric hindrance imposed by the bulky isobutyl substituent *peri* to it. However, synthesis[18] of the methyl ethers XIb and XIIb proved conclusively that pilocereine could not possibly be represented by either IX or X since the synthetic products were different from the methylated, kryptophenolic cleavage base.



XIa, R = H
b, R = CH_3



XIIa, R = H
b, R = CH_3

An explanation for this apparent inconsistency appeared when the potassium–ammonia cleavage of pilocereine was carried out near −30°. Under those conditions, in addition to the phenolic (IVa) and "kryptophenolic" fragments,[20] there was formed an appreciable amount of a colorless, crystalline (m.p. 178°) substance (named "desmethylisopilocereine"). The high melting point and in particular the analytical figures ($C_{29}H_{42}N_2O_4$) demonstrated that this substance was not a cleavage product of pilocereine but rather closely related to it. In fact, it differed from the parent alkaloid only by the absence of one methoxyl group and it was first assumed that it simply represented partially demethylated pilocereine. However, methylation of this substance with diazomethane in ether–methanol yielded an oily substance, the infrared spectrum of which was identical with that of the methylated, kryptophenolic cleavage product "isopilocereine" methyl ether. When a partial methylation was attempted with diazomethane in ether alone, some of the above kryptophenol was isolated as the crystalline picrate. It then became apparent that the kryptophenol ("isopilocereine") isolated in the original −60° (as well as in part in the −30°) cleavage could not possibly possess structures of type XI and XII since it was still dimeric.[21]

We conclude that the potassium–ammonia cleavage of pilocereine proceeds in part by the expected path to yield C_{15} fragments (IVa and IVd) and in part by rearrangement or possibly dimerization of

(18) C. Djerassi, F. X. Markley and R. Ehrlich, *J. Org. Chem.*, **21**, 975 (1956).

(19) Cleavage of an unsymmetrical aryl ether can yield all four possible products (*cf.* ref. 13). The fourth (trioxygenated) product would contain two free phenolic groups in one ring and might be expected to be unstable. It was never isolated in the cleavage of pilocereine, but it was encountered when the reaction was performed with the methyl ether where no labile polyphenols would be formed.

(20) 1-Isobutyl-2-methyl-6-methoxy-1,2,3,4-tetrahydroisoquinoline (IVd) was not encountered in those experiments.

(21) Unfortunately, while the kryptophenol itself gave a crystalline picrate on which a complete analysis (including functional groups) was performed, its methylation product was oily and only C, H and N analyses were secured. When the dimeric nature was recognized, a methoxyl determination was carried out which clearly showed the presence of three methoxyl functions. The methoxyl analysis of the kryptophenol itself was of no help in this connection since it contained two methoxyl groups based on a C_{30} formula or one methoxyl based on C_{60}, in agreement with the hypothetical structures XI or XII.

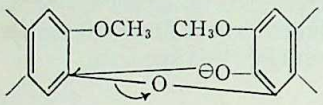
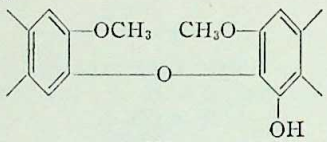
initially formed C_{15} components to yield an isomer of pilocereine in which the phenolic group is still kryptophenolic (repeated cleavage of this dimer with potassium in liquid ammonia failed). It should be noticed that at the higher temperature (−30°), rearrangement (or dimerization) is also accompanied by demethylation. The structure of the rearrangement product has not been established, but it is possible that it should be represented by IX[22] as a consequence of the transformation



XIIIa



IX

The high-melting, crystalline product would then be a demethylation product of IX, and it appears quite likely that the two phenolic groups are in different rings since the substance appears to be reasonably stable to oxidation.

The above discussion shows that the only cleavage products of structural value are IVa and IVd. In fact, the absence of any other C_{15} fragments raises the question whether the principal product—1-isobutyl-2-methyl-6-methoxy-7-hydroxy-1,2,3,4-tetrahydroisoquinoline (IVa)—might not represent *both* halves of pilocereine. Such a hypothesis would be accommodated by structure XIIIa for pilocereine, which would also be eminently satisfactory from a biogenetic viewpoint since exactly the same type of oxygenation is encountered in a variety of bisbenzylisoquinoline alkaloids[14] such as daphnandrine (XIV).[23]

A direct connection between pilocereine (XIIIa) and the bisbenzylisoquinoline alkaloids appeared feasible since the latter (*e.g.*, oxyacanthine) have been degraded[14,24] to the dialdehyde XVIII. Hofmann degradation of pilocereine methyl ether (XIIIb) proceeded smoothly and the resulting methine XV[25] was hydrogenated to the corresponding crystalline tetrahydro derivative XVI. All attempts to isolate a normal second stage Hofmann product XVII[26] or to oxidize the crude total product to the aldehyde XVIII failed in spite of elimination of trimethylamine. It appears that the predom-

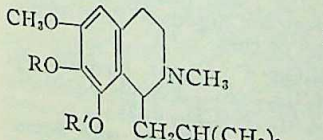
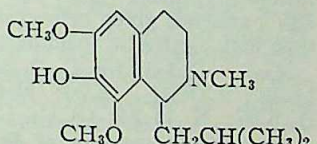
inant course of the reaction was solvolysis[27] aided by the *p*-methoxy substituent, and in one reaction conducted in the presence of ethanol, a product corresponding by analysis to the ethyl ether XIX was isolated.

In view of the unsuccessful Hofmann degradation sequence, attention was directed to the potassium–ammonia cleavage of pilocereine methyl ether (XIIIb). It was felt that if the rearrangement mechanism (XIIIa → IX) or a similar one did indeed obtain in the case of pilocereine (XIIIa), this would be inhibited in pilocereine methyl ether (XIIIb) and furthermore, it might be possible to isolate all of the possible cleavage products.[19] Indeed, the "non-phenolic" portion of such a cleavage of XIIIb could be resolved by chromatography into 1-isobutyl-2-methyl-6-methoxy-1,2,3,4-tetrahydroisoquinoline (IVd), 1-isobutyl-2-methyl-6,7-dimethoxy-1,2,3,4-tetrahydroisoquinoline (IVb) and an oily substance which after methylation[15] afforded the known[18] 1-isobutyl-2-methyl-6,7,8-trimethoxy-1,2,3,4-tetrahydroisoquinoline (XXb). The phenolic components of the pilocereine methyl ether cleavage were separated *after methylation* into 6,7-dimethoxy- (IVb) and 6,7,8-trimethoxy- (XXb) 1-isobutyl-2-methyl-1,2,3,4-tetrahydroisoquinoline.

The fact that the trioxygenated cleavage product was isolated in both the phenolic and non-phenolic portions indicates that the phenolic group in that compound is rather hindered. This would be consistent with structure XXa—hindrance being due to the *peri*-isobutyl substituent as well as to the adjacent methoxyl group—but could conceivably also apply to a phenol such as XXI in which the free phenol is flanked by methoxyl groups on either side. While either XXa or XXI would afford the same methylation product XXb (the identity of which was established rigorously by synthesis[18]) it should be noted that the presence (*prior to methylation*) of the 6,7-dimethoxy derivative IVb in the non-phenolic portion requires structure XXa.



XXa, R = CH_3; R′ = H
b, R = R′ = CH_3
c, R = C_2H_5; R′ = H



XXI

The isolation of all four possible cleavage products (IVa, IVb, IVd, XXa) from the potassium–ammonia treatment of pilocereine methyl ether (XIIIb) establishes the structure of that compound. The kryptophenolic nature of pilocereine is compatible only with structure XIIIa, and this was proved rigorously by diaryl ether cleavage of pilocereine *ethyl* ether (XIIIc) which yielded the expected products (IVa, IVc, IVd and XXc). It should be noted that considerably more drastic conditions were required in the cleavage of the ethyl ether XIIIc as compared to the lower homolog XIIIb.

(27) *Cf.* G. Norcross and H. T. Openshaw, *J. Chem. Soc.*, 1174 (1949); A. R. Battersby and H. T. Openshaw, *ibid.*, S59 (1949); A. R. Battersby and R. Binks, *ibid.*, 2889 (1955).

While according to structure XIIIa, pilocereine contains two asymmetric centers, it was nevertheless isolated in an optically inactive form.[28] Späth and Kesztler[29] already have called attention to the fact that several cactus alkaloids are isolated in the *d,l*-form[30] and they noted that synthetic, resolved pellotine (III) racemized quite readily, particularly in acid solution. It is impossible to state, therefore, whether pilocereine was racemized during the isolation process or whether it exists in the racemic form in the plant.

The presence of an isobutyl fragment at C-1, as observed in pilocereine (XIIIa), is unique among isoquinoline alkaloids. It strongly points toward the participation of leucine (or its biogenetic equivalent) in the synthesis of this alkaloid in the plant,[5] and it is not impossible that simple 1-isobutyltetrahydroisoquinolines (such as IVa) might be found in those cacti in which pilocereine has been encountered.[6–8] This would seem particularly likely in the event that diphenyl ether formation[31] should follow tetrahydroisoquinoline ring closure, and we are presently concerned with a search among cacti for such precursors. While isobutyl groups are fairly common among alkaloids, they are usually present as esters[32] and the direct connection of an isobutyl fragment to a non-oxygenated carbon atom does not appear to have been encountered before among alkaloids.

Experimental[33]

Pilocereine (XIIIa) and Pilocereine Methyl Ether (XIIIb).[34]—In order to establish the optical inactivity of pilocereine, its rotation was examined in methanol solution in a Rudolph spectropolarimeter over the range 600–350 mμ and no perceptible rotation was noted. New functional group analysis (see ref. 7) indicated the presence of two C-methyl and two N-methyl groups in the alkaloid.

Anal. Calcd. for $C_{20}H_{44}N_2O_4$: $-CH_3$, 3.03. Found: $C-CH_3$, 4.76, 5.18; $N-CH_3$, 5.16; active hydrogen, 0.95.

An alternative method[35] for the methylation of pilocereine proceeded as follows: pilocereine (8.5 g.) in methanol (200 cc.)–ether (280 cc.) solution was left for six days at 0° with 2.2 g. of distilled diazomethane. After adding an additional 2.2 g. of diazomethane and letting stand at 0° for 3 more days, the solvent was removed and the residue was recrystallized from hexane; yield 6.5 g. (in two crops), m.p. 92–105°, then resolidification and sharp melting at 153–155°. The infrared spectrum (no hydroxyl band) of this methyl ether (XIIIb) was identical with that of the earlier described[7,35] analytical sample.

(28) In order to make sure that the substance does not just happen to have zero rotation at the sodium D line, it was examined in a spectropolarimeter down to 350 mμ without observing any perceptible rotation.

(29) E. Späth and F. Kesztler, *Ber.*, **69**, 755 (1936).

(30) This is not limited to alkaloids with a free 8-hydroxyl group since this also applies to carnegine (1,2-dimethyl-6,7-dimethoxy-1,2,3,4-tetrahydroisoquinoline).

(31) See in particular p. 85 of ref. 5.

(32) For a recent example see W. Deckers and J. Maier, *Ber.*, **86**, 1423 (1953).

(33) Melting points were determined on the Kofler block. We are indebted to Mrs. Dolores Phillips for all infrared spectra. Microanalyses were carried out by Dr. Alfred Bernhardt (Mülheim, Germany), Geller Laboratories (Hackensack, N. J.) and Spang Microanalytical Laboratory (Plymouth, Mich.).

(34) In order to secure adequate amounts of pilocereine for the degradation experiments described in this paper, over 100 kg. of the cactus was collected by Dr. R. R. Humphrey (University of Arizona), and the preliminary processing was carried out in the pilot plant of Chas. Pfizer and Co. (Brooklyn, N. Y.). We are grateful for this very valuable assistance.

(35) Application of the Rodionow procedure to pilocereine has al-

Anal. Calcd. for $C_{31}H_{46}N_2O_4$: active hydrogen, 0.0. Found: active hydrogen, 0.0.

Pilocereine methyl ether with m.p. 153–155° could be transformed by recrystallization from ethyl acetate into a second crystalline form with m.p. 133–135°. The transformation was reversed by recrystallization from hexane.

Pilocereine Ethyl Ether (XIIIc).—Pilocereine (3.0 g.) in 100 cc. of absolute ethanol was treated with 3.6 g. of distilled diazoethane[36] in 150 cc. of ether. After 24 hr. at room temperature, an additional 3.6 g. of diazoethane in ether was added, and the mixture was left in the refrigerator for 6 days. Evaporation of the solvent and recrystallization from hexane gave 2.07 g. of the ethyl ether with m.p. 149–151°. An additional 0.32 g. (m.p. 143–148°) was secured by chromatography of the mother liquors. The analytical sample, recrystallized from hexane, showed a dual m. p. 90–95° and 152–153°.

Anal. Calcd. for $C_{32}H_{48}N_2O_4$: C, 73.24; H, 9.22; N, 5.34; O, 12.20; 2 N-CH_3, 5.72. Found: C, 72.64; H, 9.23; N, 5.37; O, 12.68; N-CH_3, 5.86.

Regeneration of Bases from Picrates and Styphnates by Ion Exchange Method.[37]—The following procedure was used throughout this work for the regeneration of amines from their picrate or styphnate salts: The bicarbonate salt (IRA-400-HCO_3) of the strongly basic anion exchange resin IRA-400 was prepared by passing 500 cc. of 50% sodium hydroxide solution over 200 g. of IRA-400 hydrochloride followed by 2 l. of water and 250 g. of sodium bicarbonate in saturated aqueous solution. The resin was washed with 12–16 l. of distilled water and stored under distilled water.

The styphnate or picrate salt was dissolved in acetone (or ethanol) containing about 5% of water and passed dropwise over a column of IRA-400-HCO_3. The spent resin turned bright red when acetone was used as the solvent. The column was washed with twice its volume of 10% aqueous acetone, the acetone was removed *in vacuo*, acid was added, the aqueous solution was washed with ether (discarded), made basic with ammonia and the free base was extracted with ether.

Permanganate Oxidation of Pilocereine Methyl Ether (XIIIb).—A solution of 2.5 g. of pilocereine methyl ether in 100 cc. of 10% sulfuric acid was made just alkaline with 2 *N* sodium hydroxide and then treated dropwise at room temperature with 2% aqueous potassium permanganate solution until a purple color persisted (250 cc.). After standing overnight, the colorless solution was acidified with sulfuric acid, extracted continuously with ether and the resulting acids were transformed *via* their acid chlorides (thionyl chloride procedure) into the anilides. Chromatography in the earlier described manner[17] yielded 35 mg. of isobutyric acid anilide and 10 mg. of isovaleric acid anilide. Identification was accomplished by mixture melting point determination and infrared comparison with authentic specimens. It should be noted that it has already been demonstrated[17] that oxidation of isovaleric acid under these conditions does not yield isobutyric acid.

Reductive Cleavage of Pilocereine (XIIIa) with Potassium in Liquid Ammonia at −60°.—A solution of 5.0 g. of pilocereine in 200 cc. of dry ether was added slowly with stirring to 1.5 l. of redistilled liquid ammonia cooled to −60°. Potassium metal (6 g.) was then added rapidly in small pieces and after continued stirring at −60° for 5 hr., the temperature was allowed to rise to −30° over a period of 3 hr. Anhydrous ammonium chloride was added cautiously until the blue color had been discharged. Stirring was stopped, the solvent was allowed to evaporate overnight and the residue was partitioned between ether and 3% sodium hydroxide solution. The alkaline layer was acidified with 40% sulfuric acid, extracted with ether to remove a trace of colored phenolic, non-basic material and then made basic with concentrated ammonium hydroxide. Extraction with ether, washing with water, drying and evaporation yielded 2.46 g. of *phenolic, basic* oil.

The original ether layer was extracted with 10% hydrochloric acid, dried and evaporated to yield a small amount of non-phenolic, non-basic oil which was discarded. The acid extracts were made basic with ammonium hydroxide and extracted with ether to furnish 2.40 g. of a "*non-phenolic,*" *basic* glassy (rather than mobile) fraction.

This non-phenolic, basic fraction consisted chiefly of one substance—"**isopilocereine**" (IX)—as demonstrated by chromatography and infrared examination of various fractions. It could be converted without chromatography into a crystalline, yellow *dipicrate* which melted at 235–237° after recrystallization from acetone.

Anal. Calcd. for $C_{42}H_{50}N_8O_{18}$: C, 52.82; H, 5.28; N, 11.73; 2 OCH_3, 6.51; 2 N-CH_3, 3.15. Found: C, 53.20; H, 5.36; N, 11.73; OCH_3, 6.48; N-CH_3, 3.19.

For subsequent degradation experiments with "isopilocereine," it was necessary to protect the kryptophenolic group, and 3.5 g. of "isopilocereine" picrate was converted into the free base by means of lithium hydroxide[38] and then methylated with diazomethane in ether–methanol by the procedure described above for pilocereine. The resulting "**isopilocereine" methyl ether** (55% yield) was evaporatively distilled at 180–190° and 0.005 mm. and analyzed directly since no crystalline salts could be obtained.

Anal. Calcd. for $C_{31}H_{46}N_2O_4$: C, 72.90; H, 9.08; N, 5.49; 3 OCH_3, 18.28; 2 N-CH_3, 5.88. Found: C, 72.58; H, 9.21; N, 5.40; OCH_3, 17.76; N-CH_3, 5.63.

In one experiment where rearrangement to "isopilocereine" (IX) was very much reduced and cleavage of the molecule appeared to be nearly complete,[39] treatment of a 75-mg. aliquot of the non-phenolic, basic fraction with picric acid (40 mg.) led to a new picrate (70 mg.), which after two recrystallizations from methanol exhibited m.p. 150–151°. It was identified by mixture melting point determination with a sample of synthetic picrate[18] and by infrared comparison of the free bases as **1-isobutyl-2-methyl-6-methoxy-1,2,3,4-tetrahydroisoquinoline** (IVd) picrate.

Anal. Calcd. for $C_{21}H_{26}N_4O_8$: C, 54.54; H, 5.67; N, 12.12. Found: C, 54.96; H, 5.85; N, 12.03.

A 0.26-g. portion of the phenolic, basic cleavage product, which could not be converted into a crystalline salt, was treated with ethereal diazomethane (containing a small amount of methanol) for 6 days at 0°. The solvent was evaporated, the residue extracted with ether and washed with 3% sodium hydroxide solution to give 0.2 g. of an oil which was chromatographed on 9 g. of neutral alumina and eluted in 9 fractions. Fractions 1 and 2, eluted with benzene, weighed 0.155 g., $n^{25}D$ 1.5284, and exhibited an infrared spectrum which was indistinguishable from that of synthetic[17] **1-isobutyl-2-methyl-6,7-dimethoxy-1,2,3,4-tetrahydroisoquinoline** (IVb). The melting points of the crystalline styphnate (m.p. 212–213°) and picrate (m.p. 184–185°, analysis given below) were not depressed upon admixture with synthetic specimens[17] of these salts.

Anal. Calcd. for $C_{22}H_{28}N_4O_9$: C, 53.65; H, 5.73; N, 11.38; 2 OCH_3, 12.70; N-CH_3, 3.26. Found: C, 54.17; H, 5.67; N, 11.74; OCH_3, 12.51; N-CH_3, 3.20.

Reductive Cleavage of Pilocereine (XIIIa) with Potassium in Liquid Ammonia at −30°.—The cleavage of 5 g. of pilocereine in 1.5 l. of redistilled (from sodium) ammonia with 6 g. of potassium was carried out exactly as described above except that the reaction was conducted at −30°. After separation into its components, there was obtained 1.79 g. of "non-phenolic" basic and 2.68 g. of phenolic, basic fractions. When a dried, ethereal solution of the latter was concentrated to a small volume, a white, crystalline substance (1.45 g.) precipitated. After two recrystallizations from ethanol the product ("**desmethylisopilocereine**") melted at 177.5–178°, depressed to 150° upon admixture with pilocereine, and showed significant differences in the infrared spectrum, especially the hydroxyl region. The other products were the same as those found in the −60° cleavage.

Anal. Calcd. for $C_{29}H_{42}N_2O_4$: C, 72.16; H, 8.77; N, 5.80; O, 13.26; OCH_3, 6.44; 2 N-CH_3, 6.23; mol. wt., 482. Found: C, 72.20; H, 8.86; N, 5.89; O, 13.85; OCH_3, 6.72; N-CH_3, 6.30; neut. equiv. (perchloric acid titration), 244; Rast mol. wt., 383.

Desmethyl-isopilocereine probably contains the two phenolic groups in two different rings since the substance was recovered unchanged after attempted oxidation with silver oxide.[40]

Partial methylation of desmethyl-isopilocereine was accomplished by treating 100 mg. with excess diazomethane in ether solution (no methanol present) for 2 days at 0°. Evaporative distillation of the product yielded 81 mg. of a glass, the infrared spectrum of which closely resembled that of "isopilocereine" (IX); treatment with picric acid furnished a small amount of isopilocereine picrate, identified by infrared comparison and mixture melting point determination.

Complete methylation of 210 mg. of desmethyl-isopilocereine could be carried out in methanol–ether solution for 7 days, and distillation gave 120 mg. of isopilocereine methyl ether, the infrared spectrum of which was superimposable upon that of the diazomethane methylation product of isopilocereine.

Ethylation of Phenolic, Basic Cleavage Product (1-Isobutyl-2-methyl-6-methoxy-7-hydroxy-1,2,3,4-tetrahydroisoquinoline (IVa)) Derived from Pilocereine (XIIIa).—A 300-mg. portion of the phenolic, basic cleavage product (consisting chiefly of IVa) was ethylated with 0.84 g. of diazoethane in ether solution for 7 days at room temperature. The product was freed of unreacted phenolic contaminants by washing with alkali, and it was then transformed into its picrate, m.p. 151.5–152.5°, undepressed upon admixture with a synthetic specimen[18] of **1-isobutyl-2-methyl-6-methoxy-7-ethoxy-1,2,3,4-tetrahydroisoquinoline** (IVc) picrate. Identity was established further by infrared comparison of the respective free bases.

Anal. Calcd. for $C_{23}H_{20}N_4O_9$: C, 54.54; H, 5.97; N, 11.06. Found: C, 54.66; H, 5.94; N, 11.07.

Degradation of Methylated, Phenolic, Basic Cleavage Product (1-Isobutyl-2-methyl-6,7-dimethoxy-1,2,3,4-tetrahydroisoquinoline (IVb)) Derived from Pilocereine (XIIIa).—The permanganate oxidation of natural 1-isobutyl-2-methyl-6,7-dimethoxy-1,2,3,4-tetrahydroisoquinoline (IVb) was carried out before the substance had ever been synthesized, since it formed part of the structure proof of this degradation product. However, the experimental details of this oxidation already have been reported[17] for the synthetic substance and hence will not be repeated here for the pilocereine cleavage product. By the reported[17] procedure 2.2 g. of IVb yielded 310 mg. of *m*-hemipinic acid (*Anal.* Calcd. for $C_{10}H_{10}O_6$: C, 53.10; H, 4.46; neut. equiv., 113. Found: C, 53.36; H, 4.65; neut. equiv., 117), which was further characterized as the dimethyl ester, m.p. 89.5–90°. Isobutyric and isovaleric acids, the other products of this oxidation, were identified as their anilides.

The Hofmann degradation was performed on 2.47 g. of methyl ether IVb which was converted into its gummy methiodide by standing overnight at room temperature with 10 cc. of methyl iodide. The methiodide (5.17 g.) was dissolved in a small amount of water, added to 120 cc. of 50% aqueous potassium hydroxide solution and heated under reflux for 2 hr. Isolation in the usual manner yielded 2.05 g. of oily methine V.

A 185-mg. portion of the methine was ozonized in glacial acetic acid at 15° for 30 minutes, and the reaction mixture was steam distilled into a methanol (distilled from 2,4-dinitrophenylhydrazine) solution of dimedone. After 24 hr. at 0°, 39 mg. (25%) of the formaldehyde derivative crystallized, m.p. and mixture m.p. 193–195°.

The bulk (1.87 g.) of the methine V was hydrogenated in methanol solution with 5% palladized charcoal catalyst, 1 hr. being required for the uptake of one equivalent of hydrogen. The catalyst was filtered, the solvent was removed and the reduced methine VI was evaporatively distilled at 0.1 mm.

Anal. Calcd. for $C_{17}H_{29}NO_2$: C, 73.07; H, 10.46; N, 5.01. Found: C, 72.81; H, 10.02; N, 4.96.

Conversion of the methine VI to the gummy methiodide (3.94 g.) and repeated decomposition by boiling with 50% aqueous potassium hydroxide yielded 1.06 g. of a neutral, nitrogen-free oil, evidently VII. A 90-mg. portion of it was ozonized as described above for V, and the reaction mixture was steam distilled into acidified aqueous 2,4-dinitrophenylhydrazine solution. Extraction with benzene and chromatography on neutral alumina yielded by elution with benzene 20 mg. of isobutyraldehyde 2,4-dinitrophenylhydrazone, m.p. 181–183° (recrystallized from methanol), which was not depressed when mixed with an authentic specimen.

Degradation of "Isopilocereine" Methyl Ether.—The permanganate oxidation of isopilocereine methyl ether was carried out in the manner described for pilocereine (XIIIa) and 1-isobutyl-2-methyl-6,7-dimethoxy-1,2,3,4-tetrahydroisoquinoline (IVb), but except for the volatile stench acids, isobutyric and isovaleric acids, no other acidic fragment could be characterized

For the Hofmann degradation, 104 mg. of isopilocereine methyl ether was treated in benzene solution for 4.5 hr. with 1 cc. of methyl iodide yielding 153 mg. of dimethiodide, m.p. 191–194° after recrystallization from hexane–acetone.

Anal. Calcd. for $C_{33}H_{52}N_2I_2O_4$: C, 49.82; H, 6.59; N, 3.52. Found: C, 50.01; H, 7.12; N, 3.10.

The methiodide (150 mg.) was dissolved in 5 cc. of methanol and 20 cc. of water and passed four times over a column (12 × 300 mm.) of IRA-400-OH anion exchange resin.[41] The column was washed with 20 cc. of 50% aqueous methanol, and the residue from the combined eluates was distilled at 170–175° and 0.005 mm. yielding 89 mg. of a gummy methine.

Anal. Calcd. for $C_{33}H_{50}N_2O_4$: C, 73.56; H, 9.35; N, 5.20; 2 C–CH_3, 5.59. Found: C, 73.44; H, 9.43; N, 5.12; C–CH_3, 3.97.

The above methine (100 mg.) was ozonized in chloroform solution at −60° yielding 55 mg. (51%) of the formaldehyde dimedone derivative. Another portion of the methine (500 mg.) was hydrogenated (10 minutes) in ethanol solution with palladized charcoal catalyst, and the reduced methine was distilled at a bath temperature of 160° and 0.005 mm., yield 450 mg.

Anal. Calcd. for $C_{33}H_{54}N_2O_4$: C, 73.02; H, 10.03; N, 5.16; O, 11.79; 3 OCH_3, 17.18. Found: C, 72.31; H, 9.87; N, 5.19; O, 12.46; OCH_3, 17.91.

The reduced methine (130 mg.) was transformed into its dimethiodide (180 mg.) with methyl iodide in ether solution, and it was decomposed without further purification[42] by the ion exchange resin method[41] as described above for the first stage Hofmann degradation. The resulting neutral olefin (76 mg.), which was distilled at 160–180° and 0.005 mm., was again ozonized at −60° in chloroform solution, and the distillate was passed into 2,4-dinitrophenylhydrazine solution yielding 44% of isobutyraldehyde 2,4-dinitrophenylhydrazone. Efforts to isolate any substituted diphenyl ether acids from the non-volatile ozonolysis products proved fruitless.

Hofmann Degradation of Pilocereine Methyl Ether (XIIIb).—Pilocereine methyl ether (2.56 g.) was transformed in quantitative yield into its methiodide (3.9 g., m.p. 137–150° dec.) which without further purification was added as a powdered solid to 100 cc. of refluxing 40% sodium hydroxide solution and boiled for 2.5 hr. Structure XV for the resulting methine (2.0 g., 77% yield) was established by ozonolysis of a 160-mg. portion in acetic acid solution and steam distillation into 2,4-dinitrophenylhydrazine solution. Only formaldehyde 2,4-dinitrophenylhydrazone (47 mg., 56% yield) was isolated, uncontaminated by any isobutyraldehyde derivative.

Pilocereine methyl ether methine (XV) (1.9 g.) was hydrogenated in 50 cc. of 95% ethanol with 300 mg. of 10% palladized charcoal catalyst and the product (1.85 g.) was recrystallized several times from acetonitrile to yield 0.92 g. of the reduced methine XVI, m.p. 101.5–103.5°.

Anal. Calcd. for $C_{33}H_{54}N_2O_4$: C, 73.02; H, 10.03; N, 5.16; O, 11.79; 3 OCH_3, 17.18. Found: C, 72.37; H, 9.88; N, 5.49; O, 11.53; OCH_3, 15.38.

The second stage Hofmann degradation was carried out with 1.21 g. of crystalline reduced methine XVI and was performed exactly as described above (XIIIb → XV).

(40) *Cf.* N. D. Cheronis, "Micro and Semimicro Methods" in A. Weissberger's "Technique of Organic Chemistry," Vol. VI, Interscience Publishers, Inc., New York, N. Y., 1954, pp. 270–276.

(41) *Cf.* J. Weinstock and V. Boekelheide, THIS JOURNAL, **75**, 2546 (1953).

(42) Excessive handling of this substance was avoided since it was noted by R. Mirza in this Laboratory in some preliminary abortive experiments that heating with methanol during attempted recrystallization yielded some tetramethylammonium iodide (m.p. 228°).

Elimination of trimethylamine proceeded smoothly as demonstrated by the isolation of 0.45 g. (75%) of trimethylamine picrate (m.p. 206–210°), but the nitrogen-free degradation product (0.84 g.) apparently contained very little of the desired olefin XVII since treatment with one equivalent of ozone in ethyl acetate solution at −60° by the inverse technique[43] (which worked satisfactorily in a model experiment with isoeugenol methyl ether) followed by decomposition of the ozonide with zinc in acetic acid (24 hr., room temperature) yielded only 3% of isobutyraldehyde 2,4-dinitrophenylhydrazone after chromatography on bentonite–kieselguhr.[44] Careful examination of the non-volatile portion including chromatography did not yield any of the desired aldehyde XVIII[24] even though seed crystals of authentic dialdehyde (derived from an intermediate[23] kindly provided by Sir A. R. Todd, Cambridge University) were available.

In another experiment, in which the Hofmann degradation of the dimethiodide of 1.72 g. of crystalline reduced methine XVI was carried out as described above with the modification that the dimethiodide was first dissolved in ethanol (rather than being added in the solid state to the alkaline medium), a substance was isolated which on the basis of the analysis of a distilled (155–170° at 0.005 mm.) sample (no infrared hydroxyl absorption) appeared to be the diethyl ether XIX arising by solvolysis.

Anal. Calcd. for $C_{33}H_{52}O_6$: C, 72.75; H, 9.62; O, 17.62. Found: C, 73.24; H, 9.39; O, 17.04.

Reductive Cleavage of Pilocereine Methyl Ether (XIIIb) with Potassium in Liquid Ammonia.—The cleavage of 1.98 g. of pilocereine methyl ether (XIIIb) was carried out in the manner described above with 90 cc. of ether, 600 cc. of liquid ammonia and 2.5 g. of potassium at −60° for 7 hr. and furnished 1.30 g. of "non-phenolic," basic and 0.67 g. of phenolic, basic fractions. The "non-phenolic," basic portion was dissolved in 20 cc. of hexane and chromatographed on 80 g. of alumina (deactivated with 2.4 cc. of 10% acetic acid), collecting a total of 114 fractions.

Fractions 20–46, eluted with hexane up to 1:1 hexane–benzene mixtures, upon treatment with picric acid in ethanol gave 0.53 g. (29%) of the picrate of **1-isobutyl-2-methyl-6-methoxy-1,2,3,4-tetrahydroisoquinoline (IVd)**, m.p. 152–153°, undepressed when mixed with a sample of the synthetic[18] picrate. Identity was confirmed by converting a portion of the picrate by the above-described ion-exchange method to the free base and comparing its infrared spectrum with that of the synthetic base.

Anal. Calcd. for $C_{21}H_{26}N_4O_8$: C, 54.54; H, 5.67. Found: C, 54.21; H, 5.90.

Fractions 47–83 were eluted with mixtures ranging from 1:1 hexane–benzene to 99:1 benzene–ether and after treatment with ethanolic picric acid solution, yielded 0.196 g. (10%) of **1-isobutyl-2-methyl-6,7-dimethoxy-1,2,3,4-tetrahydroisoquinoline (IVb) picrate**, m.p. 183–185°. Identity was established by mixture melting point determination of the picrates as well as by infrared comparison of the synthetic[17] and natural bases (regenerated from its picrate by the ion exchange method).

Fractions 100–112, eluted with 9:1 benzene–ether, furnished only with great difficulty a picrate (10% yield, m.p. 150–155°) which on the basis of its analysis, kryptophenolic behavior and identification of its methylation product (see below) must be **1-isobutyl-2-methyl-6,7-dimethoxy-8-hydroxy-1,2,3,4-tetrahydroisoquinoline (XXa) picrate.**

Anal. Calcd. for $C_{22}H_{28}N_4O_{10}$: C, 51.96; H, 5.55; N, 11.02; 2 OCH_3, 12.20. Found: C, 51.51; H, 5.69; N, 11.05; OCH_3, 11.98.

A 73-mg. sample of the above base XXa, regenerated from its picrate by the ion exchange procedure, was methylated for 10 days at 0° with diazomethane in ether–methanol. The product was converted into its crystalline picrate, m.p. 132–134°, which proved to be identical by mixture melting point determination and infrared comparison of the respective free bases with a synthetic[18] specimen of **1-isobutyl-2-methyl-6,7,8-trimethoxy-1,2,3,4-tetrahydroisoquinoline (XXb)**.

Fractions 112–114 were eluted with ether and with 9:1 ether–methanol. The picrate of the residue melting unsharply above 210° could not be resolved into a pure component; it may represent dimeric material.

The phenolic, basic cleavage products (0.67 g.) were methylated with diazomethane in ether–methanol for 8 days in the refrigerator. The crystalline picrate (0.43 g., 23% yield, m.p. 181–184°) of **1-isobutyl-2-methyl-6,7-dimethoxytetrahydroisoquinoline (IVb)** could be separated directly without having to resort to chromatography, and identity with synthetic material[17] was established in the usual manner.

Anal. Calcd. for $C_{22}H_{28}N_4O_9$: C, 53.65; H, 5.73; N, 11.38; 2 OCH_3, 12.60; N–CH_3, 3.05. Found: C, 54.17; H, 5.67; N, 11.74; OCH_3, 12.51; N–CH_3, 3.20.

The mother liquors from the above picrate preparation were transformed into the free amine by the ion exchange method and then chromatographed on deactivated alumina leading to 0.164 g. of an oil. Treatment with picric acid furnished 0.175 g. (9%) of the picrate of **1-isobutyl-2-methyl-6,7,8-trimethoxy-1,2,3,4-tetrahydroisoquinoline (XXb)**, thus raising the total yield of the trioxygenated cleavage product XXa to 19%.

Reductive Cleavage of Pilocereine Ethyl Ether (XIIIc) with Potassium in Liquid Ammonia.—The ethyl ether XIIIc (2.04 g.) was cleaved in 80 cc. of ether and 600 cc. of ammonia with 3.3 g. of potassium at −60°. The reaction time had to be extended to 24 hr. (in contrast to pilocereine or its methyl ether) since incomplete cleavage was observed when the time was shortened. The usual processing gave 1.30 g. of "non-phenolic," basic and 0.51 g. of phenolic, basic fractions.

Careful chromatography of the "non-phenolic" portion as described above for the methyl ether cleavage gave in order of increased polarity 0.576 g. (32%) of **1-isobutyl-2-methyl-6-methoxy-1,2,3,4-tetrahydroisoquinoline (IVd)** picrate, m.p. 151–153°, 0.227 g. (11.5%) of **1-isobutyl-2-methyl-6-methoxy-7-ethoxy-1,2,3,4-tetrahydroisoquinoline (IVc) picrate**, m.p. 152–153°, and 0.244 g. (12%) of **1-isobutyl-2-methyl-6-methoxy-7-ethoxy-8-hydroxy-1,2,3,4-tetrahydroisoquinoline (XXc) picrate**, m.p. 153–154°. Identity of the first two compounds was established by mixture melting point determination of the picrates as well as by infrared comparison of the free bases with those of synthetic samples.[18] The structure of the third compound follows from its analysis, the presence of a free hydroxyl band in the infrared spectrum of the free base and from the constitution of pilocereine itself.

Anal. Calcd. for $C_{23}H_{30}N_4O_{10}$: C, 52.87; H, 5.79; N, 10.72; O, 30.62. Found: C, 52.67; H, 5.99; N, 10.54; O, 30.35.

Methylation of the phenolic, basic cleavage fraction (0.51 g.) in the standard manner and treatment with picric acid gave 0.356 g. (19%) of the pure picrate (m.p. 183–185°) of **1-isobutyl-2-methyl-6,7-dimethoxy-1,2,3,4-tetrahydroisoquinoline**, identical in all respects with a synthetic[17] sample.

Quaternary Piperazines with Anti-pinworm Activity[1]

BY M. HARFENIST

RECEIVED NOVEMBER 13, 1956

The syntheses and properties of 100 piperazine monoquaternary salts prepared for a study of their anthelmintic activities, and of some related compounds, are reported. Most were prepared by standard methods, but attempts to decarbethoxylate three 1-carbethoxy-4-benzylquaternaries (table, lines 42, 49, 50) led to debenzylation. Anthelmintic activity (*Syphacia obvelata* in the mouse) is discussed briefly as a function of structure.

Consideration of the structures of a number of compounds active in a screening test (*Syphacia obvelata* in the mouse)[2] designed to find substances active against the pinworm of humans, *Enterobius vermicularis*, suggested that two structural features were common to piperazine, gentian violet and several other active series of compounds: all appeared likely to exist largely in the cationic form at physiological acidities,[3] and all had a ring structure near the positive charge. It was thought of interest to prepare some other compounds combining these structural features. The piperazine ring, which occurs in many physiologically active compounds, was therefore given the positive charge induced by quaternization at one nitrogen. It was also anticipated that the well-known tendency of quaternary salts to be poorly absorbed on oral administration would result in negligible systemic toxicity to the host. The high therapeutic index of some of the first compounds prepared led to the synthesis of a large number of diverse piperazine monoquaternaries, whose properties are tabulated.

The thoroughly explored route to unsymmetrical piperazines by alkylation of 1-carbethoxypiperazine[1] was used to prepare most of the compounds. The quaternizations were done in acetone at about room temperature, since some of the higher quaternaries could not be crystallized readily from alcoholic solvents. Further, solvolysis of some halides competed with the slower quaternizations especially in methanol.

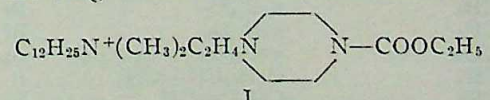
It was convenient to prepare large batches of the 1-carbethoxy-4-alkylpiperazines substituted with the smaller alkyl group and to then quaternize each of these with a number of larger alkyl bromides. In some cases, the alkyl iodides were used as quaternizing agents to speed up the reactions, but they were not as satisfactory since the hydriodides of the starting tertiary amines were sometimes the only isolable products.[4]

The quaternization of 1-carbethoxy-4-propargylpiperazine, *e.g.*, with dodecyl bromide, was so slow as to be essentially unusable. This is, of course, an example of the well-known electron-attracting ability of the ethinyl group. Propargyl bromide was therefore used to prepare quaternaries such as those on lines 38 and 71–79 of the table, and reacted rapidly as anticipated.[5] Indeed, the dipropargyl quaternary was prepared readily (line 76).

To prepare the 1,1-dialkylpiperazinium halides without an amide function at N_4 (lines 1–10 of the table) decarbethoxylation of the corresponding 4-carbethoxy quaternaries by constant-boiling aqueous hydrochloric acid was generally used.[6] The quaternary function at the other nitrogen did not appear to increase the rate of hydrolysis at the carbethoxy group appreciably more than the activation conferred by protonation of a tertiary nitrogen in this strongly acidic medium.

In the case of the attempted acid hydrolysis of 1-carbethoxy-4-methyl-4-benzylpiperazinium chloride and its 4-methyl-4-*p*-chlorobenzyl congener (table, lines 42 and 44), this treatment led to destruction of the quaternary with formation of 1-methylpiperazine (characterized both by benzoylation and by formation of the phenylthiourea) and steam-distillable material resembling the corresponding benzyl halide. The related 1-carbethoxy-4-methyl-4-*p*-anisylpiperazinium chloride (table, line 50) gave what appeared to be a polymer in addition to the 1-methylpiperazine. Raney nickel-catalyzed hydrogenolysis[7] of the 1-nitroso quaternary (table, line 100) was therefore used to prepare 1-methyl-1-benzylpiperazinium chloride.[7,8]

The 1-alkyl-4-amides (other than the carbethoxy compounds) required for preparation of the corresponding quaternaries (table, groups B, C, D, F, G) were in general prepared by the methods previously reported.[9] One exception is the preparation of the compound I, required to determine whether placing the quaternary grouping further from the ring would affect anthelmintic activity.



I

This was prepared from the commercially available aminoethylpiperazine which, on heating with benz-

(1) This paper is No. X on unsymmetrical piperazines from these laboratories. For the previous paper, see R. Baltzly, W. S. Ide and E. Lorz, THIS JOURNAL, **77**, 4809 (1955).

(2) K-F. Chan, *Am. J. Hyg.*, **56**, 22 (1952).

(3) The glycinamide quaternaries of A. J. Rachlin, *et al.*, A.C.S. Div. of Med. Chem. Abstracts, P.5M. (Apr. 8, 1956) also fit this category, as does cyanine dye No. 715 [*cf.* E. Perez-Santiago, J. Oliver-González and C. J. Thillet, *Am. J. Trop. Med. Hyg.*, **2**, 307 (1953)].

(4) E. D. Hughes and U. G. Shapiro, *J. Chem. Soc.*, 1177 (1937), have shown that the ratio of the E_2 elimination to the S_N2 hydrolysis of isopropyl iodide in alkaline ethanol–water solution is greater than for isopropyl bromide.

(5) The rapid reactions of propargyl chloride with ethoxide and with radioactive chloride have been reported by C. A. Vernon, *J. Chem. Soc.*, 4462 (1954), and that with ethoxide by L. F. Hatch and V. Chiola, THIS JOURNAL, **73**, 360 (1951). However, the occurrence of side reactions led to inconstancy of the rate, or incomplete reaction. Since the theoretical titer of acetylenic hydrogen is found in the quaternaries readily isolated in excellent yield from our quaternizations with propargyl bromide, it is hoped to measure the rate of this reaction more precisely as time permits.

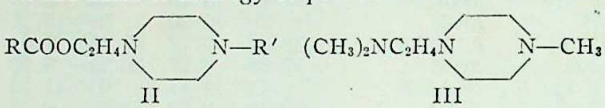
aldehyde, gave the Schiff base. On treatment of this with ethyl chlorocarbonate, it was carbethoxylated to the unstable carbethoxy Schiff base hydrochloride which, on steam distillation of the crude reaction mixture, lost its benzal group to give 1-(2′-aminoethyl)-4-carbethoxypiperazine hydrochloride. Dimethylation (Clarke–Eschweiler) and quaternization of the resulting tertiary amine led to the desired quaternary. Details of these reactions are given in the Experimental section. That quaternization occurs on the side-chain nitrogen is indicated on the basis of analogy to previous work[10] which in-



II III

dicates that the piperazines II quaternize preferentially at N–R′ and that only the bis-quaternary is produced on refluxing III with methanolic methyl iodide.[11]

The amine oxide methiodide (table, line 85) was prepared by quaternization of the oxide produced readily by hydrogen peroxide treatment of 1-carbethoxy-4-*n*-dodecylpiperazine as given in the Experimental section.

Anthelmintic Activity.—Results of the anthelmintic tests will be published in detail elsewhere. They may be summarized in part as showing that a maximum in therapeutic index occurs in the mouse at about the 4-methyl-4-tridecyl- or tetradecylpiperazinium halides. To a first approximation, the position of this maximum is independent of the amide substituent. Of these N-1-amide substituents, the carbethoxy and the diethylcarbamyl groups seem to be best[12] while the 1-nitroso and, surprisingly, the 1-carbamyl quaternaries are inactive (groups F and I). Compound 34, the best of this series, is comparable to piperazine in therapeutic index in these tests.

Activities of 1-methyl quaternaries in which the other 1-substituent is unsaturated, aryl, aralkyl or heterocyclic follow no obvious order. The therapeutic indices of those few quaternaries in which the 1-methyl group was replaced by larger groups seem lower than those of the corresponding 1-methyl quaternaries.

Acknowledgment.—We thank Mr. Samuel W. Blackman for the carbon–hydrogen analyses reported here, and Mr. Ernest Magnien for preparation of certain of the intermediates.

Experimental

Analyses for Halides.—Chlorides were determined by the exceptionally convenient method using phenosafranin as adsorption indicator in dilute nitric acid solution. Bromides and occasionally iodides were also done by this method when a spot test indicated its applicability, otherwise by use of eosin as adsorption indicator or by the Volhard titration.

Melting Points.—These normally occurred with decomposition and frequently were a function of the rate of heating, which therefore was maintained at 3°/min.

1-Carbethoxy-4-dodecylpiperazine-4-oxide.—Fifteen grams (0.13 mole) of 30% hydrogen peroxide was added to a solution of 27 g. (0.083 mole) of 1-carbethoxy-4-*n*-dodecylpiperazine in 116 ml. of glacial acetic acid maintained at about 40°. An equal amount of peroxide was added after 24 hr., and the solution was kept for 3.5 more days. Only a faint positive test with iodide–starch was obtained at this time. The solution was evaporated to a small volume on the steam-bath at 20 mm. pressure, made strongly basic with excess of saturated aqueous potassium carbonate and the resulting oil extracted with two portions of ether. The ethereal solution was dried over magnesium sulfate and concentrated and the residue crystallized from acetone–Skellysolve B. Three crops totaling 23 g. were taken and recrystallized from acetone–Skellysolve A to give 17 g. (two crops), m.p. 139.5°.

Anal. Calcd. for $C_{19}H_{38}N_2O_3$: C, 66.63; H, 11.18. Found: C, 66.95; H, 11.33.

1-Dodecylpiperazine-1-oxide.—A solution of 12 g. (0.035 mole) of the carbethoxypiperazine oxide was heated under reflux with 120 ml. of water containing 12 g. (0.07 mole) of barium hydroxide for 3 hr. Barium ion was removed from the solution by passing in an excess of carbon dioxide and then boiling the solution briefly (*cf.* ref. 9). Evaporation *in vacuo* of the filtrate from this operation gave 8 g. of white solid, which was recrystallized readily from acetone–Skellysolve B to give 5.2 g., m.p. *ca.* 68.5°. This was hygroscopic and apparently light-sensitive and so was converted to the dihydrochloride, m.p. 153–159°.

Anal. Calcd. for $C_{16}H_{36}N_2OCl_2$: Cl^-, 20.62. Found: Cl^-, 20.52.

1-(2′-Benzalaminoethyl)-piperazine.—Addition of 116 g. (1.1 moles) of freshly purified benzaldehyde in a thin stream during four minutes to a well-stirred 129 g. (1 mole if pure) of 2-aminoethylpiperazine (Carbide and Carbon Chemical Co., Inc., "95%") led to spontaneous evolution of steam from the mixture. The remaining water was distilled off at the water-pump until the bath temperature reached 160°. The remaining amber oil was distilled retaining fractions boiling at 140° at 0.2 mm. to 180° at 0.1 mm., totaling 187 g. Redistillation gave 133.5 g. boiling at 130–133° at 0.005 mm. A hard pitch was found as the boiler residue of both distillations, presumably a result of thermal decomposition of the Schiff base. The titration curve of the distillate showed only one inflection point between *p*H 11.5 and 1.5, on titration with hydrochloric acid.

Anal. Calcd. for $C_{13}H_{19}N_3$: equiv. wt., 108.5. Found: equiv. wt., 115.

1-Carbethoxy-4-(2′-aminoethyl)-piperazine.—One hundred grams (0.94 mole) of redistilled ethyl chlorocarbonate was added during 20 minutes to a stirred, cooled solution of 127 g. (0.59 mole) of 1-(2′-benzalaminoethyl)-piperazine in 1 l. of absolute ethanol maintained at 20°. After an additional 0.75 hr. of stirring, the solvent was distilled off at the water-pump, finally on a steam-bath. Distillation of 700 ml. of water from the residue at the water-pump (85% of theory of benzaldehyde was recovered) and similar distillation of 1.1 l. of 1.2 *N* HCl was followed by recrystallization of the residual oil from absolute ethanol by addition of carbon tetrachloride to faint turbidity at 40°. From 77 g. of crude product there was obtained after three recrystallizations 28.2 g. of white solid, m.p. 157.5–158.5.

Anal. Calcd. for $C_9H_{21}N_3O_2Cl_2$: Cl^-, 25.68. Found: Cl^-, 25.70.

1-Carbethoxy-4-(2′-dimethylaminoethyl)-piperazine.—Twenty grams (0.072 mole) of 1-carbethoxy-4-(2′-aminoethylpiperazine) dihydrochloride and 4.3 g. (0.041 mole) of sodium carbonate were added to 38 ml. of 98–100% formic acid, and half of 45 ml. of 38% formaldehyde was added to the mixture. It was then heated under reflux for 6 hr., treated with the rest of the formaldehyde and again refluxed for 6 hr. The reaction mixture was then acidified with 25 ml. of concentrated hydrochloric acid and evaporated on a steam-bath at the water-pump. The residue was dissolved in water, the water saturated with potassium carbonate with cooling and the resulting oil taken into 2 portions of ether. Removal of the ether, acidification with ethanolic hydrogen chloride and dilution with ether gave a white solid. This was recrystallized by addition of acetone to its solution in hot 10% aqueous ethanol. It sublimed when heated over 240° and had m.p. 282–285 when rapidly heated on a hot-stage. The yield was quantitative.

Protecting Groups in the Synthesis of Unsymmetrical Piperazines[1]

BY M. HARFENIST AND E. MAGNIEN

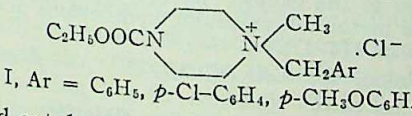
RECEIVED NOVEMBER 17, 1956

Methods for removing various groups useful in protecting one of the two nitrogens of substituted piperazines were studied using piperazine quaternaries with the following N-substituting protective groups: carbethoxyl (removal by aqueous barium hydroxide), acetyl (removal by acid), nitroso (removal by hydrogenolysis catalyzed by Raney nickel) and nitroso with an equivalent of carbamyl (removal of nitroso as nitrous acid, destroyed by the carbamyl function). The relative utility of these methods is briefly considered.

Syntheses in the field of unsymmetrical piperazines are based to a considerable extent on the mono-carbethoxylation of piperazine[2] to protect one nitrogen, although the direct preparations of other mono-amides, and even of alkyl and aralkyl piperazines,[3] have been reported.

The carbethoxy group may be removed either by heating the carbethoxypiperazines with constant-boiling (approx. 6 *N*) aqueous hydrochloric acid at its boiling point (approx. 110°) for two to three days or much more rapidly, as would be anticipated on theoretical grounds, by heating them with alkali.[2,4]

The requirement of protective groups other than carbethoxy became urgent when attempts to hydrolyze the unsymmetrical 1-carbethoxy-4-methyl-4-benzylpiperazinium chlorides (I)[1] by the hydrochloric acid method led to loss, not only of the carbethoxyl, but also of the benzyl group.[5] Further,



I, Ar = C_6H_5, *p*-Cl–C_6H_4, *p*-$CH_3OC_6H_4$–

the acid-catalyzed decarbethoxylation of 1-carbethoxy-4-methyl-4-propargylpiperazinium chloride gave a product containing an impurity of lower halide content, which could not be removed by repeated crystallization.

Although it was felt that the basicity required for saponification of the carbethoxyl group might lead to decomposition of the quaternaries, the rate of the saponification of the propargyl quaternary (I for Ar put C≡CH) by aqueous barium hydroxide was studied. At about 50°, an excess of 0.4 *N* aqueous barium hydroxide gave 85% hydrolysis of the carbethoxyl function (by acidimetric titration of aliquots) in 1 hr. The decarbethoxylated 1-methyl-1-propargylpiperazinium chloride isolated in fair yield after 140 min. under reflux or remaining overnight at 50° was moderately pure and readily gave analytically pure product on recrystallization, although each recrystallization was accompanied by great loss of material.

Theoretical considerations indicated that acid hydrolysis of a 1-acylpiperazine should be rapid, especially under conditions in which the 4-nitrogen, if not quaternized, would be protonated. As anticipated, the de-acetylations of the test substances 1-acetyl-4,4-dimethylpiperazinium chloride and 1-acetyl-4-methyl-4-benzylpiperazinium chloride had been completed (titration) after 30–40 minutes at 95° in the presence of two equivalents of 2 *N* hydrochloric acid and, indeed, were about half completed after four days at room temperature. Hydrolysis of the carbethoxy group of the 1-carbethoxy-4,4-dimethyl quaternary, in contrast, was undetectable after 24 hr. at 95°, in the presence of the same excess of acid. Although the hydrolysis mixture of the acetylmethylbenzyl quaternary had a faint odor resembling benzyl chloride (or alcohol), the appropriate de-acetylated quaternary was isolated in excellent yield from it as well as from the dimethyl analog.

The Raney nickel-catalyzed hydrogenolysis of the nitroso group[6] from 1-nitroso quaternaries was studied with 1-nitroso-4-methyl-4-dodecylpiperazinium iodide which readily gave an 86% yield of analytically pure de-nitrosated quaternary. The corresponding 1-nitroso-4-methyl-4-benzylpiperazinium chloride absorbed the theoretical amount of hydrogen rapidly, and then absorption nearly stopped. Yields averaging 75% were obtained, but the product was contaminated by nickel ion. This was removed by treatment of the reduction filtrate

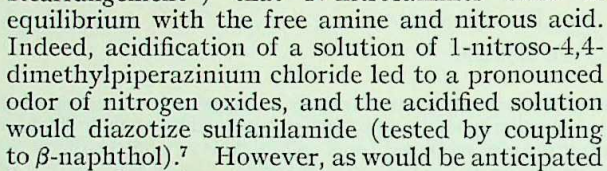
with dimethylglyoxime, as outlined in the Experimental section. However, since no source of anion for the nickel other than the quaternary chloride is evident, it is likely that slight hydrogenolysis had occurred at the quaternary nitrogen in this case. This point was not investigated further.

Another route used successfully for pilot preparations of both dimethyl- and methylbenzylpiperazinium chlorides also utilized the 1-nitrosopiperazinium compounds. It was anticipated on the basis of extension of the known intermolecular nature of rearrangements of N-nitrosamines ("Fisher–Hepp Rearrangement") that N-nitrosamines exist in equilibrium with the free amine and nitrous acid. Indeed, acidification of a solution of 1-nitroso-4,4-dimethylpiperazinium chloride led to a pronounced odor of nitrogen oxides, and the acidified solution would diazotize sulfanilamide (tested by coupling to β-naphthol).[7] However, as would be anticipated from the fact that amines are usually nitrosated in acid solution, the equilibrium strongly favors the nitrosamine, and no appreciable hydrolysis of this one could be found after several days in 2 *N* hydrochloric acid at 95°. A nitrous acid acceptor would therefore be required to make acidic de-nitrosation practical. To avoid introducing extraneous substances, the nitrous acid acceptor selected was the 1-carbamyl derivative of the same piperazine quaternary whose nitroso-derivative was used. The reaction



a, R = CH_3 = R′
b, R = CH_3; R′ = $CH_2C_6H_5$

was complete, as determined by the drop in acid titer, after 30–40 minutes at 95° in the presence of 4 equivalents (100% excess) of 2 *N* hydrochloric acid. Nearly quantitative yields of the expected quaternaries were isolated from these reactions. The rate of hydrolysis of the carbamyl compound under these conditions was separately determined and was found to be negligible by comparison. The product of such hydrolysis, ammonium chloride, would of course also react with nitrous acid rapidly.[8]

Conclusions.—Use of the N-acetyl function as a protective group, and its hydrolytic removal in the presence of mineral acid, is probably the mildest and most convenient of the protective methods discussed here. The use of a mixture of equivalent amounts of N-nitroso- and N-carbamylpiperazine requires the preparation of both, but is otherwise very satisfactory except, presumably, for compounds which might react with nitrous acid irreversibly at a rate comparable to that of the carbamyl group. The barium hydroxide method is best suited to compounds soluble in the basic aqueous solution and stable to alkali for several hours at a temperature somewhat over room temperature. The limits of the Raney nickel-catalyzed hydrogenolytic de-nitrosation have not been determined. The potential utility of this method is great, since reduction of the very readily reduced nitroso function probably would be more rapid than that of most other functional groups.

Acknowledgment.—We thank Dr. R. Baltzly for many helpful discussions during the course of the work.

Experimental

1-Propargyl-1-methylpiperazinium Bromide (Barium Hydroxide Method).—A filtered solution of 295 ml. of 0.4 *N* barium hydroxide in water at 50° was treated with 10 g. of 1-carbethoxy-4-methyl-4-propargylpiperazinium bromide.[1] Aliquots removed after 1 hr. and 5 hr. at 50° revealed an uptake of base corresponding to 86 and 100%, respectively, of the ultimate total base uptake (after 17 hr.). Analogously, 0.35 *N* aqueous barium hydroxide under reflux gave about 70% of the ultimate base uptake after 27 minutes and a base titer after 80 minutes not changed by an additional hour of heating.

This latter alkaline solution was treated with an excess of carbon dioxide and then heated on a steam-bath while nitrogen was bubbled through it to reprecipitate the barium as carbonate. It was then filtered and evaporated on the steam-bath *in vacuo*. The remaining dark oil was dissolved in absolute ethanol, an equal volume of acetone was added and the solution was cooled and filtered from inorganic solids. The hydrobromide of the quaternary was precipitated by addition of 9 g. of 30% hydrobromic acid in acetic acid followed by ether. The resulting 6.5 g. of tan solid had m.p. 160°, after much preliminary sintering. It was recrystallized with difficulty from ethanol (95%)–acetone–ether, yielding 1.5 g., melting with decomposition about 177–180°. The workup of batches decarbethoxylated at 50° was the same in all essentials.

Anal. Calcd. for $C_8H_{16}N_2Br_2$: Br^-, 53.35. Found: Br^-, 53.10.

The compound, in contrast with acetylenic piperazine amines and quaternaries with the other nitrogen present as part of an amide function, gave no usable end-point on titration for acetylenic hydrogen,[1] although qualitative tests were positive for that function.

Conversion to the chloride by the use of silver chloride suspended in methanol containing hydrochloric acid gave a product of m.p. 171–172°.

Anal. Calcd. for $C_8H_{16}N_2Cl_2$: Cl^-, 33.57. Found: Cl^-, 32.70.

1-Methyl-1-benzylpiperazinium Chloride (Nitroso-compound with Hydrogen and Raney Nickel).—A solution of 12.5 g. (0.05 mole) of 1-nitroso-4-methyl-4-benzylpiperazinium chloride[1] dissolved in 50 ml. of methanol was treated with approximately 4 g. (dry weight) of Raney nickel, and hydrogen initially at 40 pounds over-pressure in a Parr hydrogenator at room temperature (28°). The initial rapid reduction slowed markedly when very nearly the theoretical amount of hydrogen had been absorbed, but reduction was continued until the rate fell below 1% of the initial value (3.5 hr.). The green solution was filtered from catalyst and treated with a bit over the theoretical amount of solid dimethylglyoxime (determined by portionwise addition to an aliquot), refiltered and concentrated on the steam-bath *in vacuo*. The resulting pink solid was recrystallized from ethanol–ether, converted to the hydrochloride and that recrystallized from absolute ethanol–benzene–ether. Another recrystallization gave 7.2 g., m.p. 116°, apparently a monohydrate.

Anal. Calcd. for $C_{12}H_{20}N_2Cl_2 \cdot H_2O$: Cl^-, 25.20. Found: Cl^-, 25.10.

Drying for 2 hr. at room temperature and 0.01 mm. gave a product of m.p. 172–175°.

Anal. Calcd. for $C_{12}H_{20}N_2Cl_2$: Cl^-, 26.92. Found: Cl^-, 27.12.

(7) The application of a similar reaction as a spot test has been published since completion of this work; F. Feigl and C. C. Neto, *Anal. Chem.*, **28**, 1311 (1956).

(8) It should be remembered that iodides react with nitrites in acid solution. Iodides can be converted to chlorides, bromides or methanesulfonates under neutral conditions by use of the appropriate silver salt.

The Synthesis of the 2-Amino-3-(3-indolyl)-butyric Acids (β-Methyltryptophans)

BY H. R. SNYDER AND DONALD S. MATTESON[1]

RECEIVED OCTOBER 11, 1956

Indole adds to ethylideneisopropylamine to form 3-(isopropylaminoethylidene)-indole, a substance similar to a Mannich base but having an ethylidene group in place of the methylene residue. Dibenzyl acetamidomalonate is prepared from diethyl acetamidomalonate and alkylated with the new base. Hydrogenolysis of the alkylation product yields the substituted malonic acid, which is converted to 2-amino-3-(3-indolyl)-butyric acid upon decarboxylation followed by hydrolysis of the acetamido group. The amino acid is separated into its two diastereoisomeric *dl*-pairs, and it is shown that these are not structural isomers nor merely different crystalline forms of one compound.

A convenient synthesis of *dl*-tryptophan[2,3] begins with gramine (the Mannich base from indole, formaldehyde and dimethylamine). It appeared likely that β-methyltryptophan (V) could be synthesized *via* a similar route if a way could be found to condense indole, acetaldehyde and an amine to form the base I.

Attempts to employ aldehydes other than formaldehyde in reactions of the Mannich type have met with only limited success; perhaps the best examples of such reactions are those which lead to cyclic products.[4] However, simple bases of the Mannich type have been obtained by the addition of active methylene compounds to aldimines. Benzalaniline has been condensed with acetoacetic ester,[5] malonic ester[6] and related compounds,[7] indoles,[8] pyrazolones,[9] β-naphthol[6] and, in the presence of boron fluoride, with methyl ketones.[10] Recently, indole has been added to Δ^1-piperideine (stable as the trimer) and to 3,4-dihydroquinoline.[11] Indole also has been condensed with the cyanohydrins of acetaldehyde and of acetone and with acetone and chloroform.[12]

The recent observation by Hurwitz[13] that *t*-butylamine forms stable aldimines with aliphatic aldehydes suggested the possibility of adding indole to ethylidene-*t*-butylamine to prepare 3-(*t*-butylaminoethylidene)-indole (Ia).

Before an attempt was made to condense indole with ethylidene-*t*-butylamine, experiments were performed to determine whether *t*-butylamine would participate in normal Mannich reactions. Under typical Mannich conditions,[4] *t*-butylamine hydrochloride, paraformaldehyde and indole give a moderate yield of 3-(*t*-butylaminomethyl)-indole; this secondary amine is the only product. When simpler primary amines are used in Mannich reactions under these conditions, the secondary amine formed condenses with an additional mole of indole and formaldehyde to form a tertiary amine[4]; the formation of a mixture of products severely limits the usefulness of primary amines as reagents for Mannich reactions. In the present case, it appears that the bulky *t*-butyl group shields the amino nitrogen from the second reaction.

To gather preliminary data that might point to a suitable method for condensing ethylidene-*t*-butylamine with indole, methylene-*t*-butylamine and indole were allowed to react under a variety of conditions, most of which resembled those for usual Mannich reactions. Moderate yields of 3-(*t*-butylaminomethyl)-indole generally were obtained.

However, only one method was successful for the reaction of ethylidene-*t*-butylamine with indole. When the reaction was allowed to take place at 0° in a solvent mixture of 75% glacial acetic acid and 25% benzene, 15% yields of the base Ia were obtained. Numerous attempts were made to improve the procedure. The acetic acid was dried by distillation from acetyl borate,[14] but without effect upon the yield. With other variations the reaction failed entirely; an apparently trivial change, the substitution of ether for benzene in the solvent mixture, was one of these.

At this point, it appeared likely that the steric hindrance caused by the *t*-butyl group was so great as to severely repress the condensation. Examination of a Fisher–Taylor–Hirschfelder model indicated that the base Ia has very few unstrained configurations, thus a low entropy of internal rotation both in the molecule itself and in the transition state leading to its formation. An isopropyl group (Ib) allows more rotational freedom in the side chain. The steric properties of isopropyl and *t*-butyl groups are similar enough so that ethylideneisopropylamine should be a fairly stable aldimine; this stability has been observed experimentally by Tiollais.[15]

When ethylideneisopropylamine and indole were allowed to react in acetic acid–benzene at 0°, the yield of 3-(isopropylaminoethylidene)-indole (Ib) was 60%. In addition, direct condensation of indole, acetaldehyde and isopropylamine gave a 40% yield of the base (Ib) under similar conditions.

The structure of the base Ib was confirmed by hydrogenation to 3-ethylindole.

The second step in the *dl*-tryptophan synthesis is the alkylation of diethyl acetamidomalonate by gramine.[2] The properties of 3-(*t*-butylaminomethyl)-, 3-(*t*-butylaminoethylidene)- and 3-(iso-

III IV V

propylaminoethylidene)-indole as alkylating agents were investigated. The reaction rates were easily followed semi-quantitatively by titration of the volatile amine evolved. The most rapid alkylation occurred with 3-(*t*-butylaminoethylidene)-indole; the other two reagents gave approximately equal rates. Each requires a lower temperature or shorter time than reported[2] for gramine. Yields are excellent.

The next step, the alkaline hydrolysis of diethyl (3-indolylethylidene)-acetamidomalonate (IIa), took an unexpected course. Instead of the desired acid III, acetylglycine was obtained. Further investigation of this anomalous hydrolysis is being carried out, and, it is hoped, will be reported in a separate article.

This difficulty with the hydrolysis step was eliminated by the use of the dibenzyl ester IIb. Dibenzyl acetamidomalonate was prepared from diethyl acetamidomalonate by transesterification with benzyl alcohol and was alkylated by the base Ib. Dibenzyl (3-indolylethylidene)-acetamidomalonate was converted by hydrogen over a palladium–charcoal catalyst to (3-indolylethylidene)-acetamidomalonic acid (III), isolated and characterized as the ammonium salt.

Decarboxylation of the malonic acid III would be expected to yield two diastereoisomeric *dl*-pairs of 2-acetamido-3-(3-indolyl)-butyric acid (acetyl-β-methyltryptophan) (IV). Only one *dl*-pair was obtained in crystalline form; the other failed to crystallize upon treatment with various solvents, sublimation or partition chromatography (chloroform–water) on silicic acid. The crystalline *dl*-pair was produced in about 30% yields from decarboxylation of either the malonic acid III or its ammonium salt in several different solvents. Since the free acid III was difficult to crystallize, it seemed desirable to decarboxylate the ammonium salt directly. A minimum of discoloration occurred when a pyridine–water solvent was employed.

The crystalline and non-crystalline isomers of acetyl-β-methyltryptophan (IV) were separated and hydrolyzed with 4 *N* sulfuric acid, to avoid the likelihood of racemization encountered with alkaline hydrolysis. Each *dl*-pair of diastereoisomers of 2-amino-3-(3-indolyl)-butyric acid (β-methyltryptophan) (V) was obtained. The first *dl*-pair of V, hereinafter referred to as isomer A, was obtained upon hydrolysis of the crystalline acetyl-amino acid IV; the other *dl*-pair of V, referred to below as isomer B, came from the amorphous material IV. Both isomers had nearly the same decomposition point, but a mixture of the two melted considerably lower. The infrared spectra (Nujol) showed marked differences, and the gross crystalline forms were different.

Two approaches were used to prove that the isomers A and B were not merely different crystalline forms. The α-naphthylurea derivatives were prepared. Although the derivatives had the same decomposition point and gave no depression upon mixing, the infrared spectra (Nujol) were distinctly different. Other evidence was gained from a semi-quantitative determination of the solubilities of the amino acids (V) in 95% ethanol. Isomer A is soluble to the extent of at least 20 mg. per ml., while isomer B has a maximum solubility of not more than 5.5 mg. per ml. at room temperature. In addition, isomer B dissolves to the same extent in a solution of 20 mg. of isomer A per ml. as it does in pure 95% ethanol.

These solubility properties are important in the separation of the isomers, since isomer B is prepared from an impure acetylamino acid IV, but due to its lower solubility in water it is easily separated from any isomer A present by recrystallization. The isomer A, prepared from the crystalline acetylamino acid IV, is presumably free of isomer B to begin with.

To show that the isomers A and B are diastereoisomers, not structural isomers, advantage was taken of the fact that acetylation of tryptophan[16] and other amino acids[17] with excess acetic anhydride leads to racemization at the α-carbon atom; an azlactone is a probable intermediate.[18] Acetylation of isomer B gave the crystalline acetyl derivative of isomer A (28% yield).

Experimental[19]

Aldimines.—Ethylideneisopropylamine was made from acetaldehyde and isopropylamine by the general method for preparing aliphatic aldimines.[20] The most important modifications of the procedure were a final drying of the aldimine over a small amount of barium oxide and distillation at reduced pressure and room temperature with

condensation of the aldimine by a Dry Ice–acetone-bath. The yield of ethylidene-isopropylamine (1-mole scale) was 86%, $n^{19.9}$D 1.3877, reported[15] n^{14}D 1.3963; infrared C=N, 1677 cm.$^{-1}$, reported[21] 1672 cm.$^{-1}$. After storage for two months at 0° in an alkali-washed bottle, the refractive index was essentially unchanged, $n^{25.4}$D 1.3862.

A similar procedure with acetaldehyde and *t*-butylamine furnished an 82% yield of ethylidene-*t*-butylamine, $n^{19.2}$D 1.4005. No physical constants were reported by Hurwitz.[13]

Methylene-*t*-butylamine was prepared by the method of Hurwitz.[13] Freshly distilled material was used in all experiments. Contrary to the reported stability of this aldimine,[13] it was observed that the density and refractive index increased considerably after a few days storage at 0°. A sample which had been stored several months at room temperature showed no infrared absorption between 2500 and 1500 cm.$^{-1}$.

3-(*t*-Butylaminomethyl)-indole.—A hot solution of 27.4 g. (0.25 mole) of *t*-butylamine hydrochloride in 175 ml. of abs. ethanol was neutralized (*p*H 6–7) with 0.5 ml. of *t*-butylamine, and 7.51 g. (0.25 mole) of paraformaldehyde was added. The mixture was stirred and refluxed while a solution of 29.3 g. (0.25 mole) of indole in 75 ml. of abs. ethanol was added during 1 hr. Refluxing was continued for 1.5 hr., and the mixture was stored overnight in the refrigerator. The crystalline amine hydrochloride was shaken with 200 ml. of ether and 250 ml. of 1 *N* sodium hydroxide until it dissolved. The ether layer was dried over magnesium sulfate, and the ether was distilled (water-pump). The solid residue was recrystallized from ethanol–water. The yield of 3-(*t*-butylaminomethyl)-indole, m.p. 113–120°, was 19.8 g. (39%). An analytical sample was prepared by two recrystallizations from methylcyclohexane and three from methanol, m.p. 115.5–119°.

Anal. Calcd. for $C_{13}H_{18}N_2$: C, 77.20; H, 8.97; N, 13.85. Found: C, 77.37; H, 9.23, N, 14.03.

Reaction of Methylene-*t*-butylamine and Indole.—In each experiment, 0.05 mole of indole and 0.055 to 0.06 mole of methylene-*t*-butylamine were used; the product, 3-(*t*-butylaminomethyl)-indole, was isolated by extraction of basic material from aqueous solution with ether, evaporation of the ether, and recrystallization from methylcyclohexane or ethanol–water. The solvents, catalysts, reaction times, temperatures and yields are summarized as follows: 30 ml. abs. ethanol, 20 hr., reflux, 47%; 30 ml. glacial acetic acid, 10 ml. benzene, 0.5 hr., 50°, 33%; 50 ml. glacial acetic acid, 10 ml. benzene, 42 hr., 25°, 26%; 25 ml. abs. ethanol, 0.1 ml. concd. sulfuric acid, 4 hr. reflux, 31%; 25 ml. abs. ethanol, 0.2 ml. glacial acetic acid, 2 hr. reflux, 31%; 30 ml. abs. ethanol, 2 hr., reflux, 6%; 25 ml. methylcyclohexane, 16 hr., reflux, 12%.

3-(Isopropylaminoethylidene)-indole (Ib).—A solution of 29.3 g. (0.25 mole) of indole in 150 ml. of glacial acetic acid was stirred and kept below 15° while a mixture of 23.4 g. (0.275 mole) of ethylideneisopropylamine and 50 ml. of benzene was added dropwise during about 10 min. The solution was then allowed to stand at 0° for 2 to 4 days. The reaction mixture was poured into 500 ml. of ice-water and 50 ml. of ether. The ether layer was separated and extracted with two 100-ml. portions of 1 *M* potassium bisulfate. The combined aqueous solutions were washed with two 50-ml. portions of ether, then made basic with 10 *N* sodium hydroxide; during addition of the alkali, the temperature was kept below 25°. At this point, an oily layer formed and the base began to crystallize from it. To promote crystallization, 100 ml. of methylcyclohexane was added, and the mixture was allowed to stand at 5° for 3 hr. The crystals were collected and dried at room temperature. The yield of 3-(isopropylaminoethylidene)-indole (Ib), m.p. 108–114°, was 30.6 g. (60%). An analytical sample was prepared by two recrystallizations from toluene and one from acetone–toluene, m.p. 113–117.5°.

Anal. Calcd. for $C_{13}H_{18}N_2$: C, 77.18; H, 8.97; N, 13.85. Found: C, 77.39, H, 9.11; N, 13.39.

3-(*t*-Butylaminoethylidene)-indole (Ia).—The procedure used, starting with indole and ethylidene-*t*-butylamine, was similar to that described above for the preparation of 3-(isopropylaminoethylidene)-indole (Ib), except that a different method of isolating the product had to be used. After the acidic solution of the amine Ia was made basic with sodium hydroxide, the product did not crystallize, but was extracted with ether, the solution was dried with magnesium sulfate and the ether was distilled (water-pump). The oily residue was taken up in methylcyclohexane; crystallization required several days at 0°. The yields of Ia, m.p. 68–72°, were 10 to 18%. An analytical sample was prepared by five recrystallizations from methylcyclohexane, m.p. 69.5–72°.

Anal. Calcd. for $C_{14}H_{20}N_2$: C, 77.7; H, 9.31; N, 12.97. Found: C, 77.83; H, 9.53; N, 13.20.

Reaction of Indole, Acetaldehyde and Isopropylamine.—A solution of 5.86 g. (0.05 mole) of indole in 30 ml. of glacial acetic acid was chilled and stirred while 3.3 g. (0.055 mole) of isopropylamine was added. To this cold solution was added a solution of 2.3 g. (0.052 mole) of acetaldehyde in 10 ml. of benzene. The mixture was allowed to stand 2 days at 0°. The product was isolated in the manner described above for 3-(*t*-butylaminoethylidene)-indole (Ia). The yield of 3-(isopropylaminoethylidene)-indole (Ib), m.p. 110–117°, was 3.94 g., 39%.

Reduction of the Base (Ib) to 3-Ethylindole.—A solution of 3-(isopropylaminoethylidene)-indole (Ib) (2 g.) in 95% ethanol (25 ml.) was hydrogenated at 3 atm. over 0.06 g. of 30% Pd/C catalyst at 60–80° for 48 hr. (The apparatus used could not measure the small hydrogen absorption.) The 3-ethylindole was purified by vacuum distillation.

An authentic sample of 3-ethylindole was prepared by a modification of the method of Plancher and Carrasco,[22] a Fischer indole synthesis with phenylhydrazine and butyraldehyde. The reaction was run at about 190° in diethylene glycol until ammonia evolution ceased. Purified by distillation, the 3-ethylindole melted just above room temperature, reported[22] m.p. 43°.

The infrared spectra of the two samples indicated that they were identical.

Dibenzyl Acetamidomalonate.—A solution of 21.7 g. (0.1 mole) of diethyl acetamidomalonate[23] in 60 ml. of benzyl alcohol was heated with an oil-bath to 190–210°. A slow stream of nitrogen was bubbled through the solution, and ethanol was distilled out through a short Vigreux column. After 2 to 3 hr., 11 ml. of ethanol had distilled (theoretical: 0.2 mole, 11.5 ml.). The benzyl alcohol was then distilled at 20 mm.; the bath temperature was raised gradually to 185–190°, where distillation became slow. The residue was crystallized twice from 75 ml. of 2-propanol. The yield of dibenzyl acetamidomalonate, m.p. 110–113°, was 22.1 g. (65%). An analytical sample was prepared by one recrystallization from 2-propanol and two from toluene, m.p. 112–113°.

Anal. Calcd. for $C_{19}H_{19}NO_5$: C, 66.9; H, 5.61; N, 4.10. Found: C, 67.11; H, 5.64; N, 4.06.

Dibenzyl (3-Indolylethylidene)-acetamidomalonate (IIb).—A mixture of 10.11 g. (0.05 mole) of 3-(isopropylaminoethylidene)-indole, 17.07 g. (0.05 mole) of dibenzyl acetamidomalonate, 65 ml. of toluene and approx. 0.01 g. of sodium methoxide was heated at 85–95° with an oil-bath. A slow stream of nitrogen bubbled through the reaction mixture swept out the isopropylamine generated, and the rate of its evolution was followed by titration. The reaction was 95% complete in 6 to 8 hr. Crystallization was induced by scratching and allowed to proceed overnight. The yield of dibenzyl (3-indolylethylidene)-acetamidomalonate was 23.4–23.6 g. (97%), m.p. 120–125°, solidified, second m.p. 161–163°. An analytical sample was prepared by recrystallizations from 2-propanol, acetone, toluene–acetone and toluene, m.p. 166–178°.

Anal. Calcd. for $C_{29}H_{28}N_2O_5$: C, 71.9; H, 5.83; N, 5.79. Found: C, 72.22; H, 5.76; N, 5.82.

Other Alkylations.—The same general procedure described above for the preparation of dibenzyl (3-indolylethylidene)-acetamidomalonate (IIb) was used in all cases with only slight modifications.

Diethyl skatylacetamidomalonate was prepared from diethyl acetamidomalonate and 3-(*t*-butylaminomethyl)-indole at 105° in 71% yield. A low melting form, m.p. 144–145°, was obtained. When recrystallized and seeded

Digitized by Arya Samaj Foundation Chennai and eGangotri

with an authentic sample[2] of m.p. 159°, the m.p. rose to 160–161°, not depressed by mixing with the known sample.

Diethyl (3-indolylethylidene)-acetamidomalonate (IIa), m.p. 163–167°, was prepared in 97% yield from diethyl acetamidomalonate and 3-(*t*-butylaminoethylidene)-indole (Ia) at 72–75°. An analytical sample was prepared by three recrystallizations from ethanol, m.p. 176.5–178°.

Anal. Calcd. for $C_{19}H_{24}N_2O_5$: C, 63.3; H, 6.71; N, 7.76. Found: C, 63.18; H, 6.58; N, 7.94.

Dibenzyl (3-indolylethylidene)-acetamidomalonate (IIb) (see preparation above) was also prepared from 3-(*t*-butylaminoethylidene)-indole (Ia) and dibenzyl acetamidomalonate in 91% yield.

Ammonium (3-Indolylethylidene)-acetamidomalonate (Ammonium Salt of III).—Dibenzyl (3-indolylethylidene)-acetamidomalonate (35.7 g., 0.074 mole) (free from lumps) was placed in a heavy-walled bottle with 125 ml. of 95% ethanol and 0.75 g. of 30% Pd/C catalyst. The mixture was shaken under 3–4 atm. of hydrogen until the theoretical amount of hydrogen was absorbed (1 hr.). The catalyst was removed and 15 ml. of ammonium hydroxide was added. Crystallization was allowed to proceed at 0° overnight. The crystals were collected, washed with acetone and dried to constant weight at room temperature. The yield of ammonium (3-indolylethylidene)-acetamidomalonate, m.p. 160–165° dec., was 21.9 g. (87%). An analytical sample was prepared by dissolving the salt in a small amount of water (25°) and recrystallizing it by adding ethanol, m.p. 159–162° dec.

Anal. Calcd. for $C_{15}H_{22}N_4O_5$: C, 53.24; H, 6.56; N, 16.56. Found: C, 53.16; H, 6.81; N, 16.40.

2-Acetamido-3-(3-indolyl)-butyric Acids (Acetyl-β-methyltryptophans) (IV).—A solution of 92.9 g. (0.279 mole) of ammonium (3-indolylethylidene)-acetamidomalonate in 93 ml. of water and 93 ml. of pyridine was refluxed for 5 hr. in a nitrogen atmosphere. Ammonium carbonate deposited in the reflux condenser. The solution was diluted with 465 ml. of water and filtered, then acidified with 46.5 ml. of sulfuric acid dissolved in 465 ml. of water. During acidification, the solution was heated sufficiently to prevent the product from separating as an oil, and crystallization was induced by scratching when about 60% of the acid had been added (*p*H 3). Crystallization was allowed to proceed at 0° overnight.

The yield of crystalline acetyl-β-methyltryptophan, isomer A, m.p. 211–215°, was 32.2 g. (44%). This crude material did not give satisfactory yields of the amino acid on hydrolysis. It was dissolved in 64 ml. of warm dimethylformamide and recrystallized by addition of 96 ml. of water. The yield of purified material, m.p. 214–218°, was 25.0 g. (34%). An analytical sample was prepared by dissolving the crude material in ethanol and crystallizing it by adding ethyl acetate, m.p. 216–218°.

Anal. Calcd. for $C_{14}H_{16}N_2O_3$: C, 64.6; H, 6.20; N, 10.78. Found: C, 64.77; H, 6.12; N, 10.63.

The mother liquor, which contained isomer B, was extracted with four 230-ml. portions of ethyl acetate. The ethyl acetate solution was washed with two 115-ml. portions of water and extracted with two 230-ml. portions of 10% sodium bicarbonate solution. The aqueous solution was acidified with 4 *N* sulfuric acid and extracted with three 115-ml. portions of ethyl acetate. The ethyl acetate solution was washed with two 55-ml. portions of water and was concentrated under reduced pressure until a foamy gum, which weighed about 40 g., remained. This crude acetyl-β-methyltryptophan, isomer B, was satisfactory for hydrolysis to the amino acid.

2-Amino-3-(3-indolyl)-butyric Acids (β-Methyltryptophans) (V).—The purified acetyl-β-methyltryptophan (IV), isomer A described above (25.0 g.), was ground in a mortar, then refluxed under nitrogen with 150 ml. of 4 *N* sulfuric acid and 1.5 ml. of 1-octanol until it completely dissolved (about 20 hr.). The crude isomer B of IV described above (approx. 40 g.) was refluxed under nitrogen with 210 ml. of 4 *N* sulfuric acid for 5 hr. In each case, after the reflux period was complete, the sulfuric acid was neutralized (*p*H 8) with 0.4 *N* barium hydroxide. A little 1-octanol was added to prevent foaming, Dry Ice was added to precipitate excess barium ion, and the mixture was heated to boiling. The barium sulfate was filtered from the hot solution and the filtrate was concentrated to approx. 360 ml. under reduced pressure; foaming was controlled with 1-octanol. The warm solution was treated with charcoal and filtered, then concentrated to about 150 ml., at which point the amino acid began to crystallize. The product was allowed to crystallize at 0° overnight, then collected and dried under 0.1 mm. at room temperature. The yield of β-methyltryptophan (V), isomer A, from the first crop, m.p. 245–251° dec. (loses water of crystallization approx. 190°), was 14.3 g. It was recrystallized from 110 ml. of water, yield 11.2 g., m.p. 248–250° dec. An additional 1.7 g. of recrystallized isomer A, m.p. 246–250° dec., was obtained from the second crop. The yield of isomer B, m.p. 236–242° dec., was 20.7 g. It was recrystallized from 300 ml. of water, yield 13.8 g., m.p. 247–251° dec. It appeared that water of crystallization was lost at 0.5 mm. at room temperature.

Treatment of the combined aqueous mother liquors with acetic anhydride and sodium acetate yielded 4.6 g. of acetyl β-methyltryptophan (IV), isomer A, plus some of the noncrystalline isomer B. Much barium was found in these mother liquors by precipitation with sulfuric acid.

Analytical samples were prepared by dissolving the amino acid in glacial acetic acid, precipitating the acetate salt with benzene and converting the salt to the free amino acid by crystallization from water at *p*H 5. The amino acid was then recrystallized one or two times from water and dried 24 hr. at 100° (0.1 mm.) over phosphorus pentoxide; isomer A, m.p. 232–235° dec., 238–242° dec., isomer B, m.p. 237–240° dec., 246–248° dec., mixture m.p. 218–225° dec.

Anal. Calcd. for $C_{12}H_{14}N_2O_4$: C, 66.0; H, 6.45; N, 12.85. Isomer A, found: C, 66.20; H, 6.73; N, 12.58, 12.75. Isomer B, found: C, 66.31; H, 6.48; N, 12.57, 12.96.

α-Naphthylurea Derivatives of the β-Methyltryptophans.—The customary procedure[24] was followed. The sodium salt of the α-naphthylurea derivative of isomer B was only slightly soluble in water, but dissolved upon warming. Both α-naphthylurea derivatives were first obtained as amorphous solids but crystallized when warmed with ethylene dichloride. Analytical samples were recrystallized twice from 2-propanol–water: isomer A, m.p. 191–193° dec., isomer B, m.p. 192–194° dec.

Anal. Calcd. for $C_{23}H_{21}N_3O_3$: C, 71.3; H, 5.46; N, 10.88. Isomer A, found: C, 71.22; H, 5.61; N, 10.61. Isomer B, found: C, 71.62; H, 5.74; N, 10.77.

The melting point was not significantly depressed upon mixing the two isomers, but the infrared spectra (Nujol) showed large differences.

Racemization of β-Methyltryptophan by Acetylation.—To a solution of 0.10 g. of isomer B of β-methyltryptophan (V) (m.p. 244–247° dec.) and 0.5 g. of sodium bicarbonate in 5 ml. of water was added 1.0 ml. of acetic anhydride, and the mixture was agitated and warmed until a clear solution resulted. Sulfuric acid (4 *N*) was added until the solution was strongly acidic, and crystallization was induced by scratching. The yield of isomer A of acetyl β-methyltryptophan (IV), m.p. 214–218° (not depressed upon mixing with an authentic sample), was 33 mg. (28%). The infrared spectrum (potassium bromide pellet) was identical to that of a known sample. When isomer B of β-methyltryptophan was acetylated with the theoretical amount of acetic anhydride in the presence of excess sodium hydroxide, conditions which do not lead to racemization,[16] no solid acetyl derivative was obtained.

Solubility of β-Methyltryptophan Isomers.—A 20-mg. sample of the amino acid was weighed into a small vial and 1.00 ml. of 95% ethanol was added. After 2 days at room temperature (occasional shaking), the ethanol was withdrawn with a hypodermic syringe; the volume withdrawn was used in calculating solubility. The vial was dried in the oven and weighed. The solubility of isomer A was at least 20 mg./ml. The solubility of isomer B was 5.5 mg./ml.; this value was checked by dissolving the solid in hot ethanol (solubility apparently less than 15 mg./ml.) and allowing it to crystallize. The solubility of isomer B was the same in a solution of 20 mg./ml. of isomer A as in pure 95% ethanol.

(3-Indolylethylidene)-acetamidomalonic Acid (III).—An aqueous solution of the ammonium salt of III was acidified

and extracted with ethyl acetate. A small amount of chloroform was added and crystallization was induced by scratching. An analytical sample was not obtained.

The free acid III was decarboxylated by heating in several solvents, including methyl ethyl ketone, 2-propanol, acetonitrile and pyridine. The yield of crystalline acetyl β-methyltryptophan was always near 30%. Decarboxylation in water or toluene, which did not dissolve the acid III, led to red tar.

Vasodilator and Adrenergic Blocking Agents. I. 1,4-Disubstituted Piperazines and Related N-Phenylethylenediamine Derivatives

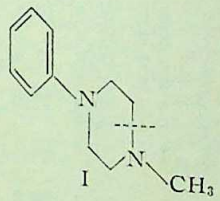
BY F. L. BACH, JR., H. J. BRABANDER AND S. KUSHNER

RECEIVED SEPTEMBER 10, 1956

The syntheses and physiological properties of a series of 1,4-disubstituted piperazines and N-phenylethylenediamine derivatives are described. Also a discussion dealing with the importance of the phenyl and pyridylpiperazine nuclei in developing strong adrenergic blocking agents of this type is included.

In recent years a considerable number of compounds exhibiting strong vasodilator or adrenergic blocking action have been described in the literature.[1] However, because of undesirable side effects and poor oral activity, very few of these agents have found therapeutic application in the treatment of peripheral vascular disease. Two classes of compounds which have received considerable attention for their ability to inhibit responses to epinephrine are the β-diaralkylaminoethyl chlorides and the aralkylimidazolines. In our laboratories, pharmacological testing indicates that 1-methyl-4-phenylpiperazine (I) is also an effective vasodilator and adrenergic blocking agent.

To elucidate the structural requirements necessary for activity in this compound, we prepared a series of N-phenylethylenediamine derivatives. These diamines are related to products which would be formed by a scission of the piperazine ring of the active structure[2] I. The diamines were



I

synthesized by the interaction of one molecular equivalent of β-(N-ethyl-N-phenylamino)-ethyl chloride monohydrochloride with two molecular equivalents of the appropriate primary or secondary amine in a refluxing water–ethanol solution. Derivatives of a similar nature have been tested as antihistamines.[3,4] The fact that structural similarities exist between adrenergic blocking agents and compounds which antagonize spasmogenic substances, such as acetylcholine and histamine, has been discussed by Burger.[5] As shown in Table I, the simple isosteres derived from the parent compound I where one amino group is substituted by lower alkyls were relatively inactive[6] when compared to Priscoline[7] which was used as a standard. However, a marked increase in vasodilator activity was observed when these substituents were replaced by di-*n*-propyl or benzyl groups.

An extension of this work was the reconstitution of a piperazine ring to include one of the terminal N-atoms of the N-phenylethylenediamine structure. This led to the synthesis of a series of 1-[β-(N-ethyl-N-phenylamino)-ethyl]-4-substituted piperazines which are described in Table II. Preparation of these compounds involved a condensation between the β-(N-ethyl-N-phenylamino)-ethyl chloride monohydrochloride and 1-substituted piperazines in refluxing ethanol using sodium bicarbonate as an acid acceptor. The biphenylpiperazine analog was synthesized stepwise by condensing the appropriate haloalkylamine with diethanolamine to yield N-ethyl-N′,N′-di-(β-hydroxyethyl)-N-phenylethylenediamine. In the next step, reductive cyclization of the di-(β-hydroxyethyl)-amino portion of the molecule with 4-aminobiphenyl was accomplished in poor yield by subjecting a solution of the two reactants in dioxane over copper chromite to approximately 93 atmospheres of hydrogen for 7 hr. at 250°. An inspection of the activity ratings listed in Table II reveals a sharp change in biological response when the N-methyl, acetyl and carbethoxy groups in the piperazine moiety are replaced by phenyl, 2-pyridyl or 2-(6-methyl)-pyridyl radicals. Based on these findings a study of the scission products of I has by a circuitous route established the importance of not only the phenyl piperazine but also the pyridyl piperazine nucleus as a center of activity. It is also apparent that strong vasodilatation and adrenergic blocking action[8] are obtained when the simple alkyl substituent in I is replaced by a β-(N-ethyl-N-phenylamino)-ethyl chain II. Preliminary studies indicate that compound II is orally active in the test animal.

[a] Vasodilator activity was determined in the isolated perfused rabbit ear (all compounds tested as hydrochlorides in 0.1% solution using buffered, perfusion fluid as diluent). The vessels of the ear were constricted by the addition of epinephrine to the perfusion fluid and the increase of venous effluent measured by a drop recorder was the index of vasodilator or adrenergic blocking action. Ratings of 0, 1, 2, 3 or 4+ were assigned to compounds which showed, respectively, 0–5, 6–69, 70–120, 121–170 or >170% of Priscoline activity. [b] When a compound showed strong vasodilator activity in initial screening, the possibility of adrenergic blocking activity was investigated in the anesthetized dog. I represents intensity of adrenergic blockade measured in % inhibition or reversal of intravenous epinephrine pressor response. A rating of 0, 1 or 2+ was assigned to 0–19, 20–50 or 51–100% inhibition. Partial reversal and complete reversal were rated 3+ and 4+, respectively. [c] D represents duration of adrenergic blockade. A rating of 1, 2, 3 or 4+ was assigned to durations of <2, 2–3, 3–4 or >4 hours. [d] Melts with sintering and evolution of gas. [e] Tested as an antihistamine, ref. 4. [f] Compounds submitted for testing as dihydrochlorides in 1.0% aqueous solution. [g] The sign > was used when an experiment was discontinued before duration of action ended. [h] See Experimental. [i] Dihydrochloride prepared by passing hydrogen chloride through ethereal solution of basic material.

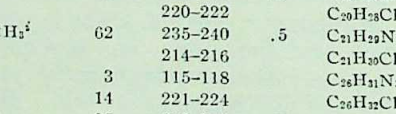
Compounds in Table III were derived from II by keeping the phenylpiperazine portion of the



II, R = $-C_2H_5$; n = 2
III, R = $-H$; n = 2
IV, R = $-C_2H_5$; n = 3

molecule intact while substituents on the terminal N-atom of the β-aminoethyl moiety were varied. Compound III[9] offered a convenient starting point for direct acylation and alkylation as described in the Experimental section. In order to incorporate some of the structural features of Dibenamine[10] in one of these congeners, we condensed the appropriate β-chloroethyldiaralkylamine with 1-phenylpiperazine. This derivative was rated[6] 4+ as a vasodilator but was not considered a strong adrenergic blocking agent.

Several miscellaneous compounds were synthesized to determine the pharmacodynamic effect of chain lengthening IV and piperazine ring substitution. None of these structural changes resulted in activity comparable to II.

Pharmacology.—The authors are grateful to Dr. W. D. Gray and his staff of this Laboratory for their evaluation of these compounds. A pharmacological interpretation of the results obtained in this program will be published elsewhere.

Acknowledgment.—We wish to thank L. Brancone and staff for the analyses contained within.

Experimental[11]

1-Substituted Piperazines.—References for the preparation of these intermediates are given in the footnotes of Table II.

β-Disubstituted Aminoethyl Chloride Monohydrochlorides.—The following preparation of β-(N-ethyl-N-phenylamino)-ethyl chloride monohydrochloride is similar to the procedure described by Dehnert.[12] Forty grams (0.24 mole) of N-ethyl-N-(β-hydroxyethyl)-aniline was dissolved in 150 ml. of chloroform, cooled to 0° and treated with thionyl chloride (20 ml.) which was added dropwise with stirring. The reaction mixture was allowed to warm to room temperature and then refluxed for 4 hr. After this time the solvent was removed and the crystalline mass was triturated with dry ether; 48.0 g. (90%). The material obtained in this manner (crude m.p. 125–128°) was suitable for use as an intermediate.

This procedure was also used in the preparation of β-(N-methyl-N-phenylamino)-ethyl chloride monohydrochloride (crude m.p. 100–105°) and β-(N-benzyl-N-methylamino)-ethyl chloride monohydrochloride (crude m.p. 135–138°).

N-Ethyl-N′-methyl-N-phenylethylenediamine Dihydrochloride.—Twenty-six grams (0.117 mole) of β-(N-ethyl-N-phenylamino)-ethyl chloride hydrochloride was warmed at the steam-cone with 100 ml. of methylamine in water (25%) for 3 hr. after which time an oily layer separated. Ethanol was added until a clear solution was obtained and the mixture was refluxed an additional 3 hr. The residual oil remaining after concentration was extracted with ether, dried over anhydrous magnesium sulfate and distilled, b.p. 148–150° (20 mm.). The dihydrochloride was formed by adding 10 ml. of concentrated hydrochloric acid in 100 ml. of ethanol to 9.0 g. (0.05 mole) of the basic material. Recrystallization from an ethyl acetate–ethanol solution yielded the pure product.

N,N-Dimethyl-N′-ethyl-N′-phenylethylenediamine Dihydrochloride.—This compound was prepared as described above without distilling the basic product. The residual oil from the reaction was acidified with an excess of concentrated hydrochloric acid and the resulting salt was recrystallized from an ethyl acetate–ethanol solution.

N-Ethyl-N′,N′-di-(β-hydroxyethyl)-N-phenyl-ethylenediamine.—Preparation of the remaining ethylenediamine derivatives in Table I is illustrated by the following procedure. β-(N-Ethyl-N-phenylamino)-ethyl chloride monohydrochloride (13.0 g., 0.058 mole) was refluxed with 6.09 g. (0.058 mole) of diethanolamine and 16.8 g. (0.20 mole) of sodium bicarbonate in 100 ml. of ethanol for 15 hr. After removing the solvent the semi-crystalline residue was made strongly alkaline with 5.0 ml. of concentrated potassium hydroxide solution and extracted with two 50-ml. portions of warm chloroform. The combined extracts were decolorized with Norit and concentrated to a residual oil which was fractionated *in vacuo* to yield 8.0 g. of pure product.

1-[β-(N-Ethyl-N-phenylamino)-ethyl]-4-phenylpiperazine (II).—The preparation of the 1,4-disubstituted piperazines and their salts (Table II) is illustrated by the following example. To a solution of 1-phenylpiperazine (17.8 g., 0.11 mole) in 150 ml. of ethanol was added 20.0 g. (0.11 mole) of β-(N-ethyl-N-phenylamino)-ethyl chloride monohydrochloride and 27.7 g. (0.33 mole) of sodium bicarbonate. After a reflux period of approximately 15 hr., the reaction mixture was concentrated to a semi-crystalline mass and then treated as described in the above procedure. The pure product boiled at 205–210° (0.2 mm.), 15.7 g. (51%). On standing this material solidified and could be recrystallized from ether; m.p. 64–66°.

The monohydrochloride was prepared by treating 30.9 g. (0.10 mole) of the basic material with 33.5 ml. (0.099 mole) of 2.98 *N* hydrochloric acid. The salt was then dissolved in 150 ml. of warm water, decolorized with Norit, filtered and concentrated to dryness; 32.0 g. (92%). A pure sample of this product was obtained after two recrystallizations from warm ethanol.

1-[β-(N-Ethyl-N-phenylamino)-ethyl]-4-(4-biphenyl)-piperazine.—A suspension consisting of 25.0 g. (0.10 mole) of N-ethyl-N′,N′-di-(β-hydroxyethyl)-N-phenylethylenediamine, 16.9 g. (0.10 mole) of 4-aminobiphenyl and 5.0 g. of copper chromite catalyst in 75 ml. of dry dioxane was placed in a steel bomb and autoclaved at 250° under 93 atmospheres of hydrogen for 7 hr. After this period of time the dioxane was removed under reduced pressure at 90–100°, leaving a residual oil. This residue was distilled *in vacuo* until a distillate boiling at 190° (0.3 mm.) was obtained. Distillation was then discontinued and the pot residue (2.0 g.) was taken up in 25 ml. of ethanol, decolorized with Norit and filtered. When the filtrate was concentrated to three-quarters of the original volume and allowed to cool, a tan, granular precipitate was deposited. This material (0.329 g.) was collected and air-dried; m.p. 115–118°.

(11) The melting and boiling points are uncorrected.

(12) H. Dehnert, German Patent 650,259.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

A monohydrochloride of this material was formed by treating 0.329 g. of the base with a calculated amount of 2.98 *N* hydrochloric acid in 20 ml. of ethanol. The salt was collected as fine, white needles, m.p. 221–224°.

1-[β-(N-Ethyl-N-phenylamino)-ethyl]-4-[2-(6-methyl)-pyridyl]-piperazine.—Following a procedure developed by Hultquist,[13] a solution consisting of 200.0 g. (1.16 moles) of 1-bromo-6-methylpyridine, 244.8 g. (2.84 moles) of anhydrous piperazine and 171 g. (2.20 moles) of pyridine was heated 6 hr. at 155° in a rocking autoclave. After cooling the autoclave, the brown reaction mass was taken up in water, the aqueous solution made strongly alkaline (1.0 l. of 10 *N* sodium hydroxide) and extracted with ether. The ethereal extracts were combined, dried over anhydrous magnesium sulfate, concentrated and the residual oil was fractionated. The desired product was a yellow oil boiling at 125–127° (1.5 mm.); 133.0 g. (65%).

A suspension of 15.0 g. (0.085 mole) of 1-[2-(6-methyl)-pyridyl]-piperazine, 18.7 g. (0.085 mole) of β-(N-ethyl-N-phenylamino)-ethyl chloride monohydrochloride and 21.4 g. (0.255 mole) of sodium bicarbonate in 100 ml. of ethanol was refluxed 15 hr. The desired basic material and monohydrochloride were obtained using the procedure described for the preparation of II.

1,4-Bis-[β-(N-Ethyl-N-phenylamino)-ethyl]-piperazine Tetrahydrochloride.—A solution consisting of 1.82 g. (0.021 mole) of anhydrous piperazine and 9.35 g. (0.043 mole) of β-(N-ethyl-N-phenylamino)-ethyl chloride monohydrochloride in 75 ml. of absolute ethanol was refluxed 7 hr. The solvent was then removed and the crystalline mass triturated with two 50-ml. portions of acetone to yield 6.0 g. (52%) of the tetrahydrochloride, m.p. 200–204°.

1-β-(N-Phenylamino)-ethyl-4-phenylpiperazine (III).—This substance was prepared by refluxing a mixture of aniline and tri-(β-chloroethyl)-amine hydrochloride for 3 hr. according to process described by van Alphen.[9]

1-[β-(N-Phenyl-N-methylamino)-ethyl]-4-phenylpiperazine.—This derivative was prepared according to the procedure described for II. β-(N-Phenyl-N-methylamino)-ethyl chloride monohydrochloride (11.2 g., 0.066 mole), 10.7 g. (0.066 mole) of 1-phenylpiperazine and 11.0 g. (0.132 mole) of sodium bicarbonate were refluxed in 150 ml. of ethanol for 15 hr. The basic material boiled at 203–208° (0.5 mm.) and was characterized as a monohydrochloride, m.p. 220–222°.

1-[β-(N-Benzyl-N-methylamino)-ethyl]-4-phenylpiperazine.—This substance was prepared as described above from β-(N-benzyl-N-methylamino)-ethyl chloride and 1-phenylpiperazine. The basic material was characterized as a dihydrochloride, m.p. 243–245°.

1-(β-Dibenzylaminoethyl)-4-phenylpiperazine.—β-Dibenzylaminoethyl chloride monohydrochloride (32.3 g., 0.109 mole) was added to 17.6 g. (0.109 mole) of 1-phenylpiperazine, 18.4 g. (0.218 mole) of sodium bicarbonate in 50 ml. of water and 50 ml. of ethanol. The reaction mixture was refluxed 12 hr. and then concentrated to a heavy brown oil which was dissolved in chloroform and decolorized with Norit. Concentration of the chloroform solution yielded a dark-yellow oil which solidified on standing. This waxy material was triturated with water until release of the white, crystalline product was complete; 38.5 g. (92%). An analytical sample was obtained after two recrystallizations from warm ethanol; m.p. 88–91°.

The dihydrochloride was formed by dissolving 4.50 g. (0.012 mole) of the base in 30 ml. of warm ethanol and 2.0 ml. of 11.7 *N* hydrochloric acid. On standing the solution deposited a crystalline material melting at 210–212°.

1-[β-(N-*n*-Heptyl-N-phenylamino)-ethyl]-4-phenylpiperazine.—A suspension consisting of 15.0 g. (0.05 mole) of III and 5.0 g. (0.12 mole) of sodamide in 100 ml. of dry toluene was refluxed 7 hr. At the end of this period of reflux, 9.0 g. (0.05 mole) of *n*-heptyl bromide was added and the mixture refluxed an additional 15 hr. The suspension was filtered hot, the filtrate decolorized with Norit and then concentrated to a heavy, brown oil. Fractionation yielded 6.2 g. (31%) of the crude product, b.p. 220–240° (0.3–0.5 mm.). A pure sample was obtained by refractionation; b.p. 235–240° (0.5 mm.).

A solid monohydrobromide salt of this substance was prepared by treating one molar equivalent of the base with one molar equivalent of hydrobromic acid in ethanol; m.p. 186–188°.

1-[β-(N-Acetyl-N-phenylamino)-ethyl]-4-phenylpiperazine.—Acetic anhydride (16.2 g., 0.159 mole) and 16.9 g. (0.06 mole) of III were mixed in a distilling flask and fractionated *in vacuo*. The acetylated derivative was collected as a viscous, yellow oil boiling at 247–252° (0.1 mm.); 15.7 g. (80%).

A calculated amount of hydrochloric acid was added to 1.69 g. of the base, and the acidic solution was concentrated to a gummy residue. A crystalline material was isolated by taking the residue up in ethanol, treating the solution with decolorizing charcoal, filtering and adding petroleum ether (90–100°) to the filtrate until turbidity. The crystalline precipitate weighed 1.6 g. (93%); m.p. 168–171°.

1-[β-(N-*o*-Iodobenzoyl-N-phenylamino)-ethyl]-4-phenylpiperazine Monohydrochloride.—Eight grams (0.029 mole) of III, 7.6 g. (0.029 mole) of *o*-iodobenzoyl chloride and 100 ml. of toluene were refluxed 2 hr. On cooling the solution deposited a crystalline precipitate which was collected and dried in an evacuated desiccator over solid potassium hydroxide. The salt obtained in this manner weighed 12.5 g. (80%); m.p. 208–210°. Two recrystallizations from warm ethanol yielded a pure salt, m.p. 209–211°.

Di-{β-[1-(4-Phenyl)-piperazinyl]-ethyl}-amine Monohydrochloride.—A suspension consisting of 4.05 g. (0.025 mole) of 1-phenylpiperazine and 4.46 g. (0.025 mole) of di-(β-chloroethyl)-amine hydrochloride was refluxed overnight in 50 ml. of absolute ethanol. The reaction mixture was then diluted with 10 ml. of water and the insoluble, quasi-crystalline material which separated was collected and triturated with two 25-ml. portions of acetone. The platelets obtained after trituration melted at 195–196° with decomposition; 1.5 g. (14%).

The more soluble trihydrochloride was prepared by adding two additional molecular equivalents of hydrochloric acid to the monohydrochloride in ethanol.

Anal. Calcd. for $C_{24}H_{38}N_5Cl_3$: N, 14.0. Found: N, 14.0.

1-(γ-Chloropropyl)-4-phenylpiperazine.—To 70.9 g. (0.340 mole) of phosphorus pentachloride in 200 ml. of chloroform was added portionwise 50.0 g. (0.227 mole) of 1-(γ-hydroxypropyl)-4-phenylpiperazine. During this addition the reaction temperature was maintained at 10–20°. The resulting dark-brown, solution was refluxed for 1 hr. at 95° and then poured on 300.0 g. of ice. The chloroform layer was separated, concentrated to a semi-crystalline mass and the residual material dissolved in warm water. The combined aqueous, acidic solutions were then treated with decolorizing charcoal and evaporated to dryness. When the residue was triturated with acetone 54.1 g. of the crude hydrochloride remained.

Twenty-seven grams (0.983 mole) of the crude salt, dissolved in 50 ml. of water, was then neutralized in the cold with 25% potassium hydroxide solution. Two 50-ml. portions of chloroform were used to extract the organic base which was isolated as a yellow oil after removing the solvent. A pure product was obtained by fractionating the oil and collecting the portion boiling at 146–150° (0.1 mm.).

Anal. Calcd. for $C_{13}H_{19}ClN_2$: C, 65.3; H, 8.0; N, 11.7; Cl, 14.9. Found: C, 65.2; H, 8.2; N, 11.9; Cl, 14.9.

1-[γ-(N-Ethyl-N-phenylamino)-propyl]-4-phenylpiperazine (IV).—Ethylaniline (3.3 g., 0.03 mole) was refluxed with 1.1 g. (0.03 mole) of sodamide in 75 ml. of dry toluene for 15 hr. After this time 6.5 g. (0.03 mole) of 1-(γ-chloropropyl)-4-phenylpiperazine was added and refluxing continued an additional 7 hr. The reaction mixture was then cooled, filtered and concentrated to a brown oil. Fractional distillation *in vacuo* yielded a pure product boiling at 198–205° (0.1 mm.).

Anal. Calcd. for $C_{21}H_{29}N_3$: N, 13.0. Found: N, 12.8.

The monohydrochloride of this material melted at 205–207°.

Anal. Calcd. for $C_{21}H_{30}ClN_3$: C, 70.0; H, 8.3; N, 11.7; Cl, 9.9. Found: C, 69.5; H, 8.3; N, 11.5; Cl, 9.7.

3,5-Dimethyl-1-[β-(N-ethyl-N-phenylamino)-ethyl]-4-phenylpiperazine.—The 2,6-dimethyl-1-phenylpiperazine used as an intermediate was prepared according to a procedure described by Pollard and Wicker.[14] This involved dis-

(13) See Table II, footnote *m*.

tilling water from a mixture of diisopropanolamine and aniline which had been made slightly acidic with concentrated hydrochloric acid. The crude piperazine derivative boiling at 120–125° (1.0 mm.) was used in the next step without further purification.

A suspension consisting of 9.0 g. (0.047 mole) of 2,6-dimethyl-1-phenyl-piperazine, 8.7 g. (0.047 mole) of β-(N-ethyl-N-phenylamino)-ethyl chloride monohydrochloride and 10.9 g. (0.13 mole) of sodium bicarbonate in 100 ml. of ethanol was refluxed for 12 hr. The basic derivative was isolated following the procedure used in synthesizing the compounds reported in Table II. This substance boiled at 215–220° (0.4 mm.); 3.9 g. (25%).

Anal. Calcd. for $C_{22}H_{31}N_3$: C, 78.4; H, 9.2; N, 12.5. Found: C, 78.1; H, 9.4; N, 12.2.

The base was not characterized as a hydrochloride because of the hygroscopicity of the salt.

2-Hydroxymethyl-piperazine Dihydrobromide.—This intermediate was prepared by the interaction of 2,3-dibromopropanol-1 and the disodio derivative of N,N′-di-*p*-tosylethylenediamine in refluxing ethanol following the procedure previously described by Bach, Kushner and Williams,[1] m.p. 254–260° dec.

Anal. Calcd. for $C_5H_{14}Br_2N_2O$: C, 21.6; H, 5.0; Br, 57.6; N, 10.1. Found: C, 22.1; H, 5.3; Br, 58.0; N, 9.8.

1,4-Di-[β-(N-Ethyl-N-phenylamino)-ethyl]-2-hydroxymethylpiperazine.—A suspension consisting of 11.8 g. (0.0425 mole) of 2-hydroxymethylpiperazine dihydrobromide, 15.7 g. (0.085 mole) of β-(N-ethyl-N-phenylamino)-ethyl chloride monohydrochloride and 42.0 g. (0.50 mole) of sodium bicarbonate in 100 ml. of ethanol was refluxed for 15 hr. After this period of time the reaction mixture was concentrated to a semi-crystalline residue and the desired product was obtained following the procedure outlined for the isolation of compounds described in Table II. This derivative was an oil distilling at 245–250° (1.5 mm.); 4.5 g. (25%).

Anal. Calcd. for $C_{25}H_{38}N_4O$: N, 13.7. Found: N, 13.6. The dihydrochloride of this material was extremely hygroscopic.

Reactions with Substituted Xanthones. III. Reactions with Hydroxy-9-xanthenones

BY AHMED MUSTAFA AND ORKEDE HASSAN HISHMAT[1]

RECEIVED OCTOBER 8, 1956

1-Hydroxy-9-xanthenone (Ia) condenses with the acyl and arylsulfonyl chlorides in the presence of aluminum chloride to give 2-acylated-1-hydroxy-9-xanthenones (Table II). The acyl, aroyl and benzenesulfonyl derivatives of Ia and of 1-hydroxy-3-methyl-9-xanthenone (Ii) undergo Fries migration of the acyl group under the influence of aluminum chloride to give the corresponding 2-acyl derivatives (Table II). 1-(β-Naphthoyloxy)-4-benzoyloxy-9-xanthenone and 4-benzoyloxy-1-methyl-10-thiaxanthenone undergo elimination reaction when treated with aluminum chloride under the Fries reaction conditions, yielding the corresponding hydroxy-9-xanthenone and hydroxy-10-thiaxanthenone derivatives, respectively, together with, *e.g.*, β-naphthoic in the case of the naphthoyl ester. Benzoyl esters of 2-hydroxy-3-methyl- and of 2-hydroxy-4-methyl-10-thiaxanthenones proved to be stable toward the action of aluminum chloride under similar conditions. Nencki's reaction offers a convenient method for the preparation of the new 1-hydroxybenzo[b]xanthene-12-one (IIIa), using resorcinol and 2-hydroxy-3-naphthoic acid. The same reaction, using salicylic acid and resacetophenone and/or 2,4-dihydroxybenzophenone, resulted in the formation of Ia in each case together with the removal of the acetyl- and/or the benzoyl group.

Previous work[2] on the study of reactions of substituted xanthenones now has been continued. Hydroxyxanthones, *e.g.*, 1-hydroxy-9-xanthenone (Ia), show the typical reactions of phenols[3] and it should be expected that they undergo the Friedel–Crafts as well as the Fries rearrangement, resulting in the formation of acylated derivatives of hydroxy-9-xanthenones which so far as we are aware[4] have not been synthesized and, meanwhile, constitute important intermediates for the syntheses of naturally occurring substances. Thus, when Ia is treated with acetyl chloride in the presence of aluminum chloride (2.5 moles), using anhydrous nitrobenzene as a solvent, on a steam-bath for three hours and kept aside at room temperature overnight, 2-acetyl-1-hydroxy-9-xanthenone (IIa) is obtained in *ca.* 50% yield. IIa forms a benzoyl derivative with benzoyl chloride in pyridine.

Although substitution may occur in more than one way, we have only been able to isolate one

product (IIa) in a pure form for analytical purposes. The Friedel–Crafts reaction seems to be of preparative nature for the *o*-isomer as we have not been able to demonstrate the presence of the *p*-isomer, since fractional crystallization of the mother liquors leads to difficultly separable mixtures of the probable isomers.

The ready acylation of Ia with acyl chloride and aluminum chloride and the stability of 9-xanthenone toward the same reagent may be attributed to the activating effect of the hydroxyl group.[5] Moreover, it seems very probable that the inhibiting action of the ketone group in xanthone toward Friedel–Crafts acylation nullifies the activating effect of the heterocyclic oxygen atom; a fact which is favored by the observation that xanthene condenses with benzoyl chloride in the presence of aluminum chloride to give 2-benzoylxanthene[6] and the ready acylation of dibenzofuran upon treatment with acetyl chloride and aluminum chloride to give 4-acetyldibenzofuran.[7]

Similar results have now been obtained by Fries rearrangement of 1-acetoxy-9-xanthenone (Ib) with aluminum chloride in hot nitrobenzene (at 130–140° for one hour, then at room temperature overnight). IIa is obtained in *ca.* 55% yield.

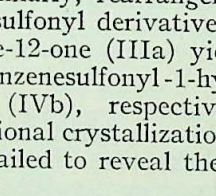
While our investigations were in progress, a publication by Davies and co-workers[8] appeared describing the preparation of IIa, by similar procedure, as an intermediate compound for the preparation of analogs of biologically active chromones, such as khellin. Though the compound IIa reported by them proved to be identical with that prepared by us, there were some points of difference,[9] however, and new material which may be of interest in view of the paucity of information pertaining to this system. IIa was synthesized according to the Friedel–Crafts procedure after Davies and co-workers[8] and we were unable to obtain the unidentified isomeric ketone (m.p. 200°), reported to be obtained in small amount and to depress the m.p. of IIa. The highest m.p. of a substance that was obtained by fractional crystallization of the product contained in the ether extract[10] was 197–198° and it does not depress the m.p. of IIa.

When 1-benzoyloxy-9-xanthenone (Ic) is allowed to undergo the Friedel–Crafts acylation reaction with acetic anhydride, the benzoyl group is eliminated and 2-acetyl-1-hydroxy-9-xanthenone (IIa) is obtained in 71% yield. It appears that the main product is the only one present in appreciable amount. The production of IIa, not contaminated with the 2-benzoyl derivatives[11] (IIb), by treatment with aluminum chloride at 130–140° is unusual in that Ic is isomerized into IIb by treatment with aluminum chloride (see below).

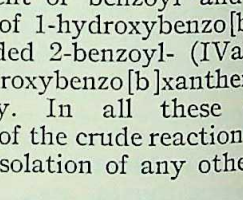
The Friedel–Crafts acylation reaction with Ia now has been extended, using benzoyl and benzenesulfonyl chlorides as acylating agents, under the same experimental conditions described for the acylation of Ia in the presence of aluminum chloride and the corresponding acylated products, believed by analogy to be 2-benzoyl- (IIb) and 2-benzenesulfonyl-1-hydroxy-9-xanthenone (IId), respectively, have been obtained. IIb and IId are obtained in 52 and 58% yield, respectively, and no other isomer was isolated in analytically pure form.

Fries rearrangement of benzoyl (Ic), *p*-nitrobenzoyl (Id) and benzenesulfonyl (Ie) derivatives of Ia, and benzoyl and benzenesulfonyl derivatives (Ij, Il, respectively) of 1-hydroxy-3-methyl-9-xanthenone (Ii), under the same experimental conditions described for the rearrangement of Ib, gave, by analogy, the corresponding 2-aroyl and 2-benzenesulfonyl derivatives (IIb-d and IIe-f, respectively). The *p*-nitrobenzoyl rearranged product IIc is obtained in 17% yield, whereas IIb is obtained in 50% yield. The marked *ortho* shift in the rearrangement of Id may agree with the observation of Baltzly and co-workers,[12] that the *para* shift is discouraged by electron-attracting substitution in the acyl portion. IIb forms a benzoyl derivative with benzoyl chloride in pyridine and a monohydrazone derivative with hydrazine hydrate.

Similarly, rearrangement of benzoyl and benzenesulfonyl derivatives of 1-hydroxybenzo[b]xanthene-12-one (IIIa) yielded 2-benzoyl- (IVa) and 2-benzenesulfonyl-1-hydroxybenzo[b]xanthene-12-one (IVb), respectively. In all these cases, fractional crystallization of the crude reaction product failed to reveal the isolation of any other isomer.



IIIa, R = H
b, R = COC_6H_5
c, R = $SO_2C_6H_5$



IVa, R = COC_6H_5
b, R = $SO_2C_6H_5$

When 1-(β-naphthoyloxy)-9-xanthenone (If) is allowed to undergo Fries rearrangement under similar conditions, the β-naphthoyl group is eliminated and Ia is obtained almost quantitatively.[13] A similar elimination reaction also has been ob-

(9) Davies and co-workers (ref. 8) reported 14% yield of 2-acetyl-1-hydroxy-9-xanthenone by Fries rearrangement of 1-acetoxy-9-xanthenone with aluminum chloride at room temperature for 60 hours and 24% yield at 80° for three hours. The Friedel–Crafts acylation with acetic anhydride in *sym*-tetrachloroethane on the steam-bath for three hours gave 41% yield, whereas 36% yield was reported when acetyl chloride in nitrobenzene at room temperature for 5 days was used.

(10) *Cf.* ref. 8, p. 2142. The m.p. of the crude product after evaporation of the ether was 160–165°.

(11) *Cf.* the same observation in the case of N-phenylsulfonyl-1,8-naphthosultam which undergoes the Friedel-Crafts acetylation reaction to give the 4-acetyl derivative, not contaminated with the 4-benzenesulfonyl derivative (A. Mustafa and M. I. Ali, THIS JOURNAL, **77**, 4593 (1955)).

(12) R. Baltzly, W. S. Ide and A. P. Phillips, *ibid.*, **77**, 2522 (1955).

(13) The elimination of the naphthoyl group and the inhibition of the Fries rearrangement may be attributed to the increase in the size of the acyl group (*cf.* A. H. Blatt, "Organic Reactions," Vol. I, John Wiley and Sons, Inc., New York, N. Y., 1943, p. 342); *cf.* also the formation of free acid and not a ketone on treatment of *o*-cresyl-1-naphthoate with aluminum chloride at 160° (G. S. Saharia, *J. Sci. Indust. Res.*, **13B**, 541 (1954)).

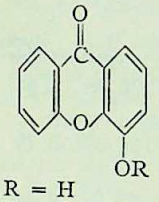
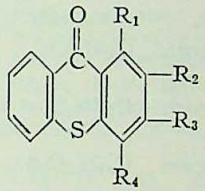
served when 4-benzoyloxy-9-xanthenone (Vb) is subjected to rearrangement with aluminum chloride, under the given conditions, yielding 4-hydroxy-9-xanthenone (Va). We now have found that, whereas elimination reaction takes place when 1-methyl-4-benzoyloxy-10-thiaxanthenone (VIb) is treated with aluminum chloride yielding 1-methyl-4-hydroxy-10-thiaxanthenone (VIa), 3-methyl-2-benzoyloxy-(VId) and 4-methyl-2-benzoyloxy-10-thiaxanthenone (VIf) are recovered almost quantitatively when treated with aluminum chloride under similar conditions. It seems very probable that the benzoyl esters of methyl substituted 2-hydroxy-10-thiaxanthenones (VId, VIf) are comparatively more stable than the benzoyl esters of VIa, Ia, and of Va toward the action of aluminum chloride under the same experimental conditions.



Va, R = H
b, R = COC_6H_5



VIa, $R_1 = CH_3$; $R_2 = R_3 = H$; $R_4 = OH$
b, $R_1 = CH_3$; $R_3 = R_2 = H$; $R_4 = OCOC_6H_5$
c, $R_1 = R_4 = H$; $R_2 = OH$; $R_3 = CH_3$
d, $R_1 = R_4 = H$; $R_2 = OCOC_6H_5$; $R_3 = CH_3$
e, $R_1 = R_3 = H$; $R_2 = OH$; $R_4 = CH_3$
f, $R_1 = R_3 = H$; $R_2 = OCOC_6H_5$; $R_4 = CH_3$

The observation that as the temperature of the reaction rises the *ortho* shift increases,[14] may agree with the general observation that high temperatures favor the *ortho* shift using nitrobenzene as solvent.[15] Moreover, that the *ortho* shift is favored at high temperatures, leading to an increase in the yield of IIa, may be attributed to the steric factors which do favor an *ortho* shift.[12] The formation of IIa at room temperature in nitrobenzene solution—under which conditions[15] the formation of the *p*-isomer is usually favored—may be paralleled to the known observation that aliphatic esters of *m*-cresol afford *o*-hydroxyketones at room temperature.[16]

Methods of Preparation.—The utilization of the Nencki reaction for the preparation of hydroxy-9-xanthenones after the procedure described by Pankajamani and Seshadri[17] now has been followed for the preparation of the new substituted xanthenone derivative IIIa.[18] Using freshly fused zinc chloride, the reaction has been effected at 230° for five minutes and at 200° for four hours. Making use of the separation of the 3-hydroxy isomer by its ready solubility in sodium carbonate,[17] does not reveal the presence of the other isomer. IIIa is insoluble in aqueous sodium carbonate, but gives an insoluble yellowish orange sodium salt when treated with cold aqueous sodium hydroxide solution, and is slightly soluble on warming. Acidification of its alkaline solution regenerates IIIa almost quantitatively. It gives a brownish color with alcoholic ferric chloride solution and forms with benzoyl or benzenesulfonyl chlorides in pyridine the corresponding derivatives.

Aroylation of the hydroxyl group in the hydroxy-9-xanthenones, used in this investigation, has been accomplished by means of the corresponding aroyl chloride in pyridine. For the acetylation reaction acetic anhydride in the presence of fused sodium acetate is used. VIb is prepared by the action of benzoyl chloride and alkali on VIa.

VIc and VIe were prepared according to the method of Sen and Sen-Gupta[19] and were reported to have m.p. 210–212° for VIc and 190° for VIe. However, the samples of VIc and VIe in our hands have m.p. 321–322° and 273–274°, respectively, and give the correct analytical values. They are partially soluble in hot aqueous sodium hydroxide solution and form readily the corresponding benzoyl derivatives VId and VIf.

Attempts to prepare acylated derivatives of Ia by condensing salicylic acid with resacetophenone, under the same conditions described for the condensation of salicyclic acid with resorcinol, resulted in elimination of the acetyl group and the formation of Ia. The same result has been obtained when 2,4-dihydroxybenzophenone was used for resacetophenone. The elimination reaction, observed in the case of resacetophenone and 2,4-dihydroxybenzophenone, has been observed when they were treated, independently, with fused zinc chloride under the same experimental conditions described for the preparation of Ia; resorcinol was isolated in every case (identified as the monobenzoyl derivative), together with marked smell of acetic acid in the case of resacetophenone and the isolation of benzoic acid in the case of 2,4-dihydroxybenzophenone.

Ia now has been further identified by preparing the corresponding methyl ether Ig by the action of dimethyl sulfate in the presence of anhydrous potassium carbonate on an acetone solution of Ia.[20] Similarly, the allyl ether of 1-hydroxy-9-xanthenone (Ih) has been obtained by the action of allyl bromide on an acetone solution of Ia in the presence of anhydrous potassium carbonate. The rearrangement of Ih is now under investigation.

Experimental

Preparation of 1-Hydroxybenzo[b]xanthene-12-one (IIIa).—A mixture of 6.8 g. of 3-hydroxy-2-naphthoic acid, 5 g. of resorcinol and 10 g. of freshly fused zinc chloride was heated at 230° (metal-bath temperature) and maintained at that temperature for five minutes to bring it to a molten

[a] Melting points are uncorrected. [b] Michael (*Amer. Chem. J.*, 5, 94 (1883)). [c] *Cf.* ref. 21. [d] Calcd.: N, 3.88. Found: N, 3.71. [e] Sulfur, %. [f] 1, benzene; 2, acetic acid; 3, ethyl alcohol.

state. Then the temperature was brought down to 200° and maintained for four hours. The product was repeatedly washed with hot water and the residue was ground up with a solution of sodium carbonate. The insoluble residue was treated with aqueous sodium hydroxide solution (10%) and the sodium salt of IIIa separated out. It was filtered off, suspended in water containing concentrated hydrochloric acid enough for acidification and the reaction mixture was boiled for 10 minutes. IIIa separated out as a dirty-yellow mass. It crystallized from acetone in the form of yellow needles, m.p. 307°, yield *ca.* 27%.

Anal. Calcd. for $C_{17}H_{10}O_3$: C, 77.86; H, 3.81. Found: C, 77.56; H, 3.68.

An acetone solution of IIIa gave a brownish color with alcoholic ferric chloride solution. IIIa is soluble in acetone and hot chloroform, but difficultly soluble in most of the common organic solvents; it gives deep reddish orange color with concentrated sulfuric acid, and is insoluble in hot aqueous sodium carbonate solution.

Acidification of the sodium carbonate extract resulted in the separation of a small amount of an unidentified substance.

Preparation of VIc and VIe.—Crude VIc, obtained after pouring the reaction[19] mixture into ice-cold water, was washed with 40 ml. of 10% aqueous sodium hydroxide and was then suspended in dilute hydrochloric acid. The resulting yellow solid, which was thoroughly washed with water and dried, was crystallized from acetic acid; yield 31% of yellow crystals, m.p. 321–322°.

Anal. Calcd. for $C_{14}H_{10}O_2S$: C, 69.42; H, 4.13; S, 13.22. Found: C, 69.02; H, 3.98; S, 13.65.

VIe, obtained in 37% yield, melted at 273–274°. *Anal.* Calcd. for $C_{14}H_{10}O_2S$: C, 69.42; H, 4.13; S, 13.22. Found: C, 69.17; H, 4.11; S, 13.26.

They were soluble in hot chloroform, hot acetic acid, but sparingly in cold alcohol. They were insoluble in aqueous sodium carbonate, but were partially soluble in hot aqueous sodium hydroxide. They gave with concentrated sulfuric acid a deep orange color.

Preparation of Esters of Hydroxyxanthenones and Hydroxy-10-thiaxanthenones.—A solution of 0.005 mole of the hydroxy-9-xanthenone in 30 ml. of freshly distilled pyridine was treated with 0.006 mole of the acyl chloride: namely, benzoyl, *p*-nitrobenzoyl, β-naphthoyl and benzenesulfonyl chlorides, respectively. The reaction mixture was heated for one hour (steam-bath), cooled, and the crystals that separated were filtered off and washed with cold alcohol.

The aroyl derivatives of hydroxy-10-thiaxanthenones were prepared by treating a solution of 0.003 mole of the thiaxanthenone derivative in aqueous sodium hydroxide (10%) with 0.006 mole of benzoyl chloride (Schotten-Baumann). The reaction mixture was shaken vigorously at room temperature for 20 minutes, cooled and the separated solid was collected by filtration.

The properties of the above new aroyl and benzene-sulfonyl derivatives are recorded in Table I. They were generally soluble in hot common solvents, formed colorless crystals and were crystallized readily from a mixture of ethyl alcohol and chloroform.

2-Acylated-9-xanthenones. Method A. General Friedel-Crafts Procedure.—In all experiments described in Table II, 0.01 mole of 1-hydroxy-9-xanthenone[17] (Ia) and 0.025 mole of aluminum chloride were used. A solution of Ia in 25 ml. of freshly distilled nitrobenzene and 0.02 mole of the acyl chloride was treated with aluminum chloride in portions as rapidly as it dissolved. The reaction mixture was heated for three hours (steam-bath) and kept aside at room temperature overnight. It was poured into 150 ml. of ice-water containing 25 ml. of concentrated hydrochloric acid, and steam distilled. The solid residue was then extracted with hot petroleum ether (b.p. 100–120°). Concentration

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

of the petroleum ether extract, by slow evaporation, gave the 2-acyl derivative of Ia which was crystallized from the solvent specified in Table II.

In the case of 2-acetyl-1-hydroxy-9-xanthenone (IIa) the crude product, after evaporation of the petroleum ether, melted at 180–185°. Fractional crystallization of the 2-substituted acyl derivatives (*cf.* Table II) did not raise the m.p.

IIa-d, when treated with cold aqueous sodium hydroxide solution, formed the corresponding deep yellow sodium salt. They formed yellow crystals which were soluble in hot benzene, but sparingly in alcohol, ether and light petroleum (b.p. 40–60°).

Identification of IIa was carried out by m.p. and mixed m.p. determinations with authentic specimens of IIa and of its 2,4-dinitrophenylhydrazone derivative.[8]

Benzoylation of 0.2 g. of IIa with 0.4 g. of benzoyl chloride and 10 ml. of freshly distilled pyridine, as described above, gave a colorless solid on cooling. It was crystallized from alcohol, m.p. 168°, in almost quantitative yield. 2-Acetyl-1-benzoyloxy-9-xanthenone gave no color with alcoholic ferric chloride and developed a yellow color with slight green fluorescence with concentrated sulfuric acid.

Anal. Calcd. for $C_{22}H_{14}O_5$: C, 73.74; H, 3.91. Found: C, 73.57; H, 3.88.

2-Benzoyl-1-benzoyloxy-9-xanthenone, obtained similarly from 0.65 g. of IIb, 0.85 g. of benzoyl chloride and 25 ml. of pyridine, separated from a mixture of ethanol and chloroform in nearly colorless crystals, m.p. 212–213°, yield 86%. It gave a yellow color with concentrated sulfuric acid and was soluble in hot chloroform and benzene, but sparingly in alcohol.

Anal. Calcd. for $C_{27}H_{16}O_5$: C, 77.14; H, 3.81. Found: C, 76.73; H, 3.72.

A solution of 0.5 g. of IIb in 30 ml. of ethyl alcohol was treated with 4 ml. of hydrazine hydrate. The reaction mixture was refluxed on the steam-bath for 6 hours. The solid, obtained on cooling, was collected and crystallized from ethyl alcohol in canary yellow crystals, m.p. 160–161°. The yield was almost quantitative.

Anal. Calcd. for $C_{20}H_{14}O_3N_2$: C, 72.72; H, 4.24; N, 8.48. Found: C, 72.46; H, 4.50; N, 8.80.

The monohydrazone derivative of IIb was soluble in hot ethyl alcohol, and benzene, but slightly in light petroleum. It gave reddish brown color with alcoholic ferric chloride and yellowish orange color with concentrated sulfuric acid, and formed a canary yellow insoluble sodium salt when treated with hot aqueous sodium hydroxide.

2-Acylated-9-xanthenones. Method B. Fries Rearrangement with Aluminum Chloride of Acyl, Aroyl and Benzenesulfonyl Derivatives of Hydroxy-9-xanthenones.—The rearrangement of Ib-e, Ij, Il and IIIb-c was carried out by heating a solution of 0.01 mole of each in 25 ml. of nitrobenzene and 0.025 mole of aluminum chloride in an oil-bath maintained at 130–140° (bath-temp.) for one hour. The reaction mixture was kept aside at room temperature overnight. The dark colored reaction mixture was cooled, decomposed with 100 ml. of cold dilute hydrochloric acid, and steam distilled. The solid residue so obtained was worked out as described above in the Friedel–Crafts procedure. The properties of the reaction products (IIa–d, IIe–f and IVa–b) are recorded in Table II. When treated with cold aqueous sodium hydroxide (10%) they gave the corresponding yellow colored sodium salt.

When 0.5 g. of IIe, obtained by method B, was treated with benzoyl chloride in pyridine in the usual procedure, 3-methyl-1-benzoyloxy-2-benzoyl-9-xanthenone was obtained in 74% yield as colorless crystals from ethyl alcohol–chloroform mixture, m.p. 214–215°.

Anal. Calcd. for $C_{28}H_{18}O_5$: C, 77.41; H, 4.14. Found: C, 77.06; H, 4.23.

3-Methyl-1-benzoyloxy-2-benzenesulfonyl-9-xanthenone was similarly obtained by the action of benzoyl chloride on 0.5 g. of IIf in pyridine. The benzoyl derivative formed colorless crystals from ethyl alcohol–chloroform mixture, m.p. 239–240°.

Anal. Calcd. for $C_{27}H_{18}O_6S$: C, 68.94; H, 3.83; S, 6.81. Found: C, 68.21; H, 3.93; S, 7.39.

When 1 g. of each of If, Vb[21] and VIb,[19] was treated with aluminum chloride at 130–140°, under the same experimental conditions described above for the Fries rearrangement, followed by working out the reaction products in a similar manner, Ia, Va and VIa were obtained in 82, 87 and 79% yield, respectively. β-Naphthoic acid was isolated in appreciable amounts (m.p. and mixed m.p. determination) in the case of If.

VId and VIf were recovered almost quantitatively when 1 g. of each was treated with aluminum chloride under the same experimental conditions.

Action of Acetic Anhydride on Ic in Presence of Aluminum Chloride.—A mixture of 1.1 g. of Ic, 25 ml. of nitrobenzene and 1.1 g. of freshly distilled acetic anhydride was treated portionwise with 1.2 g. of aluminum chloride. The reaction mixture temperature was maintained at 80° during the addition of aluminum chloride. It was raised slowly to 130–140° (bath-temp.) and the reaction mixture was kept at that temperature for one hour. It was kept aside at room temperature overnight, and was then worked out as described above in the general Friedel–Crafts procedure. IIa was obtained in 71% yield, and was identified by m.p. and mixed m.p. determination with an authentic specimen of IIa,[8] and of 2-acetyl-1-benzoyloxy-9-xanthenone.

Fractional crystallization of the crude product obtained by evaporation of the mother liquors did not reveal the presence of any other isomer. Melting point of the crude product, obtained after evaporation of the petroleum ether, was 193°.

Action of Zinc Chloride on: (a) A Mixture of Salicylic Acid and Resacetophenone.—A mixture of 5 g. of resacetophenone, 5 g. of salicylic acid and 10 g. of freshly fused zinc chloride was heated to 200° and maintained at that temperature for 5 minutes. Then the temperature was brought down to 180° and maintained for four hours. On working up the reaction product as described for the preparation of IIIa, yellow crystals of Ia were obtained in 22% yield. Identification was carried out by m.p. and mixed m.p. determination.

Ia was further identified by preparation of its methyl ether (Ig): To a solution of 1.5 g. of Ia in 50 ml. of dry acetone was added 2 ml. of dimethyl sulfate and 5 g. of anhydrous potassium carbonate. The reaction mixture was refluxed on a steam-bath for six hours and cooled. It was poured into ice-cold water and the solid so obtained was collected by filtration, washed thoroughly with cold water, and crystallized from petroleum ether (b.p. 100–120°). It formed colorless crystals, m.p. 136°, identified by m.p. and mixed m.p. determination with an authentic specimen of Ig.[22]

Five grams of resacetophenone was heated with 10 g. of fused zinc chloride at 130–140° under the same experimental conditions described above. The alkaline extract of the reaction mixture was treated with excess of benzoyl chloride (Schotten–Baumann) and the colorless solid so obtained was crystallized from ethyl alcohol; identified as benzoyl resorcinol (m.p. and mixed m.p. with an authentic sample). A marked smell of acetic acid was noticed on decomposition of the reaction mixture.

(b) A Mixture of Salicylic Acid and 2,4-Dihydroxybenzophenone.—Similarly, a mixture of 5 g. of 2,4-dihydroxybenzophenone, 5 g. of salicylic acid and 10 g. of fused zinc chloride was heated as described in the case of resacetophenone. On working up the reaction mixture, Ia was obtained in *ca.* 23% yield.

A solution of 1.6 g. of Ia (obtained after the above procedure) in 50 ml. of dry acetone, was treated with 2.2 g. of allyl bromide and 5 g. of anhydrous potassium carbonate. The reaction mixture was refluxed for eight hours and cooled. It was poured into ice-cold water, extracted with ether, dried and evaporated. The solid residue (1.1 g.) so obtained was crystallized from petroleum ether (b.p. 80–100°) in colorless crystals, m.p. 86–87°. 1-Allyloxy-9-xanthenone (Ih) was easily soluble in benzene, but sparingly in light petroleum. It gives yellow-brown color with concentrated sulfuric acid.

Anal. Calcd. for $C_{16}H_{12}O_3$: C, 76.19; H, 4.76. Found: C, 76.08; H, 4.98.

2,4-Dihydroxybenzophenone (5 g.) was treated with 10 g. of fused zinc chloride as described in the case of resacetophenone. The cold reaction mixture was poured into ice-

cold dilute hydrochloric acid and the solid so obtained was extracted with cold aqueous sodium carbonate solution. The insoluble portion was benzoylated with benzoyl chloride in the presence of sodium hydroxide solution and benzoylresorcinol was obtained (1.1 g.).

Acidification of the carbonate solution followed by crystallization of the separated product gave colorless crystals (0.9 g.), identified as benzoic acid.

Researches on Pyrimidines. Certain Derivatives of 2-Propylpyrimidine[1]

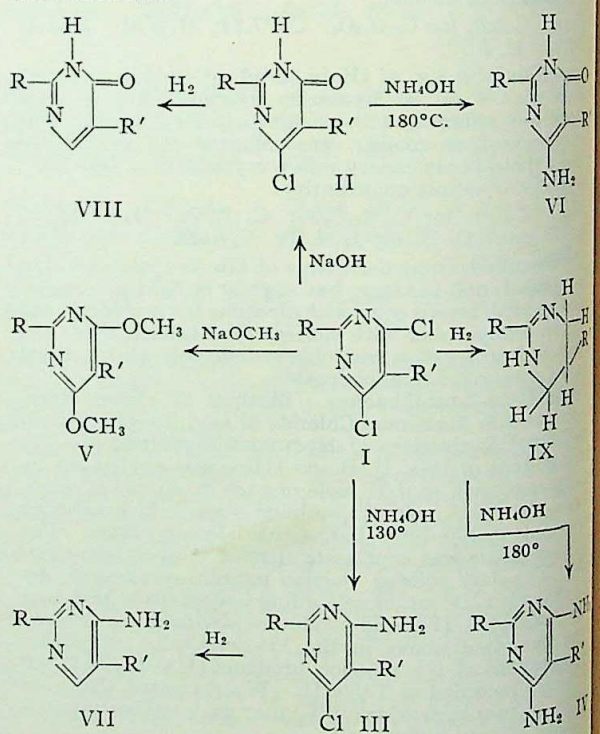
BY HENRY R. HENZE AND STANLEY O. WINTHROP[2]

RECEIVED OCTOBER 8, 1956

Series of 2-propyl-4,6(1,5)-tetrahydropyrimidinediones and 2-propyl-4,6-dichloropyrimidines have been synthesized. The dichloropyrimidines are useful starting materials for the synthesis of various pyrimidine derivatives, some of which are described.

In continuation of our investigation of the synthesis of pyrimidine derivatives through condensation of amidines with malonic esters,[3,4] we have now studied the interaction of butamidine with ethyl malonate and five ethyl alkylmalonates. The 2-propyl-4,6(1,5)-tetrahydropyrimidinediones thus obtained were converted into 4,6-dichloro derivatives by treatment with phosphorus oxychloride. With the appropriate reagents and reaction conditions, as shown below, the 4,6-dichloropyrimidines (I) yielded the corresponding 6-chloro-4(3)-dihydropyrimidones(II), 4-amino-6-chloropyrimidines (III), 4,6-diaminopyrimidines (IV) and 4,6-dimethoxypyrimidines (V). These derivatives in their turn gave 6-amino-4(3)-dihydropyrimidones (VI), 4-aminopyrimidines (VII) and 4(3)-dihydropyrimidones (VIII).

Catalytic hydrogenolysis of the monochloropyrimidines took place with ease. It was noted, however, that in each case there was an amino or keto substituent present which could have the effect of stabilizing the ring against reduction. Catalytic hydrogenolysis of the dichloropyrimidines did not stop at dechlorination but proceeded with the reduction of the pyrimidine ring. Instead of the anticipated 2-propylpyrimidine, the catalytic hydrogenolysis of 2-propyl-4,6-dichloropyrimidine, in the presence of barium oxide,[5] gave a product which analyzed for a 2-propyltetrahydropyrimidine[6] hydrochloride (IX). A search of the literature reveals little on the chemistry of partially reduced pyrimidines and usually the latter have been prepared directly through condensation reactions, rather than as a direct result of hydrogenation of pyrimidines. Thus, Aspinall[7] has reported the preparation of 2-methyl-1,4,5,6-tetrahydropyrimidine by the interaction of trimethylenediamine and ethylacetate. Naff and Christensen[8] have described a dihydrobenzopyrimidine and its conversion by catalytic dehydrogenation to the more stable benzopyrimidine. Attempts to convert our tetrahydropyrimidine to 2-propylpyrimidine by a similar catalytic dehydrogenation were not successful.



Experimental

Butamidine Hydrochloride.—The procedure utilized followed that of Derby's modification[9] of the method of Pinner[10] for the preparation of amidines. A solution was prepared containing 345 g. (5 moles) of butyronitrile, 230 g. (5 moles) of absolute ethanol, 600 ml. of dry ether and 182.5 g. (5 moles) of dry hydrogen chloride. It was stirred for four days at 0°. After standing for two weeks in the cold the imido ester hydrochloride separated and was removed by filtration. The filtrate, on standing in the cold an additional week, produced a second crop of crystals. The initial crop of imido ester was dissolved in 300 ml. of absolute ethanol, 1000 ml. of 10% alcoholic ammonia was

(5) After this work had been completed, a paper by N. Whittaker (*J. Chem. Soc.*, 1565 (1950)) came to our attention. This investigator showed that catalytic hydrogenolysis of 2,4,6-trichloropyrimidine in the presence of sodium acetate took place with the uptake of five equivalents of hydrogen indicating the formation of a tetrahydropyrimidine, while in the presence of magnesium oxide, only three equivalents of hydrogen were taken up, and pyrimidine was isolated as a mercuric chloride addition complex.

(6) The position of the remaining double bond has not been proven. The compound is most likely a 1,4,5,6-tetrahydropyrimidine.

[a] Does not melt below 300° and decomposes slowly at that temperature. [b] Analysis by Clark Microanalytical Laboratories, Urbana, Ill. [b] This compound has been previously reported by F. G. P. Remfry (*J. Chem. Soc.*, 99, 620 (1906)), who prepared it by interaction of ethylmalonamide and ethyl ethylmalonate. [d] Calcd.: N, 16.67. Found: N, 16.89. [e] Calcd.: N, 11.75. Found: N, 11.71.

5-Alkyl-2-propyl-4,6(1,5)-pyrimidinediones (Table I).—The pyrimidinediones were prepared by interaction of butamidine hydrochloride and ethyl alkylmalonates.[3,4]

5-Alkyl-2-propyl-4,6-dichloropyrimidines (Table III).—The dichloropyrimidines were prepared from interaction of the pyrimidinediones and phosphorus oxychloride.[3]

5-Alkyl-6-chloro-2-propyl-4(3)-pyrimidones (Table II).—The chloropyrimidones were prepared by the controlled hydrolysis of the corresponding dichloropyrimidines. The 5-alkyl-4,6-dichloro-2-propylpyrimidine (0.05 mole) was refluxed for approximately 48 hr. with 4 g. (0.1 mole) of sodium hydroxide in 70 ml. of water; the reaction was considered complete when all the dichloropyrimidine had gone into solution. Upon cooling, the solution was acidified by addition of glacial acetic acid and the chloropyrimidone precipitated. The product was purified by recrystallization from aqueous ethanol or benzene.

In the case of the 5-hexyl derivative, hydrolysis with sodium hydroxide gave very poor yields of product, and the major portion of the starting material was recovered. It was found that acid hydrolysis gave better yields. A mixture of 3.5 g. (0.015 mole) of 4,6-dichloro-5-hexyl-2-propylpyrimidine, 20 ml. of concentrated hydrochloric acid and 50 ml. of water was refluxed for 12 hr. During this period, the dichloropyrimidine layer disappeared and a solid settled out on the sides of the flask. Upon cooling, an additional amount of solid separated. The solid product was removed by filtration and purified by recrystallization from methanol.

[a] M.p. 24–26°. [b] Taken at 30°. [c] Analysis by Clark Microanalytical Laboratories, Urbana, Ill.

5-Alkyl-6-amino-2-propyl-4(3)-pyrimidones (Table II).—The chloropyrimidone (1–2 g.) and 50 ml. of concentrated ammonium hydroxide were placed in the glass liner of a small steel pressure vessel and heated at 180–190° for 10 hr. When cool, the bomb was opened and the solid material was removed and recrystallized from aqueous ethanol.

5-Alkyl-6-propyl-4(3)-pyrimidones (Table II).—The pyrimidones were prepared by catalytic hydrogenolysis of the chloropyrimidones. Palladium supported

added and the mixture was stirred for 24 hr. The ammonium chloride, which had separated, was removed by filtration. Approximately 800 ml. of ethanol was removed from the filtrate by distillation to leave a heavy, viscous liquid which solidified on cooling. The second crop of imido ester was worked through in the same manner. The butamidine hydrochloride weighed 372 g. (62% yield) and melted from 95–98° in agreement with the datum recorded in the literature.[11]

(11) Richter, "Beilstein Handbuch der Organischen Chimie," Vol. II, 4th Ed., Springer Verlag, Berlin, 1920, p. 276, recorded a m.p. of 96° for butamidine hydrochloride.

on barium sulfate, prepared by the method of Schmidt,[12] was found to be a suitable catalyst. One gram of catalyst and 1 g. of chloropyrimidone dissolved in 100 ml. of ethanol were shaken with hydrogen at an initial pressure of 60 cm. at room temperature; the calculated amount of hydrogen was taken up in from 1 to 4 hr. It was found that unless the ethanol solution of the chloropyrimidone was first shaken in the cold with some Raney nickel, to remove catalyst poisons, the reduction would take place only very slowly if at all. When the hydrogen uptake had ceased, the catalyst was removed by filtration and the solution evaporated to about 10 ml. On cooling, the solid product precipitated. Ethyl acetate was found to be a suitable solvent for recrystallization. In some cases, an analytical sample was prepared by vacuum sublimation.

5-Alkyl-6-amino-4-chloro-2-propylpyrimidines (Table IV).—The dichloropyrimidine (2–5 g.) and 50 ml. of concentrated ammonium hydroxide were placed in the glass liner of a small steel pressure vessel and heated at 130–140° for 12 hr. Upon cooling to room temperature, the bomb was opened and the solid product removed by filtration and recrystallized from dilute alcohol.

5-Alkyl-4,6-diamino-2-propylpyrimidines (Table IV).—The diaminopyrimidines were prepared in the same manner as the aminochloropyrimidines. A temperature of 180–190° was required for replacement of both chloro substituents by amino. Upon cooling, the product separated and was purified by recrystallizations from water or aqueous ethanol. In the case of the 4,6-diamino-2-propylpyrimidine, it was found necessary to evaporate the solution to about 20 ml. and then to add approximately 20 ml. of 30% sodium hydroxide solution in order to cause the product to separate.

5-Alkyl-4-amino-2-propylpyrimidines (Table IV).—The monoaminopyrimidines were prepared by catalytic hydrogenolysis of the corresponding aminochloropyrimidines. The same conditions and catalyst were used as in the preparation of the pyrimidines from the chloropyrimidines. When the hydrogenation was complete, the catalyst was removed by filtration and the solution evaporated down to a volume of 15 ml. The addition of 25 ml. of concentrated ammonium hydroxide caused the product to precipitate. Recrystallization from benzene gave an analytically pure aminopyrimidine.

5-Alkyl-4,6-dimethoxy-2-propylpyrimidines (Table IV).—The dimethoxypyrimidines were prepared by the interaction of the dichloropyrimidines with sodium methoxide. The dichloropyrimidine (0.04 mole), dissolved in 10 ml. of methanol, was added dropwise to a solution of 2.3 g. (0.1 g. atom) of sodium in 50 ml. of methanol. Reaction took place immediately with the evolution of heat, and sodium chloride separated from solution. When all the dichloropyrimidine had been added, the reaction mixture was refluxed for 14 hr. Methanol was then removed *in vacuo* and the residue taken up in ether. Sodium chloride was filtered off and the ether solution dried over sodium sulfate. Ether was removed *in vacuo* and the product purified by vacuum distillation.

2-Propyltetrahydropyrimidine Hydrochloride.—4,6-Dichloro-2-propylpyrimidine 13.7 g. (0.072 mole), was dissolved in 50 ml. of butanol. The solution was shaken with Raney nickel and allowed to stand at 0° for 12 hr. This procedure was found necessary to remove catalyst poisons which made the subsequent hydrogenation difficult. The Raney nickel was removed by filtration and the filtrate, together with 10.9 g. (0.02 mole) of barium oxide and 10 g. of fresh catalyst, was subjected to hydrogenation in the same manner as described for the monochloropyrimidines. The hydrogenation was considered complete after 4 hr. with the uptake of 0.25 mole (3.6 equivalents) of hydrogen. The catalyst and other solid material was removed by centrifugation and the butanol by distillation. A heavy, viscous oil remained which solidified on cooling. It was recrystallized from acetone to give 5.0 g. (43% yield) of 2-propyltetrahydropyrimidine hydrochloride as hygroscopic white crystals, m.p. 98–100°. *Anal.* Calcd. for $C_7H_{15}ClN_2$: C, 51.65; H, 9.29; N, 17.22; Cl, 21.78. Found: C, 51.28; H, 9.44; N, 16.88; Cl, 21.50.

A picrate was prepared in the usual manner. Two recrystallizations from hot water gave long yellow needles of m.p. 107–109°. *Anal.* Calcd. for $C_{13}H_{17}N_5O_7$: C, 43.94; H, 4.82; N, 19.72. Found: C, 43.84; H, 4.65; N, 19.50.

Pyrimidine N-Oxides and Their Infrared Absorption Characteristics

BY RICHARD H. WILEY AND STEPHEN C. SLAYMAKER

RECEIVED OCTOBER 11, 1956

The infrared spectra for several pyridines and pyrimidines and their N-oxides have been analyzed. Structural correlations and assignments have been made for the C–H stretching and C–H planar deformations and the ring vibrations in the parents. The N-oxides show a strong band at 1255–1300 cm.$^{-1}$ assigned to the N–O stretching frequency. A second band, also characteristic of the N-oxides, appears at 847–872 cm.$^{-1}$. Evidence for the hydrogen bonding of the N-oxide with proton donors is observed in the infrared spectra of the N-oxides in which a band near 2960 cm.$^{-1}$ appears in chloroform but not carbon tetrachloride solutions. This has been correlated with shifts in the ultraviolet absorption maxima of the N-oxides in solvents of varying donor ability.

Although a few pyrimidine N-oxides have been described in the recent literature,[1,2] the possibility of utilizing pyrimidine N-oxides in substitution and rearrangement reactions similar to those which have been developed for the pyridine N-oxides[3,4] warrants additional study of this class of compounds. We have prepared and characterized the previously unknown N-oxides of pyrimidine and its 2-methyl, 5-methyl and 2,4,6-trimethyl derivatives. The infrared spectra of these along with that of the known 4-methylpyrimidine N-oxide[1,2] and pyridine and the picoline N-oxides have been obtained. This report will present the results of these studies.

The pyrimidines were obtained in over-all yields of 43–51% from the palladium-on-charcoal[5,6] reductive dehalogenation of dichloropyrimidines obtained in turn from the corresponding dihydroxy compounds. The N-oxides, described in Table I, were prepared using hydrogen peroxide in glacial acetic acid as described previously[3] for the preparation of pyridine N-oxides although in somewhat lower yields (11–36%). The highly deliquescent nature of the pyrimidine N-oxides coupled with their tendency to sublime *in vacuo* requires that they be handled carefully.

As a preliminary to a consideration of the infrared spectra of the N-oxides, we have evaluated the assignments for a number of the ring vibrations in the pyridines and pyrimidines listed in Table II. The vibrational spectrum of pyridine itself has been fully discussed in the literature.[7,8] As compared to benzene, the introduction of nitrogen into the ring changes the symmetry group from D_{6h} to C_{2v}, with the result that the doubly degenerate benzene ring vibrations are split. The loss of one atom in the benzene–pyridine comparison also requires that three fundamental vibrations be absent in pyridine. Pyrimidine belongs to the symmetry point group C_{2v} also, and although few changes would be expected in the ring vibrations, the loss of three more fundamentals—one C–H stretching, one C–H planar deformation and one C–H out of plane deformation—would be expected. In accordance with this, pyridines normally show two bands in the aromatic C–H stretching region and the pyrimidines show only a single, rather sharp band at 3048 cm.$^{-1}$. Furthermore, the solution spectrum of pyridine clearly shows four medium strength bands (1214, 1144, 1068, 1031 cm.$^{-1}$) in the region where planar hydrogen deformations might be expected and only three bands appear in the same region in pyrimidine (1221, 1155, 1070 cm.$^{-1}$). The third band expected to be lost is a species A_2 C–H out-of-plane deformation which would be inactive in the infrared spectrum of pyridine. The ring vibrations from substituted pyrimidines, with no hydroxyl or amino substituents, have previously been assigned to single absorption bands at 1580–1520 and 990 cm.$^{-1}$.[9] For pyrimidine itself further correlations have been made[9,10] which agree for the most part with those found in this Laboratory.

Assignments for the ring vibrations, v1, v8a, v8b, v19a and v19b[11] for pyridine, the picolines and eight pyrimidines are given in Table II. The location of the v8 and v19 pairs of ring deformation vibrations appears to be quite characteristic, with a slight shift to lower frequencies in both pairs of vibrations in going from the pyridines to the pyrimidines and another shift to still lower frequencies upon chlorine substitution on the pyrimidine ring. The intensities of these four vibrations vary widely, but at least one band in each pair is strong in all of the compounds studied. The v1 band, which can be thought of as a ring "breathing" vibration, appears in the range 1001–986 cm.$^{-1}$ in 10 of the 12 compounds studied.

The spectra of several tertiary amine oxides have been reported by Mathis-Neol[12] who examined five compounds and placed the absorption of the N–O stretching vibration in the range 970–950 cm.$^{-1}$. Goubeau and Fromme[13] have assigned a band at 947 cm.$^{-1}$ in the Raman spectra of one compound to this vibration. Ito and Hata[14] have assigned a band at 832 cm.$^{-1}$ to the N–O

4,6-Dichloro-2-methyl-	1555sh	1536s	1406s	1537s	1000m

[a] Values are in frequencies (cm.$^{-1}$); s = strong, m = medium, w = weak, sh = shoulder, vs = very strong. All are in carbon tetrachloride. [b] Kline and Turkevich[7] and Corrsin[8] assign the 8a and 8b vibrations in pyridine in a slightly different manner. They find a difficultly resolvable doublet at 1570–1580 cm.$^{-1}$ which they attribute to the v8a and v8b vibrations. They find also a band at 1597 cm.$^{-1}$ which they attribute to a combination tone strengthened by resonance with the v8 vibrations. These studies were conducted in the gas phase and in pure liquid pyridine. It would seem possible that the solution spectra used in our series of measurements could effect a further separation of the bands. It seems highly improbable that all of the bands in the first column can be attributed to a combination band since in γ-picoline and again in 2,4,6-trimethylpyrimidine the first band is far stronger than any other band in either spectra. [c] This extremely strong band probably involves some contribution from the asymmetric carbon hydrogen deformation bands expected in this region. The other methyl-containing compounds in this list show this to be a band of medium strength falling very near 1449 cm.$^{-1}$. The symmetric methyl deformation appears in the range 1390–1370 cm.$^{-1}$ in all of the methyl-containing compounds. [d] Bands not assigned.

stretching vibration in pyridine N-oxide on the basis that acetoxime shows an absorption in this same range which may also be attributed to an O–N stretching vibration. The absorption characteristics of the nine N-oxides studied are given in Table IV. All show an extremely strong band near 1266 cm.$^{-1}$ in carbon tetrachloride solution. For pyridine N-oxide itself and in α- and γ-picoline N-oxides this band falls at 1264–1260 cm.$^{-1}$. In β-picoline N-oxide, where the methyl group is not attached to an electron-deficient carbon, the band appears at 1290 cm.$^{-1}$. The location of this band [illegible] cm.$^{-1}$ in chloroform. Since chloroform itself ab-

is similar in the pyrimidine N-oxides but is often more complex. It is split into two strong bands in both 2- and 4-methylpyrimidine N-oxides. 2,4,6-Trimethylpyrimidine N-oxide shows a shift to 1255 cm.$^{-1}$. As in the case of β-picoline N-oxide, 5-methylpyrimidine N-oxide shows a shift to higher frequencies with its absorption appearing at 1300 cm.$^{-1}$. Pyrimidine N-oxide itself, although not sufficiently soluble to obtain a spectrum in carbon tetrachloride, shows a strong band at 1261 cm.$^{-1}$ in chloroform. The exact position of this band is affected by the formation of hydrogen bonds with the solvent. This has been shown to produce a

TABLE III

THE ULTRAVIOLET SPECTRA OF γ-PICOLINE N-OXIDE IN VARIOUS SOLVENTS

Solvent	Wave length, mμ	log ε
Water[15]	256	4.155

sorbs strongly near this region, the resulting loss of resolution encountered makes the assignment somewhat approximate in the case of pyrimidine N-oxide.

The strength of this band near 1266 cm.$^{-1}$ and the solvent shift have caused us to assign this band to the N–O stretching frequency in these compounds despite the previous assignments.[12–14] This need not be an inconsistency, since it is well known that other physical and chemical properties of the heterocyclic N-oxides differ greatly from those of the trialkyl amine oxides. A number of ionic resonance forms are possible in the heterocyclic N-oxides, and these would give the N–O bond considerable double bond character. The pyrimidine and pyridine N-oxides show no consistent absorption in the 950 cm.$^{-1}$ region previously stated to be characteristic of the N–O stretching vibration.

A second band which appears to be characteristic of the heterocyclic N-oxides is found near 847 cm.$^{-1}$. In pyridine N-oxide this band occurs at 841 cm.$^{-1}$, while in pyrimidine N-oxide the absorption occurs at 845 cm.$^{-1}$. All of the methyl-containing compounds show this band in the narrow range 860–855 cm.$^{-1}$ with the exception of 2-methylpyrimidine N-oxide where the band falls at 872 cm.$^{-1}$. This band is in the region tentatively assigned previously[14] to the O–N stretching vibration. Since it is not subject to the displacement in chloroform as is the 1260 cm.$^{-1}$ band, it now seems advisable to revise this assignment.

An interesting phenomena is observed in the spectra of chloroform solutions of N-oxides. A sharp and unusually strong band occurs near 2960 cm.$^{-1}$ which is absent from the spectra obtained in carbon tetrachloride solutions. This is probably due to the absorption associated with the C–H stretching vibration in chloroform which is shifted to longer wave lengths by hydrogen bonding. A number of other compounds capable of acting as donors have been shown to produce shifts in this band. Quinoline, for example, is known to produce a shift from 3067 to 2960 cm.$^{-1}$ as well as a fourfold strengthening of the absorption.[15] A shift of this magnitude would bring the chloroform frequency to a point where the compensating cell would not eliminate it, thus introducing an entirely spurious band in the N-oxide spectra. Further indication of hydrogen bonding is found in the ultraviolet spectra. Thus, the absorption band for γ-picoline N-oxide shows a strong hypsochromic shift in going from non-polar solvents to polar solvents (see Table III). It has been suggested[16] that this band arises from a $\pi \rightarrow \pi^*$ transition. This type of transition has usually been known to produce a bathochromic (red) shift under the effect of solvation.[17] Large hypsochromic (blue) shifts normally are evidence of $n \rightarrow \pi^*$ transitions,[17] but such a transition is inconsistent with the high intensity of the absorption.

In contrast with the similarities previously noted[12] between the infrared spectra of tertiary amine N-oxide and the corresponding amine, the spectra of the heterocycles and their N-oxides are not greatly similar. While pyridine, pyrimidine and their methyl derivatives show characteristic ring vibrations which are strong and easily assigned, the N-oxides show much less regularity. There is a striking weakening of absorption below 1490 cm.$^{-1}$ as compared to the parent compounds. A number of the bands found in these N-oxides are listed in Table IV. Although the spectrum of pyrimidine shows many resemblances to that of pyridine, the spectra of the N-oxides show fewer resemblances between the two ring systems.

Acknowledgment.—The authors wish to express their appreciation for a grant from the National Science Foundation (Grant NSF-G1918) in support of this research.

Experimental

Details of typical procedures are given in the following paragraphs. Complete data are given in Table I. Combustion analyses were performed by Micro Tech Laboratories, Skokie, Ill.

The pyridine, picolines and their N-oxides used in the spectroscopic studies were generously furnished by Reilly Tar and Chemical Co. These compounds were redistilled or recrystallized before use. The tetraethoxypropane was generously donated by Carbide and Carbon Chemical Co. and was used as received.

5-Methylpyrimidine.—Forty-eight grams (0.3 mole) of 4,6-dichloro-5-methylpyrimidine was divided into three portions of 16.0 g., and each portion was hydrogenated in a Parr hydrogenation apparatus with 10.0 g. of powdered magnesium oxide and 2.0 g. of 5% palladium-on-charcoal catalyst in 300 ml. of 50% aqueous methanol. From an initial pressure of about 50 pounds the theoretical amount of hydrogen was absorbed smoothly in 90 minutes. The filtered solution was poured into 1500 ml. of hot water containing 180 g. of mercuric chloride. The thick white precipitate was collected on a filter after cooling, then was dried and placed in a 2000-ml. distilling flask containing 600 ml. of water and 85 g. of sodium sulfide. After removal of 400 ml. of distillate, saturation with sodium hydroxide caused the amine layer to form. This layer was separated and the aqueous solution extracted with three 80-ml. portions of ether. The combined ether fractions and the amine were dried over calcium sulfate, concentrated to 40 ml. and distilled. After removing a small amount of ether, a rather large forerun was collected (b.p. 80–150°), followed by the methylpyrimidine, b.p. 150–155°. The forerun was dried over potassium hydroxide and redistilled to give more of the crude methylpyrimidine. Redistillation gave 15.5 g. (55%) of 5-methylpyrimidine, b.p. 152–154° (760 mm.). The clear, colorless liquid solidified on chilling, m.p. 28–30°; reported[18] b.p. 151.5° (735 mm.), m.p 30.5°.

Other pyrimidines were prepared similarly: pyrimidine (48% from uracil), b.p. 121–123° (760 mm.), $n^{23}D$ 1.4983 (reported[8] b.p. 123–124° (762 mm.); 2-methylpyrimidine (43% from 2-methyl-4,6-dihydroxypyrimidine), b.p. 129–133° (760 mm.), $n^{26}D$ 1.4878 (reported[19] b.p. 130–131° (750 mm.); 4-methylpyrimidine (51% from 4-methyluracil), b.p 139–141° (760 mm), $n^{29}D$ 1.4918 (reported[6] b.p. 141–145° (760 mm.), n_D 1.4940). 2,4,6-Trimethylpyrimidine was prepared in 26% yield from acetamidine and acetylacetone,[20] b.p. 84–87° (45 mm.). The direct condensation of tetraethoxypyropane with acetamidine in hydrochloric acid saturated ethanol gave only a 2% yield of 2-methylpyrimidine isolated as the mercuric chloride complex.

2,4,6-Trimethylpyrimidine N-Oxide.—Six and one-tenth grams (0.05 mole) of 2,4,6-trimethylpyrimidine was heated with 30 ml. of glacial acetic acid and 8 ml. of 30% hydrogen peroxide at 70° for 5 hr. Six additional ml. of peroxide was

added and the temperature maintained for 16 hr. Evaporation to 10 ml., addition of 20 ml. of water and evaporation again to 10 ml. gave a yellow oil which was saturated with sodium carbonate and extracted with five 20-ml. portions of chloroform. The chloroform extracts were dried with calcium sulfate and evaporated in vacuum to leave a viscous oil. Distillation of this gave 2.3 g. of crude product, b.p. 100–102° (1 mm.), which partially solidified to white crystals in the receiver. Careful drying on a clay plate in a desiccator gave crystals, m.p. 67–72°. The product was very hygroscopic and formed a solid complex with mercuric chloride. One recrystallization of this complex from water gave crystals, m.p. 143.5–145°.

5-Methylpyrimidine N-Oxide.—Seven and five one-hundredth grams (0.075 mole) of 5-methylpyrimidine was heated at 70° for 6 hr. in 30 ml. of glacial acetic acid containing 8 ml. of hydrogen peroxide solution (30%). Eight additional ml. of peroxide was added and the heating continued for 20 hr. The resulting solution was treated as before. The crude solid from the chloroform extracts was recrystallized from carbon tetrachloride to yield white, hygroscopic crystals, m.p. 113–116°. A mercuric chloride complex, m.p. 170–170.5°, was obtained.

The infrared spectra were obtained with a Baird double beam recording spectrophotometer equipped with sodium chloride optics using 0.1-mm. sodium chloride cells. All measurements were calibrated against the 3.419 band of polystyrene. The ultraviolet spectra were obtained using a Beckman DU spectrophotometer in 1-cm. quartz cells.

The Reaction of 2-Bromopyridine N-Oxides with Active Methylene Compounds

BY ROGER ADAMS AND WALTER REIFSCHNEIDER

RECEIVED NOVEMBER 10, 1956

2-Bromopyridine N-oxides condense with active methylene compounds holding a carboalkoxy group to give derivatives of 2-isoxazolono[2,3-a]pyridines. These products react with aqueous alkali; the isoxazolone ring is opened and carbon dioxide is lost with formation of the 2-substituted pyridine N-oxides. 2-Carbethoxy-2-isoxazolono[2,3-a]pyridine is hydrogenated with platinum oxide catalyst to 3-carbethoxy-2-isoxazolono[2,3-a]piperidine.

The electron-attracting power of the ring nitrogen accounts for the facile attack of halogen in the 2- and 4-halopyridines by nucleophilic reagents. In spite of this reactivity, the bromine atom in 2-bromopyridine fails to respond to treatment with diethyl sodiomalonate.[1] The introduction of the malonic ester group in the 2-position of pyridine was achieved[2] by using 5-nitro-2-chloropyridine in which the halogen is further activated by the electron-withdrawing nature of the nitro group.

The introduction of an N-oxide into the pyridine system also is known to increase the reactivity of the 2-, 4- and 6-positions of the ring. A reaction between 2-bromopyridine 1-oxide (I) and diethyl sodiomalonate might therefore be expected. A reaction does take place between these reagents under relatively mild conditions, but diethyl 2-pyridylmalonate 1-oxide (III) is not isolated. Instead, a compound of the formula $C_{10}H_9NO_4$ results. The reaction apparently does not stop after the initial condensation but loss of ethanol occurs to form 3-carbethoxy-2-isoxazolono[2,3-a]pyridine (IV).

To demonstrate the generality of this reaction, 2-bromopyridine 1-oxide (I) and 2-bromo-6-methylpyridine 1-oxide (II) were subjected to the action of various active methylene compounds. 2-Bromo-6-methylpyridine 1-oxide (II) is a stable compound in comparison with 2-bromopyridine 1-oxide (I) and therefore was more often used in this study. Upon addition of ethyl sodioacetoacetate and ethyl sodiobenzoylacetate to 2-bromopyridine 1-oxide (I) and 2-bromo-6-methylpyridine 1-oxide (II) the expected cyclized products V, VI, IX and X were obtained.

When ethyl sodiocyanoacetate was treated with 2-bromo-6-methylpyridine 1-oxide (II) and benzene was used as the solvent, three compounds were isolated, (1) 2-imino-3-carbethoxy-7-methylisoxazolo[2,3-a]pyridine (XIV), (2) 3-cyano-7-methyl-2-isoxazolono[2,3-a]pyridine (XI) and (3) ethyl [α-cyano-β-amino-β-(7-methyl-2-isoxazolono[2,3-a]pyridyl-3)]-acrylate (XII).

XV

The structure of the first compound XIV, a yellow product, was established by analysis ($C_{11}H_{12}N_2O_3$) and the presence in the infrared spectrum of an N–H band at 3285 $cm.^{-1}$ and a conjugated ester band at 1688 $cm.^{-1}$.

The second compound XI was a colorless product with the empirical formula $C_9H_6N_2O_2$ and showed bands in its infrared spectrum for CN at

2220 cm.$^{-1}$ and for an isoxazolone-CO at 1766 cm.$^{-1}$.

The third product XII, $C_{14}H_{13}N_3O_4$, was colorless but turned yellow upon exposure to light. The infrared spectrum showed bands for NH_2 at 3225 and 3375 cm.$^{-1}$, for CN at 2205 cm.$^{-1}$, for an isoxazolone-CO at 1745 cm.$^{-1}$ and for a conjugated ester at 1672 cm.$^{-1}$. The structure assigned assumes initial formation of a dimer of the ethyl cyanoacetate which then reacted with 2-bromo-6-methylpyridine 1-oxide. This was confirmed by dimerizing ethyl cyanoacetate[3] and condensing it with the 2-bromo-6-methylpyridine 1-oxide to give the same product.

If the condensation of ethyl sodiocyanoacetate with 2-bromo-6-methylpyridine 1-oxide (II) was carried out in dioxane, only compounds XI and XII could be isolated.

Attempts to achieve reaction between 2-bromo-6-methylpyridine 1-oxide (II) and the sodium salts of acetylacetone, benzoylacetone or dibenzoylmethane failed.

The derivatives of 2-isoxazolono[2,3-a]pyridine were all subjected to hydrolysis with 5% aqueous sodium hydroxide. In both 3-acetyl-7-methyl-2-isoxazolono[2,3-a]pyridine (IX) and 3-benzoyl-7-methyl-2-isoxazolono[2,3-a]pyridine (X) opening of the isoxazolone ring and decarboxylation occurred leading to formation of 6-methyl-2-acetonylpyridine 1-oxide (XVIII) and 6-methyl-2-benzoylmethylpyridine 1-oxide (XIX), respectively. Upon hydrolysis of 3-cyano-7-methyl-2-isoxazolono[2,3-a]pyridine (XI), 6-methyl-2-pyridylacetic acid 1-oxide (XVII) was obtained; besides ring opening and decarboxylation the nitrile group underwent hydrolysis. 6-Methyl-2-pyridylacetic acid 1-oxide (XVII) also resulted from hydrolysis of ethyl [α-cyano-β-amino-β-(7-methyl-2-isoxazolono[2,3-a]-pyridyl-3-)]-acrylate (XII). Hydrolysis of both 3-carbethoxy-2-isoxazolono[2,3-a]pyridine (IV) and its 7-methyl derivative VIII resulted in a mixture of two compounds. 3-Carboxy-2-isoxazolono-[2,3-a]pyridine (VII) and 2-pyridylacetic acid 1-oxide (XVI) were obtained from IV, while the corresponding methyl analogs (XIII and XVII) were formed from VIII. The ratio of the two products in each case is dependent on the duration of the hydrolysis.

2-Pyridylacetic acid 1-oxide (XVI) and 6-methyl-2-pyridylacetic acid 1-oxide (XVII) are much more stable than 2-pyridylacetic acid and 6-methyl-2-pyridylacetic acid. The former do not decompose with loss of carbon dioxide to form 2-picoline 1-oxide and 2,6-dimethylpyridine 1-oxide until their melting points are reached.

3-Carbethoxy-2-isoxazolono[2,3-a]pyridine (IV) was hydrogenated using a platinum oxide catalyst. Two moles of hydrogen were absorbed and 3-carbethoxy-2-isoxazolono[2,3-a]piperidine (XX) was formed.

Experimental Part

2-Bromo-6-methylpyridine 1-Oxide (II).—To a solution of 172 g. of 2-bromo-6-methylpyridine[4] in 150 ml. of glacial acetic acid was added 310 ml. of 40% peracetic acid. The temperature rose and was kept below 50° by external cooling. After the initial reaction subsided the solution was heated for 5 hours at 50° and then overnight at 70°. After concentration of the solution *in vacuo* on the water-bath to about 200 ml., it was poured onto ice and made strongly alkaline by adding 40% aqueous potassium hydroxide. An oil separated. The solution was extracted thrice with chloroform. The combined chloroform solutions were dried over potassium carbonate, filtered and the chloroform was removed under reduced pressure on the water-bath. Addition of ether to the oily residue and cooling yielded crystalline 2-bromo-6-methylpyridine 1-oxide. It was recrystallized from ethanol–ether, m.p. 70°. The yield was 181.0 g. (96.3%).

Anal. Calcd. for C_6H_6BrNO: C, 38.32; H, 3.22. Found: C, 38.44; H, 3.17.

Hydrochloride, m.p. 196–197° (lit.[5] m.p. 185–186°).

Anal. Calcd. for $C_6H_7BrClNO$: C, 32.10; H, 3.14. Found: C, 31.98; H, 3.09.

2-Bromopyridine 1-Oxide (I).—The procedure described for making 2-bromo-6-methylpyridine 1-oxide (II) was used. The product was obtained in 72.4% yield. It was recrystallized from ethanol–ether, m.p. 64°; hydrochloride, m.p. 132–135° (lit.[5] m.p. 130–135°).

Anal. Calcd. for C_5H_4BrNO: C, 34.51; H, 2.32. Found: C, 34.55; H, 2.40.

2-Bromopyridine 1-oxide is unstable at room temperature. A sample detonated without apparent cause on standing at room temperature for several days.

Reaction of Active Methylene Compounds with 2-Bromo-6-methylpyridine 1-Oxide and 2-Bromopyridine 1-Oxide. General Procedure.—The sodium salt of an active methylene compound was prepared by adding 0.1 mole of the active methylene compound to 2.4 g. (0.1 mole) of sodium hydride kept under 100 ml. of dioxane, benzene or ether. To this was added 0.1 mole of 2-bromo-6-methylpyridine 1-oxide (II) or 2-bromopyridine 1-oxide (I), and the mixture was heated under reflux for 24 hours. After cooling, the solid part of the reaction mixture was collected by filtration, and the filtrate was evaporated to dryness under reduced pressure on the water-bath. The combined residues were triturated with about 100 ml. of water. The insoluble portion was collected by filtration, washed with water and recrystallized from ethanol.

To recover any unreacted N-oxide, the filtrate was extracted with three 80-ml. portions of chloroform and the combined chloroform extracts were extracted with three 50-ml. portions of 20% hydrochloric acid. The hydrochloric acid solution was concentrated *in vacuo* on the steam-bath until the N-oxide hydrochloride began to crystallize. After cooling, the N-oxide hydrochloride was collected by filtration and was recrystallized from ether.

See Table I for constants of the products.

Hydrolysis of 3-Acetyl-7-methyl-2-isoxazolono[2,3-a]-pyridine (IX): 2-Acetonyl-6-methylpyridine 1-Oxide (XVIII).—A mixture of 2.0 g. of 3-acetyl-7-methyl-2-isoxazolono-[2,3-a]pyridine (IX) and 10 ml. of 5% aqueous sodium hydroxide was boiled under reflux until a clear solution was obtained (about 70 min.). After cooling, the solution was extracted with three 10-ml. portions of chloroform. The combined chloroform extracts were dried over potassium carbonate, and the chloroform then removed under reduced pressure. The residual oil was dissolved in warm ether which on cooling yielded 1.6 g. (92.5%) of colorless needles. The substance was recrystallized from ether, m.p. 67–68°.

Anal. Calcd. for $C_9H_{11}NO_2$: C, 65.44; H, 6.71; N, 8.48. Found: C, 65.71; H, 6.95; N, 8.49.

[a] Compound XIV was isolated from the solid part of the reaction mixture. It was recrystallized from water. Compounds XI and XII were isolated from the residue after removing the benzene under reduced pressure. [b] Compounds XI and XII were separated by fractional crystallization from chloroform.

Hydrolysis of 3-Benzoyl-7-methyl-2-isoxazolono[2,3-a]-pyridine (X): 2-Benzoylmethyl-6-methylpyridine 1-Oxide (XIX).—A suspension of 0.7 g. of 3-benzoyl-7-methyl-2-isoxazolono[2,3-a]pyridine (X) in 8 ml. of 5% aqueous sodium hydroxide was boiled under reflux for 1.5 hours. The clear solution was treated in the same manner as described for 6-methyl-2-acetonylpyridine 1-oxide to yield 0.61 g. (97.1%) of white crystals. The substance was recrystallized from ethanol–ether, m.p. 143–145°.

Anal. Calcd. for $C_{14}H_{13}NO_2$: C, 73.99; H, 5.76; N, 6.17. Found: C, 74.11; H, 5.74; N, 6.21.

Hydrolysis of 3-Cyano-7-methyl-2-isoxazolono[2,3-a]-pyridine (XI): 6-Methyl-2-pyridylacetic Acid 1-Oxide (XVII).—A mixture of 1.15 g. of 3-cyano-7-methyl-2-isoxazolono[2,3-a]pyridine (XI) and 15 ml. of 5% aqueous sodium hydroxide was boiled under reflux until a clear solution was obtained (1 hr.). After cooling, the solution was acidified with 2 *N* sulfuric acid and then exhaustively extracted with chloroform. The chloroform extracts were dried over magnesium sulfate and the chloroform was removed under reduced pressure. A crystalline residue was obtained and was recrystallized from ethanol, m.p. 147–148° dec. The yield was 1.05 g. (95%).

Anal. Calcd. for $C_8H_9NO_3$: C, 57.48; H, 5.43; N, 8.38. Found: C, 57.81; H, 5.66; N, 8.66.

Hydrolysis of Ethyl [α-Cyano-β-amino-β-(7-methyl-2-isoxazolono[2,3-a]pyridyl-3-)]-acrylate (XII): 6-Methyl-2-pyridylacetic Acid 1-Oxide (XVII).—A mixture of 2.4 g. of ethyl [α-cyano-β-amino-β-(7-methyl-2-isoxazolono[2,3-a]-pyridyl-3-)]-acrylate (XII) and 50 ml. of 5% aqueous sodium hydroxide was treated as described for the hydrolysis of 3-cyano-7-methyl-2-isoxazolono[2,3-a]pyridine (XI) to yield 1.28 g. (91.4%) of 6-methyl-2-pyridylacetic acid 1-oxide (XVII), m.p. 147–148° dec.

Anal. Calcd. for $C_8H_9NO_3$: C, 57.48; H, 5.43. Found: C, 57.53; H, 5.35.

Hydrolysis of 3-Carbethoxy-7-methyl-2-isoxazolono[2,3-a]pyridine (VIII): 3-Carboxy-7-methyl-2-isoxazolono[2,3-a]pyridine (XIII) and 6-Methyl-2-pyridylacetic Acid 1-oxide (XVII).—A suspension of 3.3 g. of 3-carbethoxy-7-methyl-2-isoxazolono[2,3-a]pyridine (VIII) in 40 ml. of

5% aqueous sodium hydroxide was boiled under reflux for one hour. The clear solution was cooled and then acidified with 2 *N* sulfuric acid. The white substance which precipitated was collected by filtration and washed with water. The material was recrystallized from ethanol, m.p. 211–212° dec. The yield was 1.5 g. (52.1%).

Anal. Calcd. for $C_9H_7NO_4$: C, 55.96; H, 3.65; N, 7.25. Found: C, 55.67; H, 3.74; N, 7.54.

The filtrate, after removal of 3-carboxy-7-methyl-2-isoxazolono[2,3-a]pyridine, was exhaustively extracted with chloroform. The chloroform extracts were dried over magnesium sulfate and the chloroform removed under reduced pressure. The crystalline residue was recrystallized from ethanol. The yield was 1.1 g. (44.2%) of 6-methyl-2-pyridylacetic acid 1-oxide (XVII), m.p. 146–147° dec.

Anal. Calcd. for $C_8H_9NO_3$: C, 57.48; H, 5.43. Found: C, 57.86; H, 5.37.

Hydrolysis of 3-Carbethoxy-2-isoxazolono[2,3-a]pyridine (IV): 3-Carboxy-2-isoxazolono[2,3-a]pyridine (VII) and 2-Pyridylacetic Acid 1-Oxide (XVI).—A mixture of 3.0 g. of 3-carbethoxy-2-isoxazolono[2,3-a]pyridine (IV) and 30 ml. of 5% aqueous sodium hydroxide was treated as described for its 7-methyl derivative. A yield of 0.8 g. (30.9%) of 3-carboxy-2-isoxazolono[2,3-a]pyridine (VII), m.p. 204–205° dec., resulted from acidification of the alkaline solution.

Anal. Calcd. for $C_8H_5NO_4$: C, 53.64; H, 2.81; N, 7.82. Found: C, 53.67; H, 2.78; N, 7.73.

From the filtrate 0.4 g. (18.0%) of 2-pyridylacetic acid 1-oxide (XVI), m.p. 140° dec., was obtained.

Anal. Calcd. for $C_7H_7NO_3$: C, 54.90; H, 4.61; N, 9.14. Found: C, 54.60; H, 4.54; N, 8.82.

Hydrogenation of 3-Carbethoxy-2-isoxazolono[2,3-a]pyridine (IV): 3-Carbethoxy-2-isoxazolono[2,3-a]piperidine (XX).—A suspension of 0.4 g. of 3-carbethoxy-2-isoxazolono[2,3-a]pyridine (IV) in 100 ml. of ethanol was hydrogenated in the presence of platinum oxide catalyst. An uptake of 92 ml. of hydrogen at 24° and 745 mm. was observed (theoretical for 2 moles at 24° and 745 mm. is 96.0 ml.) The catalyst was removed by filtration and the filtrate was concentrated until the substance started to crystallize. Ether was added and after cooling the compound was collected by filtration. It was recrystallized from ethanol–ether, m.p. 157–158°.

Anal. Calcd. for $C_{10}H_{13}NO_4$: C, 56.86; H, 6.20; N, 6.64. Found: C, 56.71; H, 6.23; N, 6.37.

Alkaloids of *Lunasia amara* Blanco. 4-Methoxy-2-phenylquinoline

BY SIDNEY GOODWIN, A. F. SMITH AND E. C. HORNING

RECEIVED SEPTEMBER 16, 1956

From the leaves of *Lunasia amara* Blanco there was isolated an alkaloid which did not correspond to any of the previously reported *Lunasia* alkaloids. It was identified as 4-methoxy-2-phenylquinoline. This substance has not hitherto been reported to occur in nature.

Alkaloids of the genus *Lunasia* (fam. *Rutaceae*) have been investigated on several occasions since their discovery by Lewin[1] and by Boorsma.[1] Several alkaloids of unknown structure were described by Steldt and Chen,[2] who found that, contrary to previous reports, the alkaloids did not possess a digitalis-like action. Pertinent early references are given by Steldt and Chen.

In the present work, a number of alkaloids were isolated from leaves of *Lunasia amara* Blanco obtained from the Philippine Islands.[3] Of the total of seven compounds isolated by chromatography on alumina, only the one eluted first will be discussed in this paper. This material, with an empirical formula $C_{16}H_{13}ON$, crystallized from pentane in colorless, optically inactive needles melting at 66–67°. It was identified through its reactions and by synthesis as 4-methoxy-2-phenylquinoline (I). This substance has not heretofore been reported as a naturally occurring compound, and it was not observed in earlier *Lunasia* work.

An interesting property of this compound, which provided one of the first keys to its structure, was observed through the melting point behavior of the hydrochloride. The salt melted with effervescence to a colorless liquid which resolidified and thereafter melted above 240°. These effects suggested a thermal demethylation to yield a 2- or 4-quinolone. Salts of cusparine (a 4-methoxyquinoline) were reported to yield a 4-quinolone on heating to decomposition temperature,[4] and a preparative pyrolysis of the *Lunasia* alkaloid hydrochloride

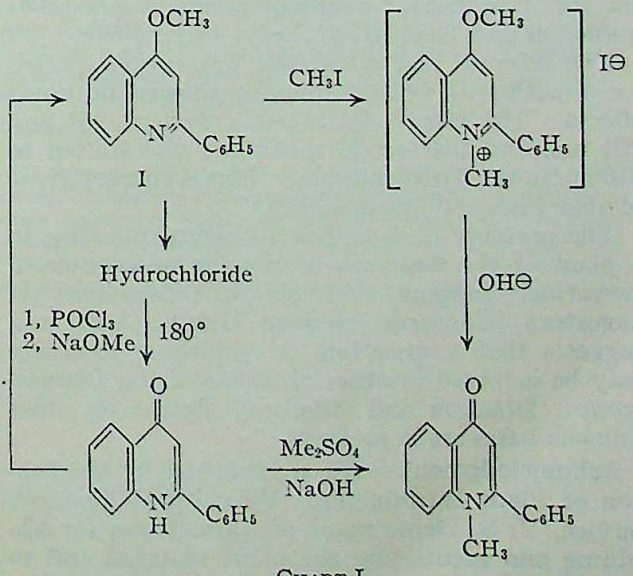

CHART I

was therefore carried out. The high-melting (256–258°) product, later recognized as 2-phenyl-

Digitized by Arya Samaj Foundation Chennai and eGangotri

4-quinolone, was obtained in good yield in this way.

The methiodide of the alkaloid was prepared in nearly quantitative yield by heating the base with methyl iodide at 100°. Under these circumstances, some methoxyquinolines are converted into N-methylquinolones; this is true, for example, for dictamnine. Since the immediate reaction product in this instance was the methiodide, it was treated in aqueous solution with dilute sodium hydroxide, and an *iso*alkaloid separated in excellent yield. These results pointed to a 4-methoxyquinoline structure.

The chief problem in selecting the most likely structure for synthesis involved a few points of non-correspondence with the literature. 4-Methoxy-2-phenylquinoline was described about fifty years ago by Knorr[5] with a melting point (69–70°) very close to that found for the *Lunasia* alkaloid, but treatment with methyl iodide at 90° was reported to give 1-methyl-2-phenyl-4-quinolone directly. This behavior was not duplicated in our experience. In addition, the N-methylquinolone was reported as melting at both 85°[5] and 136°,[6] while the reaction product obtained in this work melted at 143.5–144.5°. The first structural comparison selected for investigation was that for 2-phenyl-4-quinolone (the pyrolysis product); the materials derived from synthesis and from the alkaloid were found to be identical. 4-Methoxy-2-phenylquinoline was then prepared, and identity was established for the synthetic and natural substances.

The synthetic route followed Fuson and Burness[7] in the preparation of 2-phenyl-4-quinolone from ethyl anthranilate and acetophenone diethyl ketal. Treatment of the quinolone with phosphorus oxychloride gave the 4-chloro compound, and this was converted to the 4-methoxy compound by sodium methoxide in methanol at 100°. Relationships between the synthetic and natural series are indicated in the reaction chart. Comparisons were made by mixed m.p., infrared and ultraviolet spectra for 4-methoxy-2-phenylquinoline, 2-phenyl-4-quinolone and 1-methyl-2-phenyl-4-quinolone.

The infrared and ultraviolet absorption spectra for 4-methoxy-2-phenylquinoline showed no novel effects. The ultraviolet maxima were at 254 and 294 mμ, and the second maximum was shifted to 316 mμ in the hydrochloride. This is characteristic of quinolines and isoquinolines.[8]

The presence of 4-methoxy-2-phenylquinoline in a plant of the *Rutaceae* recalls the occurrence of cusparine, galipine and simpler quinolines in angostura (*Cusparia febrifuga* Humb.) bark and suggests that a quinoline or quinolone structure may be involved in other alkaloids of the *Lunasia* group. Isolation and structural studies on other *Lunasia* bases are in progress.

Acknowledgment.—We are indebted to the Section of Plant Introduction, Agricultural Research Service, U. S. Department of Agriculture, for obtaining and identifying the plant material and to Dr. Felipe R. Amos, Director, Bureau of Forestry, Department of Agriculture, Republic of the Philippines, for making available the collections. Extractions were carried out by Mr. D. L. Rogerson and Mr. J. Link. The instrumental work was carried out by Mr. H. F. Byers and Miss Catherine Monaghan. Analyses were performed in the laboratories of Mr. W. Manser, Zurich, Switzerland, and Dr. W. C. Alford, National Institute of Arthritis and Metabolic Diseases.

Experimental[9]

Natural Series. Isolation of 4-Methoxy-2-phenylquinoline from *Lunasia amara* Leaves.—A 20-kg. quantity of dried, ground leaves was extracted with 30 gal. of 95% ethanol at 50–60° for 1 hr. The treatment was repeated, and the combined extracts were concentrated under reduced pressure to a volume of 8 l. The concentrate was processed in two parts. To 4 l. of concentrate there was added 3 l. of water and 1 l. of 2 *N* sulfuric acid, and the mixture was filtered (Supercel). The combined filtrate and filtrate washings (500 ml. of 2 *N* sulfuric acid and 500 ml. of water) were extracted with trichloroethylene (the wash contained no alkaloids and was discarded). The solution was made alkaline with sodium carbonate, and an organic base fraction was separated by extraction with trichloroethylene (fifteen 200-ml. portions) and by continuous extraction with chloroform. From the combined organic solvent phases from the entire run there was obtained 300 g. (1.5%) of black viscous residue.

An 80-g. portion of this residue was dissolved in 200 ml. of ethanol, and this was added with rapid stirring to 2 l. of 1% hydrochloric acid at 50°. After filtration (Supercel), the combined filtrate and washings (500 ml. of water at 70°) were cooled and washed with ether to yield 6.8 g. of discolored, viscous oil which gave weak positive tests with Mayer and silicotungstic acid reagents. The aqueous solution was made alkaline (potassium carbonate) and the organic bases were extracted with chloroform to yield 42 g. of crude, mixed alkaloids.

This residue was treated with 400 ml. of warm benzene (about 1 g. of insoluble material remained); the benzene solution was filtered and used for chromatography with 1400 g. of alumina (Merck, acid-washed). Sixty fractions were collected. Fractions 1–6 (benzene, 1.5 l. total) gave 0.19 g. of non-basic oil; fractions 7–14 (benzene, 3.5 l. total) gave 2.02 g. of colorless oil which soon solidified.[10] Recrystallization from pentane gave colorless needles, m.p. 66–67°.

Anal. Calcd. for $C_{16}H_{13}ON$: C, 81.68; H, 5.57; N, 5.95. Found: C, 81.42; H, 5.47; N, 5.90.

Alkaloid Derivatives.—The hydrochloride was prepared from 200 mg. of the base with hydrogen chloride in methanol. Recrystallization from methanol–ether gave an analytical sample whose melting point exhibited an unusual behavior. The crystalline material sintered at 110–120° and melted at 148–151° with gas evolution; the colorless melt solidified on cooling and thereafter melted at 240–243°. The latter m.p. is close to that of 2-phenyl-4-quinolinol (2-phenyl-4-quinolone), indicating that demethylation occurred during the heating period.

Anal. Calcd. for $C_{16}H_{13}ON \cdot HCl \cdot H_2O$: C, 66.31; H, 5.62; N, 4.84; OMe, 10.71. Found: C, 66.28; H, 5.54; N, 4.87; OCH_3, 10.62; NCH_3, none.

The perchlorate was prepared from 160 mg. of base in ethanol with perchloric acid. Recrystallization from ethanol gave an analytical sample; colorless rods, m.p. 215–218°.

Anal. Calcd. for $C_{16}H_{13}ON \cdot HClO_4$: C, 57.23; H, 4.20; N, 4.17. Found: C, 57.30; H, 4.32; N, 4.17.

The methiodide was prepared from 500 mg. of the base by heating in methyl iodide (2 ml.) at 100° for 18 hr. The product (780 mg.) was recrystallized from methanol to yield bright yellow needles, m.p. 148–151°.

Anal. Calcd. for $C_{17}H_{16}ONI$: C, 54.12; H, 4.28; N, 3.71. Found: C, 54.12; H, 4.39; N, 3.73.

2-Phenyl-4-quinolinol (2-Phenyl-4-quinolone).—A small sample (50 mg.) of the base hydrochloride was heated (oil-bath) at 180° for 5 minutes (the material melted and resolidified). The product was dissolved in 1 *N* sodium hydroxide solution (2 ml.), precipitated by acidification with acetic acid, and recrystallized from aqueous ethanol to give 32 mg. of colorless needles, m.p. 256–258° with crystal transformations at 215° and at 247–251° (partial melting and resolidification occurred at the latter temperature).

A mixed m.p. with synthetic material showed the same effects, and the infrared spectra (potassium bromide disks) of the synthetic material and that obtained *via* the plant alkaloid were identical.

1-Methyl-2-phenyl-4-quinolone.—To a solution of 160 mg. of the alkaloid methiodide in 10 ml. of warm water there was added 2 ml. of 1 *N* sodium hydroxide solution. After warming (steam) for 10 minutes, the product was collected, dried (crude yield, 91%) and recrystallized from ethyl acetate–pentane to give 62 mg. of colorless needles, m.p. 142.5–144.5°. Further crystallization from ethyl acetate gave a sample with m.p. 143.5–144.5°.

Synthetic Series. 2-Phenyl-4-quinolinol (2-Phenyl-4-quinolone).—This compound was prepared according to Fuson and Burness[7] from acetophenone diethyl ketal and ethyl anthranilate. The crude product (74%, m.p. 249–251°) was recrystallized from aqueous ethanol to give colorless needles, m.p. 257–258°, with crystal transformations at 243° and 250° (reported[7] m.p. 259–260°).

2-Phenyl-4-chloroquinoline.—2-Phenyl-4-quinolone was converted to the 4-chloro compound by heating with phosphorus oxychloride according to Knorr.[5] The product (crude yield 97%) was recrystallized from ethanol; colorless needles, m.p. 60–61.5° (reported[5] m.p. 63–64°).

4-Methoxy-2-phenylquinoline (I).—To a solution of 2.7 g. of sodium in 65 ml. of anhydrous methanol there was added 5.0 g. of the 4-chloro compound. After 48 hr. at 90–100° the product was isolated by the usual manipulations. A 4.5-g. (92%) yield of colorless needles, m.p. 66–67° (from pentane) was obtained. This material was unchanged in melting point on further recrystallization from pentane (reported[5] m.p. 69–70°). A mixed melting point with the natural alkaloid was not depressed. The ultraviolet and infrared absorption spectra of this material were found to be identical with those of the natural alkaloid.

1-Methyl-2-phenyl-4-quinolone.—One gram of 2-phenyl-4-quinolone was methylated with dimethyl sulfate, using a total of 80 ml. of 20% sodium hydroxide solution and 25 ml. of dimethyl sulfate. The crude product (1.0 g., 92%) was recrystallized several times from ethyl acetate to yield colorless rods, m.p. 143.5–144.5°, which proved to be identical (mixed m.p., ultraviolet and infrared spectra) with the corresponding material obtained as described in the previous section.

Anal. Calcd. for $C_{16}H_{13}ON$: C, 81.68; H, 5.57; N, 5.95. Found: C, 81.39; H, 5.71; N, 6.03.

This melting point is not in complete agreement with literature values.[5,6] It was found that crystallization from aqueous ethanol formed a labile material, m.p. 70–79°, followed by resolidification and remelting at 142–145°. The infrared spectrum of this material in chloroform was essentially the same as that of the usual product, but in a Nujol mull two new medium intensity bands at 2.91 and 5.97 μ were noted. After drying *in vacuo* only the higher m.p. was observed, and the Nujol mull spectrum was identical with that of the product obtained from ethyl acetate. In one experiment a sample melting at 136° was obtained.

Ultraviolet absorption spectra were taken with a Cary model 11 spectrophotometer. Values for significant compounds are in Table I.

Synthesis of Allothreonine–Threonine from Acetaldehyde and Glycine by a Rat Liver Enzyme[1]

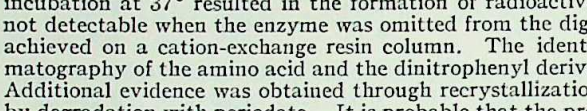
BY JAMES B. GILBERT[2]

RECEIVED OCTOBER 22, 1956

Addition of acetaldehyde and radioactive glycine to a buffered (*p*H 7.9) aqueous solution of a rat liver fraction followed by incubation at 37° resulted in the formation of radioactive allothreonine–threonine.[3] This β-hydroxy-α-amino acid[3] was not detectable when the enzyme was omitted from the digest. Separation of the radioactive products of the reaction was achieved on a cation-exchange resin column. The identification of allothreonine–threonine was accomplished by chromatography of the amino acid and the dinitrophenyl derivative of the amino acid with the respective authentic compounds. Additional evidence was obtained through recrystallization to constant specific activity with carrier DL-allothreonine, and by degradation with periodate. It is probable that the predominant end product of the reaction was one or both isomers of allothreonine. The significance of this finding in relation to intermediary metabolism is discussed.

I. Introduction

A relationship between glycine and β-hydroxy-α-amino acid metabolism was first stated by Knoop.[4] The hypothesis that β-phenylserine was cleaved *in vivo* to benzoic acid and glycine was made on the evidence of the isolation of hippuric acid as the excretory product of this β-hydroxy-α-amino acid. Considerably later, Braunshtein[5] described the enzymatic conversion of several β-hydroxy-α-amino acids, including threonine but not serine,[6] to glycine and the corresponding aldehyde.



(1)

The reaction consisted of cleavage of the bond between the second and third carbon atoms; *e.g.*, β-phenylserine yielded glycine and benzaldehyde as end products.[7] The same reaction was also observed non-enzymatically. For example, in strongly alkaline solutions, β-hydroxy-α-amino acids yielded glycine.[8,9]

The interesting and suggestive finding that a reversible splitting of threonine occurred in the presence of pyridoxal and certain metal ions in aqueous solution was described by Metzler, Longenecker and Snell.[10] It therefore appeared of interest to examine the reversibility of the reaction, eq. 1, when the enzyme was the catalyst. Indeed, this might well be the synthetic route suggested by the work from several sources[11–13] that demonstrated that glycine was a precursor of threonine in yeast. This enzyme which has been variously termed "glycinogenase"[5] and "threonine aldolase"[14] has been shown to be present in liver and kidney tissue of numerous mammals and the pigeon,[5] and probably in Neurospora.[15,16]

II. Experimental

Enzymatic Digests.—The rat liver fractions employed were prepared as previously described.[7] Activities of the three enzyme preparations used were expressed as 20, 26 and 33 μmoles benzaldehyde/hr./mg. N, with *erythro*-β-phenyl-DL-serine as substrate under conditions previously specified.[7] The reaction mixtures consisted of 200 μmoles of glycine plus a trace amount of glycine-2-C^{14} or glycine-1-C^{14}, 200 μmoles of acetaldehyde, and 10 mg. of the purified rat liver enzyme in a volume of 5 ml. of which 3 ml. were 0.15 *M* borate buffer, *p*H 8.0. The digests were incubated at 37° under aerobic conditions with agitation for 4 hours. The final *p*H of the digests was 7.9. The reaction was stopped by addition of 1 ml. of a 5% solution of trichloroacetic acid (aqueous). After precipitation of the protein, the solutions were lightly centrifuged and the supernatant decanted. Two types of controls accompanied the above, consisting of (1) enzyme (10 mg.) plus 3 ml. of borate buffer plus a trace of labeled glycine and (2) 200 μmoles of acetaldehyde and glycine each, plus a tracer amount of radioactive glycine.

Compounds.—Glycine-1-C^{14} and glycine-2-C^{14} were commercially obtained (Nuclear Instrument and Chemical, and Tracerlab, Inc., respectively). They were purified by Dowex 50 column chromatography followed by unidimensional paper chromatography in "formix" followed by elution. After these procedures, the purity was tested by two-dimensional paper chromatography. A radioautograph and a test of the chromatogram for ninhydrin positive areas were made. No spots other than that of glycine were present. Threonine-C^{14} (uniformly labeled) was a Schwarz Laboratory product. The specific activities of the three radioactive amino acids were 39, 18 and 0.8 μC./mg., respectively. The glycine, DL-threonine and DL-allothreonine used were recrystallized commercial compounds with correct analytical values. Dinitrophenyl (DNP) derivatives of several amino acids were kindly supplied by Dr. H. Sober.[17]

Chromatographic Materials and Technique.—Dowex 50 (200 mesh) was used in a column measuring 2.2 × 50 cm.

at a flow rate of 7.5 ml./hr. Size of fractions cut was approximately 9–10 ml.; 1.5 *N* HCl was used as the eluting agent throughout.[18]

All two-dimensional chromatograms employed 17 in. squares of Whatman no. 1 paper. Unidimensional chromatograms were either on this size paper or on paper strips 1/4 in. wide and 15 in. long. Solvents employed were (a) for amino acids (1) phenol, H_2O (the phenol was saturated with respect to a 10% sodium citrate aqueous solution) followed by (2) formic acid, *t*-butyl alcohol, H_2O ("formix") (volume proportions 15:70:15); (b) for DNP-amino acids (1) toluene, chloroethanol, pyridine, 0.8 *N* NH_3 (5:3:1.5:3)[19] (2) 1.5 *M* phosphate (*p*H 6).[19] The dinitrophenyl derivative of enzymatically synthesized allothreonine–threonine was prepared by the procedure of Sanger.[20]

Assay of Radioactivity.—Counting of radioactive samples was accomplished on a continuous-flow windowless counter using helium (98.7%)-butane (1.3%) as the self-quenching gas mixture. Only aluminum planchets were employed for $BaCO_3$ samples. All other samples were plated directly on ground glass or aluminum planchets. Where measurement of low activities was important, *e.g.*, Fig. 4, a Robinson counter with background of 3.8–4.0 c.p.m. was employed. Counting was for such a period of time as to make the standard error 5% or less on the corrected sample measurements.

Degradation of Threonine.—Allothreonine–threonine was degraded by the periodate method[21] with some modification. The periodate oxidation flask was connected to two ice-cold bubblers containing 0.1% 2,4-dinitrophenylhydrazine in 2 *N* HCl, followed by a bubbler containing 0.5 *N* sodium hydroxide. The acetaldehyde, as the 2,4-dinitrophenylhydrazone, was filtered, plated and counted. Carbonate from the sodium hydroxide bubbler was precipitated by addition of ammonium chloride and $BaCl_2$.[22]

III. Results

After removal of the protein, an aliquot of the enzymatic digest containing acetaldehyde and glycine-C^{14} was chromatographed in two dimensions (Fig. 1) with the result that a ninhydrin positive, radioactive spot (labeled B) was observed in addition to the glycine area (A). No such spot appeared in a control from which enzyme had been excluded.

The protein-free reaction mixtures, originally incubated with and without enzyme added to the initial incubation mixtures, were placed on a Dowex 50 resin column and eluted with 1.5 *N* HCl. The results (Fig. 2) indicated that where enzyme was originally present, two peaks appeared at 340 and 360 ml., respectively. When the rat liver fraction was absent, only the peak at 360 ml. was present. The two peaks at 360 ml. contained approximately equal amounts of radioactivity. The radioactivity contained in the 490–600 ml. fractions represented glycine.

The several fractions representing the peaks at 340 and 360 ml. were combined and chromatographed in two dimensions with the result shown in Fig. 3. It was noted that when carrier DL-threonine was added, the radioactivity was congruent with this spot when enzyme was present in the incubation mixture. In the other chromatogram, where no enzyme was added, no radioactivity was present; only the ninhydrin positive carrier, DL-threonine area, was demonstrable.[23] The identity of the second component was not ascertained. However, it was present predominantly

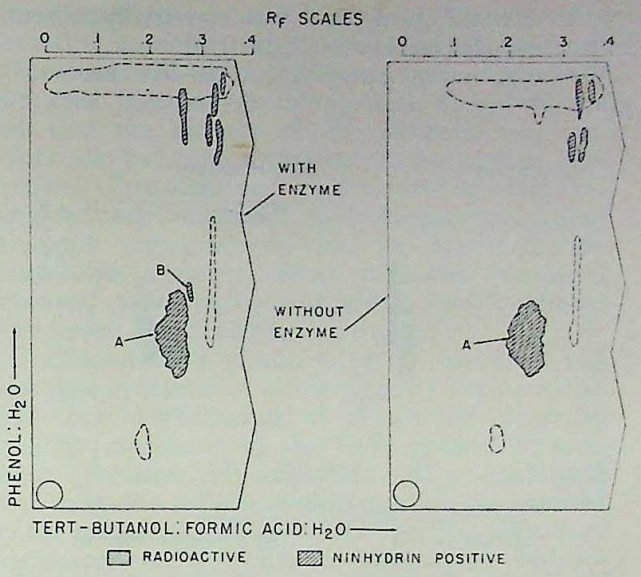

Fig. 1.—Two-dimensional paper chromatograms of aliquots from reaction mixtures of glycine-2-C^{14} and acetaldehyde, with and without enzyme added. Areas of color development following application of ninhydrin are indicated as well as optical densities on a coincident radioautograph. The origin is designated by the circle at the lower left corner in both instances. The chromatograms have been interrupted in the *t*-butyl alcohol:formic acid:H_2O dimension and R_f scales substituted: A, glycine; B, area suggesting synthesis of allothreonine–threonine; radioactive areas in upper right portion are unidentified; areas enclosed by dashed line represent light radioactive or ninhydrin positive areas which may be ignored.

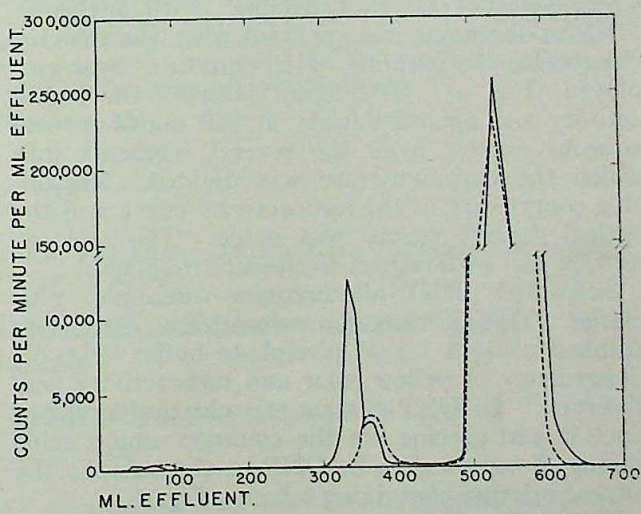

Fig. 2.—Separation on Dowex 50 column of products of reaction of acetaldehyde with glycine-1-C^{14}, 1.5 *N* HCl employed as eluant: ——, original incubation mixture contained enzyme; – – –, enzyme absent from the initial digest.

(23) The second type of control, which contained enzyme and radioactive glycine only, was also subjected to column and paper chromatography. Essentially no radioactivity was found in the 300–400 ml. interval from the cation-exchange resin column. One-third of this interval volume was concentrated and examined by two-dimensional paper chromatography. No ninhydrin color was located in the chromatograms. It was concluded that the enzyme was a negligible source of threonine, if it contributed any at all.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

in the 360 ml. peak and was essentially absent from the early fractions of the 340 ml. peak.

The area marked threonine on the left chromatogram of Fig. 3 was eluted and reacted with 1-

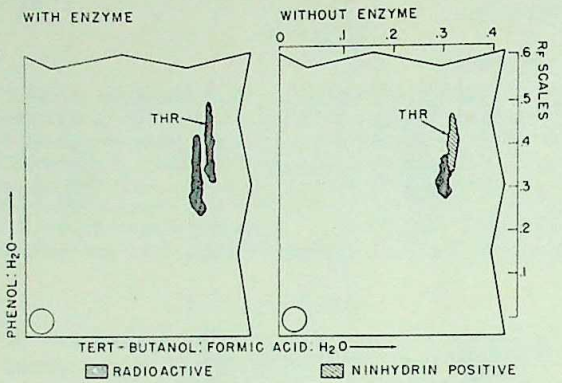

Fig. 3.—Two-dimensional paper chromatograms of aliquots from the radioactive fractions eluted from Dowex-50 column in the interval 300 to 400 ml., inclusive (*cf.* Fig. 2). Carrier DL-threonine added and location indicated (THR). Conventions as in Fig. 1 except that chromatograms have been interrupted in both solvent dimensions and approximate R_f scales substituted. The "with enzyme" chromatogram is drawn to the same R_f scale as the chromatogram on the right.

fluoro-2,4-dinitrobenzene. The resulting dinitrophenyl derivative was chromatographed unidimensionally in two solvent systems: toluene, chloroethanol, pyridine, NH_3 and phosphate buffer. Coincidence of DNP-"threonine" with authentic DNP-DL-threonine was apparent when the toluene, chloroethanol, pyridine, NH_3 mixture was employed (Fig. 4). The figure presents the radioactivity and optical density at 360 mμ of several aqueous eluates from the several segments into which the chromatogram was divided. Reasonable congruency of the radioactivity curve and the optical density curves was noted. The sole exception was with respect to the dinitrophenol.

Suspected DNP–allothreonine–threonine plus carrier DNP-DL-threonine were also chromatographed using a 1.5 *M* phosphate buffer (Fig. 5). Congruency of yellow color and radioactivity was observed. Di-DNP-cystine was chromatographed since it and glycine are the common amino acids having R_f values close to DNP-DL-threonine in the solvent mixture containing toluene (Fig. 4).

The radioactivity corresponding to allothreonine–threonine was eluted from a paper chromatogram and recrystallized with DL-threonine. This was effected by addition of absolute alcohol to an aqueous solution of the amino acid. The result was: original solution, 44 c.p.m./mg. DL-threonine; first crystallization, 37; third, 30; sixth, 22; ninth, 17. When eluted allothreonine–threonine was recrystallized with DL-allothreonine, the result was: original solution, 118 c.p.m./mg. DL-allothreonine; third crystallization, 108; fifth, 110; sixth, 105.

Degradation of allothreonine–threonine-1-C^{14}, *i.e.*, initial substrate glycine-1-C^{14}, together with carrier by the periodate method yielded the following data: % of activity of original allothreonine–threonine in C-1, 70%; C-2, < 1%; C-3,4, <1%.[24] This localization of the isotope is compatible with

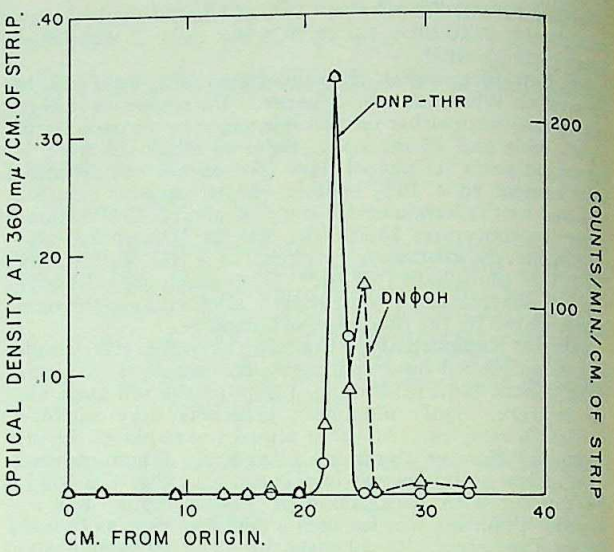

Fig. 4.—Radioactivity and yellow color recorded as a function of distance along a unidimensional paper chromatogram to which was added DNP-"threonine" and authentic carrier DNP-DL-threonine, prior to development in the toluene, chloroethanol, pyridine, NH_3 solvent system. DNP-"threonine" = a fraction from an enzymatic digest which was purified and tentatively identified as allothreonine-threonine by the procedures indicated in Figs. 2 and 3, and which reacted with fluorodinitrobenzene. DNφOH, dinitrophenol: Δ---Δ, optical density; O——O, radioactivity. Chromatogram divided into segments prior to elution and measurement of data. Abscissa points represent distance of midpoint of each segment from origin.

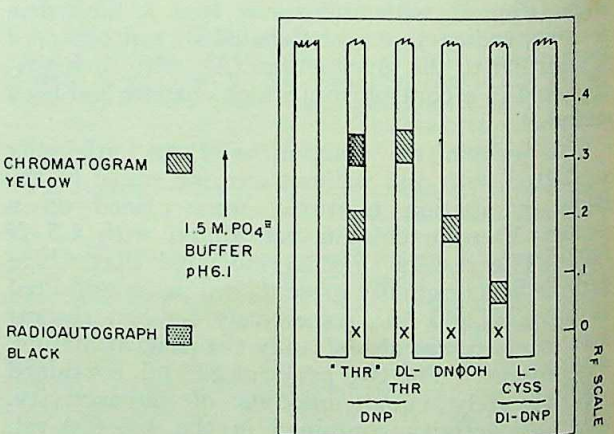

Fig. 5.—Unidimensional chromatogram of several DNP-derivatives: developing solvent, 1.5 *M* phosphate buffer, *p*H 6.1. Except for DNP-"THR," the compounds were authentic. DI-DNP-L-CYSS, di-DNP derivative of L-cystine. Other compounds identified by convention of Fig. 4. Origin on each of the narrow strips is at X.

(24) The recovery of radioactivity of carbons one and two of threonine was somewhat low in our experience. Yield was approximately 70% whereas Delluva[21] reported a yield of 85% for carbon two but made no mention of recovery of carbon one. For example, L-threonine-C^{14} (uniformly labeled—checked by specific activity determination by this periodate method, and stated in arbitrary units: C-1 0.68; C-2, 0.66; C-3,4, 0.76) yielded a recovery of 72% in C-1 and 69% in C-2. However, yield is adequate to prove localization.

the reaction proceeding as a simple reversal of eq. 1. More devious routes might well introduce randomization.

The conclusion reached from these results is that the predominant product of this enzymatic reaction *in vitro* is an isomer or isomers of DL-allothreonine. Indeed, this may be the only product. However DL-threonine (or L- or D-threonine) could be present in rather large proportion and not be detected. The specific stereoisomer(s) produced awaits future recrystallization, microbiological experiments, etc., in order to determine its configuration.

IV. Discussion

Inasmuch as allothreonine has not been identified in biological material, it obviously is impossible to relate this compound to present schemes of intermediary metabolism. The present findings do suggest the possible natural occurrence of this diastereoisomer, however.[25]

It is worth reiterating that no serious attempt has been made in this present work to identify D- or L-threonine except as a large component. The compound might well escape detection if present in less than approximately 30% of the total amount of threonine. Indeed suggestive of the probability of this occurrence, but in lower forms of life, is the previously cited evidence obtained in yeast.[11-13,26]

Also suggestive is the fact that L-allothreonine was cleaved at approximately seven times the rate that L-threonine was split by the enzyme concerned[5] (prepared from rat liver).[14] So it may well be true that the kinetics of the synthetic reaction, favors allothreonine formation in some such proportion. Furthermore, in the corresponding reversible model reaction[10] both threonine and allothreonine are produced and in approximately comparable amounts. Since both are pyridoxal catalyzed, a somewhat similar relationship should be expected for the enzymatic reaction.

The essentiality of threonine for mammals implies that synthesis of L-threonine by such a route, if it does indeed occur, is of a relatively small quantity compared to the daily growth requirement. Perhaps the availability of acetaldehyde may limit the utility of this reaction in animals. By the same token in yeast, the reaction may be of importance as a synthetic mechanism because acetaldehyde is a major metabolite.

Acknowledgment.—The author wishes to thank Dr. J. P. Greenstein for his interest, Drs. H. Sober and E. Peterson for their advice on chromatography, Mr. R. J. Koegel for the elemental analyses, and Dr. M. Calvin for the opportunity to acquire experience in radioactive isotopic procedure some time ago.

(25) Relative to metabolic utilization, if not metabolic occurrence, D-allothreonine was used by certain mutant microörganisms in the biosynthesis of isoleucine and threonine [H. E. Umbarger and E. A. Adelberg, *J. Biol. Chem.*, **192**, 883 (1951)]. Therefore, this enzyme present in certain lower forms may well serve the production of a precursor of certain amino acids in such microörganisms. However, in the rat it is well established that only one isomer, L-threonine, is utilized for growth purposes [H. D. West and H. E. Carter, *ibid.*, **122**, 611 (1938)].

(26) A more remote possibility is suggested by a *Neurospora crassa* mutant which revealed properties which may be explained by an alternate metabolic pathway for the synthesis of threonine [E. A. Adelberg, C. A. Coughlin and R. W. Barratt, *J. Biol. Chem.*, **216**, 425 (1955)]. This is suggested inasmuch as this double mutant was blocked as follows: homoserine —¦→ threonine ⟶ α,β-dihydroxy-β-ethylbutyric acid —¦→ α-keto-β-ethylbutyric acid. It, in minimal medium, synthesized threonine at a slow rate. That one strain of this species, at least, has the enzyme in question, has been reasonably well authenticated by Wagner and Bergquist (footnote 15). However, glycine did not stimulate production of α,β-dihydroxy-β-ethylbutyric acid. Compare also discussions of the possibility of L-threonine synthesis by this condensation reaction in *Escherichia coli* [J. O. Meinhart and S. Simmonds, *J. Biol. Chem.*, **213**, 329 (1955)] and in *Clostridium kluyveri* [N. Tomlinson, *ibid.*, **209**, 597 (1954)].

Some New *o*-Phenylenediamines and the Related Benzimidazoles, Benzotriazoles and Quinoxalines

BY H. B. GILLESPIE, MORRIS ENGELMAN, FRANCIS SPANO AND SAMUEL GRAFF

RECEIVED NOVEMBER 28, 1956

The synthesis of 3,4-diamino-5-nitrophenetole and 3,4-diamino-2-nitroanisole is described. These *o*-diamines have been used to prepare the related benzimidazoles, benzotriazoles and quinoxalines which were needed to continue an investigation of the inhibition of developing *R. pipiens* embryos by such heterocyclic compounds. Derivatives of 3,4-diamino-2-nitroanisole have served as useful reference compounds for the solution of several problems of structure.

Among a number of benzimidazoles, benzotriazoles and quinoxalines previously reported,[1,2] several have shown interesting properties as inhibitors of developing *R. pipiens* embryos. The most active of these were 4-methoxy-6-nitrobenzimidazole, 4-methoxy-6-nitrobenzotriazole and 5-methoxy-7-nitroquinoxaline.[3] Isomers of these heterocyclic compounds, in which the nitro and methoxy groups were interchanged, exhibited an approximately equal level of activity.[4] It seemed of interest, therefore, to investigate whether the activity of such compounds might be enhanced or diminished by changing the methoxy group to ethoxy and changing the relative configuration of the nitro and methoxy groups to *ortho* rather than *meta*. The synthesis of the desired substances required the preparation of two new substituted *o*-phenyl-

enediamine intermediates, 3,4-diamino-5-nitrophenetole and 3,4-diamino-2-nitroanisole.

4-Amino-3,5-dinitrophenetole was obtained by nitration of an alcoholic suspension of *p*-toluenesulfonyl-*p*-phenetidide according to the procedure of King and Beer[5] for the preparation of 3,5-dinitro-4-*p*-toluenesulfonamidoanisole and hydrolysis of the intermediate 3,5-dinitro-4-*p*-toluenesulfonamidophenetole. This procedure was more effective than the hydrolysis of the nitration product of 3-nitro-4-*p*-toluenesulfonamidophenetole.[6] Reduction of the 4-amino-3,5-dinitrophenetole by ammonium sulfide gave a 70% yield of 3,4-diamino-5-nitrophenetole. The *o*-diamine was treated with formic acid, nitrous acid, glyoxal and diacetyl to give, respectively, 6-ethoxy-4-nitrobenzimidazole, 6-ethoxy-4-nitrobenzotriazole, 7-ethoxy-5-nitroquinoxaline and 2,3-dimethyl-7-ethoxy-5-nitroquinoxaline. Amino derivatives were prepared by catalytic reduction of the nitro group.

Attempts to obtain 3,4-diamino-2-nitroanisole by ammonium sulfide reduction of 4-amino-2,3-dinitroanisole yielded only resinous products. The *o*-diamine, however, was isolated readily as the hydrochloride on treating the aminodinitroanisole in alcohol with the calculated quantity of stannous chloride and hydrochloric acid for the reduction of one nitro group. The product was shown to be an *o*-diamine by reaction with benzil to give 2,3-diphenyl-6-methoxy-5-nitroquinoxaline. The desired 5-methoxy-4-nitrobenzimidazole, 5-methoxy-4-nitrobenzotriazole, 6-methoxy-5-nitroquinoxaline and 2,3-dimethyl-6-methoxy-5-nitroquinoxaline were obtained by ring closure of the *o*-diamine with appropriate reagents as indicated in the case of 3,4-diamine-5-nitrophenetole. The 5-methoxy-4-nitrobenzotriazole obtained in this fashion was identical with that prepared earlier[7] by nitration of 1-acetyl-5-methoxybenzotriazole, thus confirming the previous assignment of structure. Hydrolysis of the methoxynitrobenzimidazole and benzotriazole by 48% hydrobromic acid gave the corresponding hydroxy compounds.

Meldola and Eyre[8] obtained 2,3,4-triaminoanisole in the form of a crude hydrochloride by complete reduction of 4-amino-2,3-dinitroanisole with tin and hydrochloric acid. The triamine condensed with benzil to yield an aminomethoxydiphenylquinoxaline, m.p. 215°. This product could be either 5-amino-6-methoxy- or 5-amino-8-methoxy-2,3-diphenylquinoxaline. A definite assignment of structure at that time was not possible for lack of reference compounds. Catalytic reduction of 2,3-diphenyl-6-methoxy-5-nitroquinoxaline gave the 5-amino-6-methoxy derivative having m.p. 156–157°. To obtain the 5,8-isomer, 4-acetamido-2,3-dinitroanisole was reduced by hydrogen at atmospheric pressure in the presence of palladium-on-carbon. The crude 4-acetamido-2,3-diaminoanisole thus produced reacted with benzil to give 5-acetamido - 2,3 - diphenyl -8 - methoxyquinoxaline which was hydrolyzed by alcoholic hydrogen chloride to the free amino compound, m.p. 214–215°. The product obtained by Meldola and Eyre must have been 5-amino-2,3-diphenyl-8-methoxyquinoxaline.

Nitration of 3,4-diacetamidoanisole in acetic acid with concentrated nitric acid yielded a mononitro derivative, m.p. 224–227°. This could be any one of three compounds: namely, 3,4-diacetamido-2-nitroanisole (A), 3,4-diacetamido-5-nitroanisole (B) or 4,5-diacetamido-2-nitroanisole (C). Attempts to prepare A and B by acetylation of 3,4-diamino-2-nitroanisole and 3,4-diamino-5-nitroanisole, respectively, led to mixtures difficult to purify. These mixtures undoubtedly contained some of the monoacetyl derivatives along with the diacetyl derivatives and also traces of 2-methylbenzimidazoles. Phillips[9] has shown that mono- and diacetyl derivatives of *o*-diamines readily cyclize to 2-methylbenzimidazoles. The structure of the nitration product was elucidated by the preparation of the isomeric 2-methylbenzimidazoles. A modification of Phillips' procedure for the preparation of 2-substituted benzimidazoles was employed to convert 3,4-diamino-2-nitroanisole to 5-methoxy-2-methyl-4-nitrobenzimidazole, m.p. 204–205°, and 3,4-diamino-5-nitroanisole yielded 6-methoxy-2-methyl-4-nitrobenzimidazole, m.p. 226–227°. When the nitration product was heated with hydrochloric acid, it cyclized to a 2-methylbenzimidazole, m.p. 172–174°. This must be 5-methoxy-2-methyl-6-nitrobenzimidazole, since the melting point eliminates the other two possibilities. The nitration product is therefore 4,5-diacetamido-2-nitroanisole (C).

All of the benzimidazoles, benzotriazoles and quinoxalines here reported are being biologically screened against various test systems. The results of the biological work will be reported elsewhere.

Experimental[10]

3,5-Dinitro-4-*p*-toluenesulfonamidophenetole.—A stirred suspension of 39 g. of *p*-toluenesulfonyl-*p*-phenetidide[11] in 150 ml. of ethanol was treated dropwise during a 2-hr. period with 85 ml. of concentrated (d. 1.4) nitric acid. The suspended material dissolved when approximately one-third of the acid had been added, and shortly thereafter the dinitro derivative began to separate. After all the acid had been added, the mixture was stirred for 1 hr. at room temperature, refluxed for 1 hr. and cooled. The product was collected, washed with 50% ethanol and recrystallized from 1.5 liters of 50% acetic acid. The 3,5-dinitro-4-*p*-toluenesulfonamidophenetole separated as light yellow needles melting at 161–163°. The yield was 30 g. (60%).

Anal. Calcd. for $C_{15}H_{15}O_7N_3S$: N, 11.02; S, 8.40. Found: N, 10.86; S, 8.30.

4-Amino-3,5-dinitrophenetole.—A solution of 20 g. of 3,5-dinitro-4-*p*-toluenesulfonamidophenetole in 50 ml. of sulfuric acid (90%) was kept at room temperature overnight, poured onto ice and diluted with water to one liter. The bright red precipitate of 4-amino-3,5-dinitrophenetole was collected and washed with water. It crystallized as needles (10.7 g., 90%) from hot 50% acetic acid (500 ml.); m.p. 136–139° (lit.[6] m.p. 138–139°).

3,4-Diamino-5-nitrophenetole.—To 260 ml. of freshly prepared 10% ammonium sulfide, there was added 520 ml. of ethanol and 11.4 g. (0.05 mole) of 4-amino-3,5-dinitrophenetole. The reaction mixture was kept at 50–60° and mechanically stirred for 2 hr. After cooling, the crude

product was collected and washed successively with 25-ml. portions of carbon disulfide and 50% ethanol. The *o*-diamine was recrystallized from ethanol (400 ml.). It separated as dark red needles having m.p. 144–146°. The yield was 7.0 g. (70%).

Anal. Calcd. for $C_8H_{11}O_3N_3$: C, 48.73; H, 5.59; N, 21.32. Found: C, 48.81; H, 5.78; N, 21.13.

2,3-Diphenyl-7-ethoxy-5-nitroquinoxaline.—A mixture of 579 mg. (3 mmoles) of 3,4-diamino-5-nitrophenetole, 630 mg. of benzil and 500 mg. of anhydrous sodium acetate in 150 ml. of ethanol was refluxed for 3 hr. The dark red solution was concentrated to 50 ml. and cooled. The 2,3-diphenyl-7-ethoxy-5-nitroquinoxaline (381 mg.) crystallized from ethanol (30 ml.) as light yellow needles, m.p. 142–144°.

Anal. Calcd. for $C_{22}H_{17}O_3N_3$: C, 71.16; H, 4.85; N, 11.32. Found: C, 71.33; H, 4.70; N, 10.99.

6-Ethoxy-4-nitrobenzimidazole.—To 1.5 g. of 3,4-diamino-5-nitrophenetole in 20 ml. of 3 *N* hydrochloric acid, there was added 1 ml. of 98% formic acid. After refluxing for 0.5 hr., another 1-ml. portion of formic acid was added and heating was continued for 30 minutes more. The hot solution was diluted with boiling water to 200 ml. and filtered. The filtrate was made slightly alkaline by cautious addition of concentrated (28%) aqueous ammonia. When cold, the crude 6-ethoxy-4-nitrobenzimidazole was collected and washed with water. The yield was 1.5 g. The compound crystallized from ethanol (400 ml., Nuchar) as tiny bright yellow needles melting at 268–269°. A sample for analysis was sublimed at 210–225° under reduced pressure.

Anal. Calcd. for $C_9H_9O_3N_3$: C, 52.17; H, 4.35; N, 20.29. Found: C, 52.29; H, 4.37; N, 19.83.

4-Amino-6-ethoxybenzimidazole.—A solution of 420 mg. (2 mmoles) of 6-ethoxy-4-nitrobenzimidazole in 200 ml. of ethanol was stirred in the presence of 90 mg. of palladium-on-carbon (10%) and hydrogen at one atmosphere pressure for 3 hr. when reduction was complete. The catalyst was removed by filtration and the filtrate concentrated to dryness *in vacuo* in the absence of air. This procedure was employed for all other catalytic reductions which follow. The 4-amino-6-ethoxybenzimidazole (340 mg., 96%) was recrystallized from a small volume (6 ml.) of water; white crystals, m.p. 144–145°.

Anal. Calcd. for $C_9H_{11}ON_3$: C, 61.01; H, 6.21; N, 23.73. Found: C, 61.17; H, 6.50; N, 23.80.

6-Ethoxy-4-nitrobenzotriazole.—A solution of 1 g. of 3,4-diamino-5-nitrophenetole in 100 ml. of hot 2 *N* sulfuric acid was cooled to 5°. The sulfate of the base separated. Keeping the temperature at 5°, there was added gradually with stirring, a solution of 500 mg. of sodium nitrite in 5 ml. of water. After standing overnight at room temperature, the black product (1.01 g.) was collected and washed with water. It was finely powdered and heated under reflux for 1.5 hr. with 250 ml. of 50% ethanol. The hot solution was treated with Nuchar and filtered. After cooling, the 6-ethoxy-4-nitrobenzotriazole (648 mg., 61%) was collected and recrystallized to constant m.p. 240–242°.

Anal. Calcd. for $C_8H_8O_3N_4$: C, 46.15; H, 3.85; N, 26.94. Found: C, 46.35; H, 4.04; N, 26.87.

4-Amino-6-ethoxybenzotriazole.—Catalytic reduction of 970 mg. (4.8 mmoles) of 6-ethoxy-4-nitrobenzotriazole in 200 ml. of ethanol yielded 800 mg. (96%) of crude 4-amino-6-ethoxybenzotriazole. A solution of the crude product in 20 ml. of hot 1 *N* sulfuric acid was boiled briefly with Darco and filtered. The free base precipitated on making the filtrate slightly alkaline (*p*H 8.0) by adding concentrated (28%) aqueous ammonia. It was recrystallized from hot water and separated as pink plates which had m.p. 120–122°, with previous shrinking at 88°. Analysis was done on a sample dried at 110°.

Anal. Calcd. for $C_8H_{10}ON_4$: C, 53.93; H, 5.62; N, 31.46. Found: C, 54.20; H, 5.50; N, 31.84.

7-Ethoxy-5-nitroquinoxaline.—A mixture of 2 g. of 3,4-diamino-5-nitrophenetole, 46.5 ml. of absolute ethanol and 3.5 ml. of a 30% aqueous solution of glyoxal was refluxed for 1 hr. and the hot solution filtered. On cooling there was obtained 930 mg. of crude 7-ethoxy-5-nitroquinoxaline. It was recrystallized from ethanol and separated as yellow needles, m.p. 142–144°. The yield was 611 mg. (27.5%).

Anal. Calcd. for $C_{10}H_9O_3N_3$: C, 54.79; H, 4.11; N, 19.17. Found: C, 54.95; H, 3.78; N, 19.26.

5-Acetamido-7-ethoxyquinoxaline.—Two millimoles (440 mg.) of 7-ethoxy-5-nitroquinoxaline in 150 ml. of ethanol was catalytically reduced as previously described. The product was a brown oil which would not crystallize. The oil was dissolved in 5 ml. of hot acetic anhydride. The solution was refluxed for 15 minutes and poured onto ice. After standing overnight, there was collected 211 mg. of 5-acetamido-7-ethoxyquinoxaline. It was recrystallized from 25% ethanol; white needles, m.p. 190–191°.

Anal. Calcd. for $C_{12}H_{13}O_2N_3$: C, 62.34; H, 5.63; N, 18.18. Found: C, 62.37; H, 5.58; N, 18.00.

2,3-Dimethyl-7-ethoxy-5-nitroquinoxaline.—A suspension of 1 g. of 3,4-diamino-5-nitrophenetole in 50 ml. of 25% acetic acid was stirred and heated on the steam-bath while a solution of 528 mg. of diacetyl in 4 ml. of 10% acetic acid was added dropwise during 20 minutes. On cooling the resultant solution, there separated 1.08 g. of 2,3-dimethyl-7-ethoxy-5-nitroquinoxaline which was collected and washed with water. The compound could be recrystallized from either 50% acetic acid or 50% ethanol, m.p. 151–153°. The yield was 822 mg. (66%).

Anal. Calcd. for $C_{12}H_{13}O_3N_3$: C, 58.30; H, 5.26; N, 17.00. Found: C, 58.26; H, 5.37; N, 16.91.

3,4-Diamino-2-nitroanisole Hydrochloride.—To a solution of 13.6 g. (60 mmoles) of stannous chloride in 100 ml. of ethanol, there was added 4.2 g. (20 mmoles) of 4-amino-2,3-dinitroanisole.[8] The base was kept in suspension by stirring while adding dropwise 25 ml. of concentrated hydrochloric acid. The temperature of the reaction mixture gradually rose to 45°. From the resulting clear, red solution, the monohydrochloride of 3,4-diamino-2-nitroanisole separated on cooling as a felted mass of yellow needles. The crude product was collected, washed with ethanol and recrystallized from 3 *N* hydrochloric acid.

Anal. Calcd. for $C_7H_9O_3N_3 \cdot HCl$: N, 19.14; Cl, 16.13. Found: N, 19.28; Cl, 16.03.

3,4-Diamino-2-nitroanisole.—Concentrated (28%) aqueous ammonia was cautiously added to a solution of 537 mg. of 3,4-diamino-2-nitroanisole hydrochloride in 30 ml. of hot water until the *p*H was approximately 8. The free base separated, on cooling, as a felted mass of dark red needles. The 3,4-diamino-2-nitroanisole was recrystallized from 25 ml. of water, m.p. 116–117°. The yield was 366 mg. (85%).

Anal. Calcd. for $C_7H_9O_3N_3$: C, 45.90; H, 4.92; N, 22.95. Found: C, 46.01; H, 4.86; N, 23.02.

2,3-Diphenyl-6-methoxy-5-nitroquinoxaline.—A mixture of 366 mg. of 3,4-diamino-2-nitroanisole hydrochloride, 180 mg. of anhydrous sodium acetate and 335 mg. of benzil in 25 ml. of 50% ethanol was heated under reflux for 1 hr. The resultant solution, on cooling, deposited 508 mg. (85%) of 2,3-diphenyl-6-methoxy-5-nitroquinoxaline which was recrystallized from ethanol (100 ml.), m.p. 216–217°.

Anal. Calcd. for $C_{21}H_{15}O_3N_3$: C, 70.59; H, 4.20; N, 11.77. Found: C, 70.72; H, 4.10; N, 11.77.

5-Methoxy-4-nitrobenzotriazole.—Ten millimoles (2.2 g.) of 3,4-diamino-2-nitroanisole hydrochloride was suspended by stirring in 100 ml. of ice-cold 1 *N* hydrochloric acid while a solution of 800 mg. of sodium nitrite in 5 ml. of water was being added dropwise. After 1 hr., the crude 5-methoxy-4-nitrobenzotriazole was collected and washed with water. It was recrystallized from ethanol (300 ml.), m.p. 237–238°. The yield was 1.5 g. (80%).

Anal. Calcd. for $C_7H_6O_3N_3$: C, 43.29; H, 3.09; N, 28.87. Found: C, 43.50; H, 3.13; N, 29.42.

5-Hydroxy-4-nitrobenzotriazole.—A solution of 938 mg. (4.8 mmoles) of 5-methoxy-4-nitrobenzotriazole in 10 ml. of hydrobromic acid (48%) was refluxed for 5 hr., cooled and diluted with 50 ml. of water. The precipitate was collected, dissolved in 25 ml. of 1 *N* sodium hydroxide and the solution filtered. A yellow precipitate of 5-hydroxy-4-nitrobenzotriazole (786 mg., 90%) was obtained when the filtrate was acidified with acetic acid. The compound decomposed at about 210°. A sample for analysis was sublimed at 200° under reduced pressure.

Anal. Calcd. for $C_6H_4O_3N_3$: C, 40.00; H, 2.22; N, 31.11. Found: C, 40.23; H, 1.98; N, 31.54.

5-Methoxy-4-nitrobenzimidazole.—This compound was obtained in almost quantitative crude yield from 1.83 g.

(10 mmoles) of 3,4-diamino-2-nitroanisole by the procedure described for 6-ethoxy-4-nitrobenzimidazole. The 5-methoxy-4-nitrobenzimidazole was recrystallized from 250 ml. of 50% ethanol, m.p. 245–247°.

Anal. Calcd. for $C_8H_7O_3N_3$: C, 49.74; H, 3.63; N, 21.76. Found: C, 50.05; H, 3.67; N, 22.23.

5-Hydroxy-4-nitrobenzimidazole.—Three millimoles (549 mg.) of 5-methoxy-4-nitrobenzimidazole was dissolved in a hot mixture of 5 ml. of acetic acid and 5 ml. of hydrobromic acid (48%). The solution was refluxed for 5 hr., diluted with 50 ml. of boiling water, treated with Darco and filtered. The hot filtrate was made slightly alkaline (*p*H about 8.0) by adding concentrated (28%) aqueous ammonia. After cooling, the yellow precipitate of 5-hydroxy-4-nitrobenzimidazole was collected and washed with water. The yield was 525 mg. (97%). It was recrystallized from boiling water. The compound decomposed at about 220°. A sample for analysis was sublimed at 200–210° under reduced pressure.

Anal. Calcd. for $C_7H_5O_3N_3$: C, 46.93; H, 2.79; N, 23.46. Found: C, 47.18; H, 3.00; N, 23.07.

2,3-Dimethyl-6-methoxy-5-nitroquinoxaline.—A mixture of 1 g. (11.6 mmoles) of diacetyl and 1.83 g. (10 mmoles) of 3,4-diamino-2-nitroanisole in 200 ml. of 35% ethanol was refluxed for 1 hr. The solution, on cooling, deposited 2.14 g. (92%) of crude 2,3-diphenyl-6-methoxy-5-nitroquinoxaline. It was recrystallized from 35% ethanol (Nuchar) and separated as tiny, almost colorless needles, m.p. 145–146°.

Anal. Calcd. for $C_{11}H_{11}O_3N_3$: C, 56.66; H, 4.72; N, 18.03. Found: C, 57.03; H, 4.41; N, 18.33.

5-Amino-2,3-dimethyl-6-methoxyquinoxaline.—The catalytic reduction of 466 mg. (2 mmoles) of 2,3-dimethyl-6-methoxy-5-nitroquinoxaline in 50 ml. of ethanol by the usual procedure required 2 hr. A solution of the crude product in 50 ml. of hot 0.5 *N* hydrochloric acid was treated with Darco and filtered. On adding concentrated (28%) aqueous ammonia to the filtrate until slightly alkaline (*p*H 8.0), the 5-amino-2,3-dimethyl-6-methoxyquinoxaline precipitated. It recrystallized from 60 ml. of water and separated as yellow needles, m.p. 135–136°. The yield was 209 mg. (50%).

Anal. Calcd. for $C_{11}H_{13}O_3N_3$: C, 65.02; H, 6.40; N, 20.69. Found: C, 65.05; H, 6.23; N, 20.92.

5-Amino-2,3-diphenyl-6-methoxyquinoxaline.—One millimole (357 mg.) of 2,3-diphenyl-6-methoxy-5-nitroquinoxaline suspended in 75 ml. of ethanol was catalytically reduced in the usual manner. The crude 5-amino-2,3-diphenyl-6-methoxyquinoxaline was recrystallized from 50 ml. of ethanol (Nuchar), m.p. 156–157°. The yield was 266 mg. (81%).

Anal. Calcd. for $C_{21}H_{17}ON_3$: C, 77.07; H, 5.19; N, 12.84. Found: C, 77.27; H, 5.11; N, 12.82.

5-Acetamido-2,3-diphenyl-8-methoxyquinoxaline.—Two millimoles (510 mg.) of 4-acetamido-2,3-dinitroanisole[8] in 50 ml. of ethanol was reduced in the usual manner in 4 hr. The catalyst was removed by filtration. To the alcoholic solution of 4-acetamido-2,3-diaminoanisole, there was added 420 mg. (2 mmoles) of benzil, and the mixture was refluxed for 1 hr. On cooling, there was obtained 427 mg. (58%) of 5-acetamido-2,3-diphenyl-8-methoxyquinoxaline. It was recrystallized from ethanol (Nuchar) and separated as bright yellow needles, m.p. 236–237°.

Anal. Calcd. for $C_{23}H_{19}O_2N_3$: C, 74.80; H, 5.15; N, 11.38. Found: C, 75.10; H, 4.91; N, 11.10.

5-Amino-2,3-diphenyl-8-methoxyquinoxaline.—To a mixture of 27 ml. of absolute ethanol and 3 ml. of concentrated hydrochloric acid, there was added 376 mg. (1.02 mmoles) of 5-acetamido-2,3-diphenyl-8-methoxyquinoxaline. The acetamido compound gradually dissolved when the mixture was refluxed for 1 hr. The solution was concentrated to dryness *in vacuo*. The residue was washed with 3% aqueous ammonia and recrystallized from ethanol (30 ml., Nuchar). The 5-amino-2,3-diphenyl-8-methoxyquinoxaline (275 mg., 84%) separated as tiny reddish-orange needles, m.p. 214–215°.

Anal. Calcd. for $C_{21}H_{17}ON_3$: C, 77.07; H, 5.19; N, 12.84. Found: C, 77.12; H, 5.24; N, 12.92.

5-Methoxy-2-methyl-4-nitrobenzimidazole.—Four millimoles (738 mg.) of 3,4-diamino-2-nitroanisole dissolved in 5 ml. of acetic anhydride was warmed on the steam-bath. To the solution there was added slowly 15 ml. of 3 *N* hydrochloric acid. The mixture was refluxed for 20 minutes, diluted with 30 ml. of hot water, boiled briefly with Darco and filtered. Concentrated (28%) aqueous ammonia was added to the hot filtrate until slightly alkaline (*p*H 8.0). After cooling, the yellow precipitate of 5-methoxy-2-methyl-4-nitrobenzimidazole was collected and washed with water. The yield was almost quantitative. It was recrystallized from 50% ethanol, m.p. 204–205°.

Anal. Calcd. for $C_9H_9O_3N_3$: C, 52.17; H, 4.35; N, 20.29. Found: C, 52.23; H, 4.09; N, 20.25.

6-Methoxy-2-methyl-4-nitrobenzimidazole.—This compound was prepared by the procedure given above from 369 mg. (2 mmoles) of 3,4-diamino-5-nitroanisole.[12] The crude product was recrystallized from 25% ethanol, m.p. 226–227°. The yield of 6-methoxy-2-methyl-4-nitrobenzimidazole was 319 mg. (77%).

Anal. Calcd. for $C_9H_9O_3N_3$: C, 52.17; H, 4.35; N, 20.29. Found: C, 52.51; H, 4.03; N, 20.35.

3,4-Diacetamidoanisole.—To a solution of 1.16 g. of 4-acetamido-3-aminoanisole[13] in 3 ml. of acetic acid, there was added 1.5 ml. of acetic anhydride. The reaction mixture became warm and the product soon began to crystallize. After standing at room temperature for 30 minutes, the almost solid mass was stirred up with 10 ml. of 1-butanol and filtered. The crude product (1.18 g., 82.5%) was recrystallized from approximately 20 ml. of water. The 3,4-diacetamidoanisole separated as short needles having a pinkish tinge, m.p. 182–184°.

Anal. Calcd. for $C_{11}H_{14}O_3N_2$: C, 59.46; H, 6.31; N, 12.61. Found: C, 59.61; H, 6.30; N, 12.50.

4,5-Diacetamido-2-nitroanisole.—One gram of 3,4-diacetamidoanisole was suspended by stirring in 5 ml. of glacial acetic acid while a mixture of 0.8 ml. of concentrated (d. 1.4) nitric acid and 1.5 ml. of acetic acid was gradually added. When approximately one-half of the mixed acids had been added, the diacetamidoanisole was almost completely in solution. The reaction mixture became warm as the remainder of the mixed acids was added and the nitro derivative began to crystallize. After all the nitric acid had been added, the mixture was stirred at room temperature for 30 minutes before pouring onto ice and diluting with water to approximately 75 ml. The yellow precipitate of 4,5-diacetamido-2-nitroanisole (1.04 g., 87%) was collected, washed with water and recrystallized from 50 ml. of 50% ethanol, m.p. 225–227°.

Anal. Calcd. for $C_{11}H_{13}O_5N_3$: C, 49.44; H, 4.87; N, 15.73. Found: C, 49.64; H, 5.12; N, 15.66.

5-Methoxy-2-methyl-6-nitrobenzimidazole.—A mixture of 2 g. of 4,5-diacetamido-2-nitroanisole and 50 ml. of 2 *N* sulfuric acid was heated under reflux until a complete solution resulted. The hot, red solution was filtered. The filtrate was diluted with an equal volume of hot water, made slightly basic by adding concentrated (28%) aqueous ammonia and kept at 5° overnight. The precipitated 5-methoxy-2-methyl-6-nitrobenzimidazole (1.4 g., 90%) was collected, washed with water and recrystallized from 25% ethanol (125 ml.) with the aid of Nuchar. The purified material was dried at 110° and had m.p. 172–174°.

The diacetamidonitroanisole also cyclized to the 2-methylbenzimidazole when heated in alcoholic potassium hydroxide.

Anal. Calcd. for $C_9H_9O_3N_3$: C, 52.17; H, 4.35; N, 20.29. Found: C, 52.01; H, 4.33; N, 19.47.

Acknowledgments.—The authors are indebted to the Damon Runyon Memorial Fund and The American Cancer Society for support of this work.

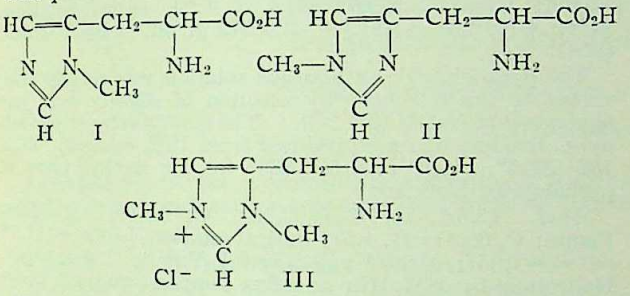
A Synthesis of Radioactive Methylhistidines[1]

BY ROBERT W. COWGILL[2]

RECEIVED NOVEMBER 9, 1956

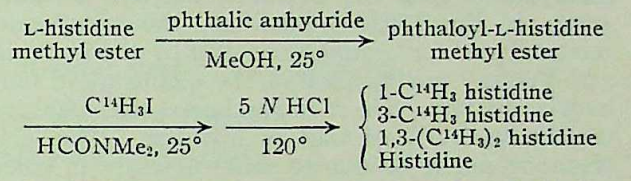
The methyl ester of phthaloyl-L-histidine was synthesized. This ester was methylated with $C^{14}H_3I$, and then acid hydrolysis was employed to remove the phthaloyl and ester groups. The products were separated by ion-exchange chromatography; they were 1-$C^{14}H_3$-L-histidine, 3-$C^{14}H_3$ histidine, 1,3-$(C^{14}H_3)_2$-L-histidine chloride and histidine.

Biochemical studies of the function and the metabolism of methyl-L-histidine compounds in animals would be facilitated by the availability of 1-methyl-L-histidine (I), 3-methyl-L-histidine (II) and 1,3-dimethyl-4-(β-carboxyl-β-aminoethyl)-imidazolium chloride or 1,3-dimethyl-L-histidine (Cl^-) (III) labeled with C^{14} in the methyl groups. The present methods were developed to provide an



efficient path for the synthesis of these labeled compounds; a path free of undesirable by-products with the C^{14}-methyl substituent on the α-amino nitrogen.

Early attempts[3] to synthesize the methylhistidines by methylation of phthaloyl histidine were thwarted by difficulties in the separation of products. Syntheses which did not involve L-histidine as an intermediate led to racemic products.[4] More recently, both 1-Me- and 3-Me-L-histidines have been prepared by methylation of L-histidine in liquid ammonia.[5] However, the existence of by-products methylated on the α-amino nitrogen renders this procedure unpromising for the specific incorporation of $C^{14}H_3$- groups on the imidazole ring. Protection of the α-amino group during methylation would be necessary in order to eliminate products methylated at the α-amino position. Tallan, Stein and Moore[5] methylated phthaloylhistidine but they reported that racemization occurred during the formation of the phthaloylhistidine. Attempts by this writer to form phthaloyl-L-histidine by heating an intimate mixture of L-histidine and phthalic anhydride[6] to 180° or by reaction of this mixture in boiling glacial acetic acid[7] led to racemization. However, it was found that the methyl ester of phthaloyl-L-histidine could be formed by reaction of the methyl ester of L-histidine and phthalic anhydride in anhydrous methanol by the general procedure of King and Kidd[8] for phthaloylamino acids.



Methylation of the methyl ester of phthaloyl-L-histidine occurred smoothly in dimethylformamide. The product, following hydrolysis of the phthaloyl and methyl ester groups, was a mixture of 1-methyl-L-histidine, 3-methylhistidine,[9] 1,3-dimethyl-L-histidine (Cl^-) and histidine. These amino acids were separated on a Dowex 50 (Na^+) ion-exchange column[5] and a representative separation is depicted in Fig. 1. The per cent. recovery of

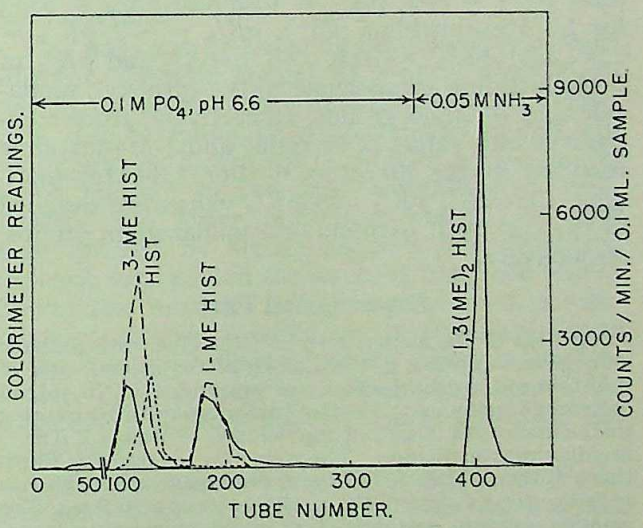


Fig. 1.—Separation of the methylhistidines on a column of Dowex 50 (Na^+); --- quantitative ninhydrin analysis[11]; - - - - Pauly diazo analysis[12]; —— radioactivity.

amino acids introduced into the column was 75% and the per cent. recovery of radioactive compounds was 78%. The average composition of the products of five preparations was 40% histidine and 20% each of 1-Me-histidine, 3-Me-histidine and 1,3-$(Me)_2$-histidine (Cl^-).

The methylhistidines were characterized by paper chromatography,[10] by the ninhydrin analy-

sis[11] for free α-amino nitrogen, and by analysis[12] for histidine unsubstituted on the ring nitrogen. Preparations that contained C^{14} were also analyzed by radioactivity techniques. Both the 1-Me- and 3-Me-histidines were found to move on paper chromatograms in five solvent systems[10b] at rates identical with those of authentic samples of the compounds.[13] The 1-Me-, 3-Me- and 1,3-$(Me)_2$-histidines all gave spots on paper chromatograms that were radioactive, gave a blue-green color with the ninhydrin spray,[14] but gave no color with the Pauly diazo spray[15] that is reactive only with those imidazole compounds that bear no substituent on the imidazole ring nitrogen. To ensure that methylation had not occurred on the α-amino group of the 1,3$(Me)_2$-histidine, this compound was analyzed for α-amino nitrogen by the Cocking and Yemm[11] modification of the quantitative ninhydrin method. On a molar basis, the color intensity was 80% of that of histidine. This discrepancy might be due to some decrease in color formation by the presence of the imidazolium structure of the 1,3-$(Me)_2$-histidine (Cl^-), but the difference in color intensity is not of the magnitude that would be anticipated if the α-amino group were methylated. The quaternary-base character of this compound was shown by the fact that it did not migrate toward the anode during electrophoresis at *p*H 9.5, and by titration data. pK values were determined in 0.1 M KCl. For 1-Me-histidine, $pK'_1 = \sim 2$, $pK'_2 = 6.58$ and $pK'_3 = 8.60$; for 1,3$(Me)_2$-histidine (Cl^-), $pK'_1 = \sim 2$, $pK'_2 = 7.95$, and $pK'_3 > 10.5$. pK'_1, pK'_2 and pK'_3 of 1-Me-histidine are assigned to the carboxyl, imidazole and α-amino groups, respectively, from comparison with values of histidine and 1-Me-histidine reported in the literature.[16] For 1,3-$(Me)_2$-histidine, the pK'_1, pK'_2 and pK'_3 values are assigned to the carboxyl, α-amino and imidazolium groups, respectively.

Experimental Part

Reaction of the methyl ester of L-histidine with phthalic anhydride.[8] Twelve g. (0.05 mole) of the methyl ester of L-histidine dihydrochloride[17] was suspended in 75 ml. of anhydrous methanol. The free base was formed by treating this solution with 60 ml. (damp volume) of Dowex 2 (OH^-) in anhydrous methanol. The resin was removed by filtration and then 14.2 g. (0.057 mole) of phthalic anhydride was added to the solution of the methyl ester of histidine. The reaction mixture was stored at room temperature overnight, before it was concentrated on a bath at 70° to about 30 ml. First acetone (about 170 ml.) and then ether were added slowly to bring about precipitation of 13 g. of the products as crystalline or oily material. (The product was usually an oil unless the solution was seeded.) A further 1.5 g. of oil was obtained on concentration of the mother liquor and addition of more ether. Total yield was 93.5%. The product was crystallized from water as clear, cubic crystals. A 24-tube countercurrent distribution of this product between 0.1 M aqueous phosphate buffer of *p*H 6.5 and benzene revealed that it was a mixture of approximately 85% as the methyl ester of phthaloyl-L-histidine and 15% as the methyl ester of *o*-carboxybenzoyl-N-histidine. The proportions of these two compounds in the crude product varied from batch to batch and in four preparations ranged from 50–95% as the methyl ester of phthaloylhistidine.

Conversion of the methyl ester of *o*-carboxybenzoyl-N-histidine to the methyl ester of phthaloylhistidine.[8] Ten ml. of freshly distilled thionyl chloride was dissolved in 40 ml. of benzene and 5 g. of the mixture of methyl esters of *o*-carboxybenzoyl-N-histidine and phthaloylhistidine was added slowly and with stirring. The suspension of fine, white, granular precipitate was allowed to stand at room temperature overnight. The solvent was evaporated and the residual product was crystallized from a mixture of anhydrous methanol and ether. The white crystals of methyl ester of phthaloyl-L-histidine hydrochloride amounted to 3.3 g. (63% yield). The product was recrystallized from 10% ethanol; m.p. 200–200.7°; Keil[3] reported 238–240° for the methyl ester of phthaloyl-DL-histidine·HCl.

Anal. Calcd. for $C_{15}H_{14}O_4N_3Cl$: C, 53.66; H, 4.20. Found: C, 53.63, 54.07; H, 4.52, 4.29, optical rotation, $[\alpha]^{20}D$ −101° ($\alpha = -1.96$; 0.00972 g./ml. in H_2O; 2 dm. tube).

The hydrochloride in aqueous solution was readily converted to the free base by addition of slightly over one equivalent of NaOH (*p*H > 9). The methyl ester of phthaloyl-L-histidine was recrystallized from 10% ethanol; m.p. 182–182.5°; Keil[3] reported 188° for the methyl ester of phthaloyl-DL-histidine.

Anal. Calcd. for $C_{15}H_{13}O_4N_3$: C, 60.19; H, 4.38. Found: C, 60.31; H, 4.57; optical rotation, $[\alpha]^{20}D$ −111.7° ($\alpha = -1.65°$; 0.0074 g./ml. in 0.1 N HCl; 2 dm. tube). Hydrolysis by 48% HBr at reflux temperature for 9 hours gave histidine of $[\alpha]^{20}D$ −40° (H_2O).

Methylation of the methyl ester of phthaloyl-L-histidine. One and one-half g. (0.005 mole) of the methyl ester of phthaloyl-L-histidine free base was dissolved in 7 ml. of dimethylformamide. Methyl iodide (0.005 mole that contained 0.5 millicurie of C^{14}) was added and the flask was securely stoppered. The mixture was stored at room temperature for three days, and then it was concentrated *in vacuo* at 50° to a sirup. The sirup was dissolved in 3 ml. of constant boiling hydrochloric acid and was heated in an autoclave at 15 p.s.i. (121°) for 7 hours. The solution then was concentrated *in vacuo* at 50° to yellow salts, and the salts were extracted with a total of 10 ml. of water. The residue of phthalic acid amounted to 0.916 g.; 110% of theory, as phthalic acid. The solution of methylated products contained a total of 3.96×10^7 c.p.m.,[18] which represents 71% of the initial activity of the methyl iodide.

Separation of the methylation products on an ion-exchange column. The mixture of methylhistidines and histidine was introduced into a 7 × 35 cm. column of Dowex 50 (Na^+) described by Tallan, Stein and Moore,[5] and elution was made with 0.1 M phosphate of *p*H 6.6. The progress of the elution is shown in Fig. 1. The 1,3-dimethylhistidine was held tightly on the column but could be removed by 0.05 M ammonia.

Each fraction in the eluate was desalted and recovered by the procedure of Tallan, Stein and Moore.[5] Of the 3.96×10^7 c.p.m. introduced onto the column, 16% was recovered as 3-methylhistidine, 18% as 1-methylhistidine and 44% as 1,3-dimethylhistidine. This represents about 0.62×10^5 ct./min./mg. for 1-Me- and 3-Me-histidines and 1.0×10^5 ct./min./mg. for 1,3-$(Me)_2$-histidine (Cl^-).

1-Methyl-L-histidine·2HCl.—The desalted fraction from the ion-exchange column which contained the 1-methylhistidine (300 mg.) as the dihydrochloride salt was dissolved in 1.0 ml. of water and 1-Me-histidine·2HCl crystallized upon addition of ten volumes of 1:1:: acetone: absolute ethanol. This salt was recrystallized from 99% ethanol.

Anal. Calcd. for $C_7H_{13}O_2N_3Cl_2$: C, 34.72; H, 5.41. Found: C, 34.95; H, 5.47; $[\alpha]^{20}D$ −17.6° ± 3.0° ($\alpha = -0.0058°$; 0.0066 g. as free base/ml. in H_2O of *p*H 9; 0.5 dm. tube). Linnewek and Linnewek[19] reported $[\alpha]^{18}D$

$-25.8°$ (H_2O) for 1-Me-L-histidine free base isolated from the hydrolysis of anserine.

1-Methyl-L-histidine Diflavianate.—The diflavianate salt was formed by the general method of Vickery,[20] and it was recrystallized from water; m.p. 234.7° dec.

Anal. Calcd. for $C_{27}H_{23}O_{18}N_7S_2$: C, 40.65; H, 2.92; N, 12.29. Found: C, 40.45; H, 3.08; N, 12.09.

3-Methylhistidine.—The 3-Me-histidine fraction from the ion-exchange column contained 10% histidine. In the radioactive tracer experiments for which this preparation was to be used,[10b] the contamination by histidine was not deleterious, and no further purification was attempted.

1,3-Dimethyl-L-histidine (Cl^-) or 1,3,-Dimethyl-4-(β-carboxyl-β-aminoethyl)-imidazolium Chloride.—The dry, desalted fraction from the ion-exchange column that contained 1,3-$(Me)_2$-histidine was taken up in about 1.0 ml. of H_2O, treated with Norite, filtered and adjusted to about *p*H 8 with ammonia. Acetone was added to the appearance of fluffy white crystals upon cooling the mixture. The crystals were washed on the filter funnel with acetone and dried *in vacuo* at 80°. The hygroscopic salt must be stored under desiccation.

Anal. Calcd. for $C_8H_{15}O_2N_3Cl$: C, 43.50; H, 6.86. Found: C, 43.4; H, 6.7. $[\alpha]^{20}D$ $+18.1° \pm 1.6°$ ($\alpha = 0.23°$; 0.0125 g./ml. in 1 *N* HCl; 1 dm. tube).

1,3-Dimethyl-L-histidine Diflavianate.—The diflavianate was prepared by the general method of Vickery,[20] and it was recrystallized from water; m.p. 237.5° dec.

Anal. Calcd. for $C_{29}H_{25}O_{14}N_7S_2 \cdot H_2O$: C, 40.53; H, 3.28. Found: C, 40.58, H, 3.17.

Purines. VII. The Preparation of Certain 6-Alkylamino- and 6-Dialkylaminopurines[1]

BY MELVIN SUTHERLAND AND BERT E. CHRISTENSEN

RECEIVED DECEMBER 5, 1956

The procedures for the preparation and isolation of high molecular weight alkylamino- and dialkylaminopurines are described. Twenty such compounds have been prepared by the methods described herein.

A great deal of interest has centered in the 6-substituted purines following the recent discovery of the biological importance of kinetin[2] and 6-mercaptopurine.[3] This activity has been divided between the development of new synthetic routes to kinetin itself and to the synthesis[4] and testing of many of its analogs.

Miller and co-workers originally prepared 6-furfurylaminopurine by the aminolysis (in a sealed tube) of 6-methylmercaptopurine[2] following the procedure of Elion and Hitchings. Since then a number of other approaches to the synthesis of kinetin have been reported. One of the most recent methods for the preparation of the 6-substituted aminopurines involves the synthesis and reduction of the corresponding 6-amidopurine with lithium aluminum hydride.

In this Laboratory an aminolytic procedure based on the use of 6-chloropurine was successfully applied to the preparation of a number of 6-substituted purines.[4] Since this procedure appeared to have a wide degree of applicability and in view of the possibility of turning up other biologically active analogs, this work has been expanded to include a number of other potentially active purine derivatives. Recently several new 6-substituted aminopurines have been reported to possess activity.[5] Since this activity may be dependent in part on fat solubilities of the compound, this Laboratory has prepared a number of high molecular weight alkylaminopurines with the side chain in the 6-position.

This was done by refluxing the chloropurine with different aliphatic amines in *n*-butyl alcohol according to the procedure described earlier.[4] However, due to solubility characteristics of the aliphatic amines, it was not possible to isolate the reaction product by the usual crystallization techniques. The lower molecular weight homologs were isolated by steam distilling the unreacted aliphatic amine from the aqueous basic solution of the reaction mixture. The course of the steam distillation could be followed by the slow progression of the insoluble aliphatic amine through the condenser. The product was then obtained by the ethereal extraction of the basic media left in the distilling flask.

As the aliphatic side chain increased in length the products became contaminated with traces of the starting amine which could not be removed by continuous distillation with steam.

Attempts to remove the unreacted amine by co-distillation at reduced pressures with diphenyl ether were quite successful but no practical way was found for isolating the product in turn from the diphenyl ether. Co-distillation under similar conditions with ethylene glycol was successfully applied to the isolation of 6-isohexylaminopurine, but the process proved to be impractical for the distillation of the higher homologs.

Finally it was observed that it was possible to remove amines as large as octadecylamine from sirupy mixtures of 6-substituted purines by the use of super-heated steam. This was the procedure which was adopted for the isolation of the higher molecular weight 6-substituted purines.

One rather interesting steric effect was noted in

these studies. All the hindered secondary amines (diisopropylamine, di-1-methylbutylamine, di-*sec*-butylamine and dicyclohexylamine) which were treated were found to be unreactive under these conditions of amination. However, the secondary amine di-(2-ethylhexyl)-amine, on the other hand, coupled with the 6-chloropurine.

Furthermore, it is interesting to note that the primary amine 1-methylheptylamine, which might have presented a steric problem, was reactive.

Experimental

Aminolysis Procedure.—One gram of 6-chloropurine (6.4×10^{-3} mole) was suspended in 10 ml. of *n*-butyl alcohol and to this mixture was added 16×10^{-3} mole of the desired amine. The mixture was then refluxed for four hours; the course of the reaction could be followed by the disappearance of the insoluble 6-chloropurine.

Isolation Procedure A.—The reaction mixture was placed in a 500-ml. round-bottomed flask containing 100 ml. of 0.1 *N* sodium hydroxide. This flask was suspended in an oil-bath and the contents were steam distilled until 500 ml. of distillate had been collected. This amount of distillate was sufficient to remove all the unreacted amine as well as the *n*-butyl alcohol. The non-volatile residue was then extracted with ether, which upon evaporation yielded the product. The 6-substituted amine was then in turn recrystallized from one of the several solvents.

Isolation Procedure B.—To the reaction mixture was added 100 ml. of 0.1 *N* sodium hydroxide. The mixture was stirred for 30 minutes and then extracted with ether. This extract was placed in a 500-ml. flask and the ether and butanol removed by distillation. The flask was then immersed in an oil-bath maintained at 150° and then steam distilled with super-heated steam. The steam was prepared by passing ordinary steam, with all condensate removed, through a Fisher super-heater which was maintained at a temperature of 350° with a Fisher burner. Because of the elevated temperatures it was necessary to use metal to glass connections on the discharge side of the super-heater.

Sufficient steam pressure was applied to cause the sirupy product to spread out in a thin film over the bottom of the flask. The distillation was continued until no more unreacted amine could be observed collecting in the condenser. Upon cooling, the product solidified in the flask and was removed by extraction with absolute alcohol.

The results of these experiments are given in Table I.

Evidence for Intramolecular Hydrogen Bonding in Aryl Allophanates and Alkyl or Aryl–Alkyl Biurets

BY I. C. KOGON

RECEIVED FEBRUARY 18, 1957

The near infrared absorption spectra of 1-ethyl-3-phenylurea, 1-methyl-1,3-diphenylurea, 1,1,3-triethylurea, ethyl carbanilate, *p*-chlorophenyl and *p*-methoxyphenyl carbamate show a strong absorption band in the region of 6750 cm.$^{-1}$. The band is not exhibited by ethyl α,γ-diphenylallophanate, ethyl α,p-chlorophenyl-γ-phenylallophanate, ethyl α,p-methoxyphenyl-γ-phenylallophanate, 1,3,5,5-tetraethylbiuret and 1-phenyl-3,5,5-triethylbiuret. It is proposed that the absence of this band is due to the presence of an intramolecular hydrogen bond.

Although examples of intramolecular hydrogen bonding in compounds containing an OH group have been demonstrated by means of near infrared spectra studies,[1] no use has been made of this method of investigation for determining intramolecular hydrogen bonding in molecules containing the NH group.

The hydroxyl group has an absorption band in the region of 7000 cm.$^{-1}$ when no intramolecular hydrogen bonding is expected.[2] This represents the first overtone of the fundamental stretching vibration of the OH group. Hilbert, Wulf, Hendricks and Liddel[3,4] found that absorption in this region is absent for a large number of compounds which have configurations that favor the formation of the intramolecular hydrogen bond. They found absorption was present in related compounds, the configuration of which excluded possible formation of such a bond; *e.g.*, in *o*-nitrophenol, absorption in the 7000 cm.$^{-1}$ region is absent, but it is present in *m*- and *p*-nitrophenol.

Correspondingly, the NH group has an absorption band in the region of 6700–6800 cm.$^{-1}$ which has been correlated with the first harmonic of the fundamental NH stretching vibration at 3500 cm.$^{-1}$.[5] We now have found that intramolecular hydrogen bonding can be detected by means of near infrared absorption spectra in α,γ-diaryl allophanates and in *unsym*-aryltrialkyl and *sym*-tetraalkyl biurets.

The aryl and alkyl ureas and aryl carbamates that we have examined exhibited strong absorption bands in the region of 6750, 5000, 4900 and 4850 cm.$^{-1}$ (Table I). The absence of the absorption band at 6750 cm.$^{-1}$ in the spectra of the allophanates (no. 1–7, Table II) and of the biurets (no. 8 and 9, Table II) strongly suggests that these compounds are intramolecularly hydrogen bonded. The molecular weight of the allophanates and biurets (no. 1–9, Table II) indicated these compounds to be in the monomeric state. In the region of 4831–4877 cm.$^{-1}$, a broad absorption band was found for those compounds suspected of having hydrogen bonding. Kaye,[6] in his study of methanol, showed that a broadening of the absorption bands in this region took place when hydrogen bonding increased.

TABLE I

RNHCOR′

No.	R	R′	Concn.[a] moles/liter	Absorption band, cm.$^{-1}$			
1	C_6H_5	OC_2H_5	2.425	6756	5045	4970	4880
2	p-$CH_3OC_6H_5$	OC_2H_5	0.5020	6743	5083	4940	4850
3	p-ClC_6H_5	OC_2H_5	.5150	6748	5038	4945	4855
4	C_6H_5	$N(CH_3)C_6H_5$	.1500	6710	5022	4946	4867
5	C_2H_5	NHC_6H_5	.0500	6725	4915	(broad band)	
6	C_2H_5	$N(C_2H_5)_2$	.7500	6780	4974	4915	4865

[a] All spectra were determined at 26 ± 0.5° and were carried out in 10.00-mm. and 25.00-mm. quartz cells using carbon tetrachloride as the solvent.

Interestingly, *sym*-triethyl and triphenyl biuret exhibited a weak absorption band in the region of 6750 cm.$^{-1}$ (no. 10 and 11, Table II) and showed three distinct absorption bands at 5000–5276, 4920–4943, 4825–4870 cm.$^{-1}$ instead of one broad band. An examination of Fisher–Hirschfelder–Taylor molecular models indicated that only one NH group can be intramolecularly hydrogen bonded at any one time to an oxygen atom, and therefore an absorption band should appear in the region of 6750 cm.$^{-1}$. Thus the three absorption bands are probably due to the unassociated NH of the biuret which completely masks the broad band due to associated NH.

Additional evidence lending support to the theory that the allophanate molecule is intramolecularly hydrogen bonded is found in the reactions of phenyl isocyanate with ethyl carbanilate[7] and cyanic acid with alcohol.[8] The products of the reactions are always the carbanilate and allophanate. No polyallophanate is isolated as might be expected if no intramolecular hydrogen bonding were present to tie up the NH group.

Experimental[9]

Materials.—Ethyl carbanilate, m.p. 48–49°, ethyl *p*-chlorophenylcarbamate, m.p. 66–67°, and ethyl *p*-methoxyphenylcarbamate, m.p. 65°, were prepared by the procedure of Vittenet.[10] Ethyl-α,γ-diphenylallophanate, m.p. 94°, ethyl α,p-chlorophenyl-γ-phenylallophanate, m.p. 89–90°, and ethyl α,p-methoxyphenyl-γ-phenylallophanate were

[a] All spectra were determined at 26 ± 0.5° and carried out in 10.00- and 25.00-mm. quartz cells. [b] Carbon tetrachloride was used as the solvent. [c] Benzene was used as the solvent.

prepared according to the procedure of Kogon.[11] 1-Ethyl-3-phenylurea was prepared according to the procedure of Thiele and Pickard,[12] m.p. 96–97°. 1-Methyl-1,3-diphenylurea was prepared according to the procedure of Gebhardt[13] m.p. 104°. 1,1,3-Triethylurea was prepared according to the procedure of Hofmann,[14] m.p. 62°. 1,3,5-Triphenylbiuret, m.p. 150–151°, and 1,1,3-triethyl-5-phenylbiuret, m.p. 113–113.5°, were kindly supplied by E. J. Goldberg.[15] 1,3,5-Triethylbiuret[16] (*Anal.* Calcd. for $C_8H_{17}N_3O_2$: N, 22.4. Found: N, 22.6) and 1,1,3,5-tetraethylbiuret (*Anal.* Calcd. for $C_{10}H_{21}N_3O_2$: N, 19.4. Found: N, 19.6) were prepared according to the procedure of Baker and Holdsworth.[17] A boiling point for these compounds was not obtained due to their ease of decomposition.

Preparation of Solutions.—The solutions were carefully made up by weighing the compound directly into a 50-ml. or 100-ml. volumetric flask and diluting with sufficient carbon tetrachloride or benzene to give 50 or 100 ml. of solution. The solution was then added directly to a 100.0- or 25.0-mm. quartz cell. Prior to each run the cells were washed once with acetone, followed by three to five washings with reagent grade carbon tetrachloride, then dried *in vacuo*. The cells were rinsed twice with 2 ml. of the solution to be examined and then filled.

Spectrophotometric Method.—Measurements were made in a 100.0- or 25.0-mm. quartz cell using the Cary spectrophotometer model No. 14. The cell holder was held at a temperature of 26 ± 0.5°. The samples were run at a scan speed of 50 Å./sec., chart speed of 5″/min., and a slit control of 0.15 mm.

Paper Chromatography of Flavins and Flavin Nucleotides[1,2]

BY G. L. KILGOUR[3], S. P. FELTON AND F. M. HUENNEKENS

RECEIVED SEPTEMBER 19, 1956

Methods and solvent systems are described for the paper chromatographic separation and identification of flavins and flavin nucleotides.

Numerous investigations concerned with flavins and flavin nucleotides have been facilitated greatly by the application of chromatographic methods to these problems. Following the work of Crammer,[4] who first separated Rb,[5] FMN and FAD by paper chromatography, this technique has been utilized further in such studies as: the isolation[6–8] and chemical synthesis[9–11] of FAD and FMN, the identification of riboflavinyl glucoside,[12] the identification of Rb analogs,[13] the failure of P^{32}-labeled orthophosphate to be incorporated into FAD by respiring tissue homogenates[14] and the identifica-

tion of the prosthetic group of various flavoproteins.

The present communication describes methods of paper chromatography which are applicable for the separation and identification of known flavins, and which provide information concerning the structure of unknown flavins of natural or synthetic origin.

Experimental

Materials.—Rb and FMN were commercial products from Merck and Co. and Hoffmann-La Roche Inc., respectively. FAD[6] and FAD-X[15] were isolated by methods previously described. LF and LC were prepared by ultraviolet irradiation of neutral and basic solutions of Rb, with subsequent isolation of the products by chloroform extraction of the acidified aqueous phase. Rb-4′,5′-diphosphate was obtained as a by-product in the synthesis of Rb-5′-pyrophosphate; details of these preparations are described in a subsequent communication.[16]

Intestinal phosphatase was purchased from Armour & Co. and nucleotide pyrophosphatase was isolated from potatoes.[17]

The following materials were generously provided for this investigation: Lx by Drs. K. Folkers and E. Snell; IsoRb and GalF by Dr. Folkers; RbG by Dr. L. G. Whitby; and cyc-FMN by Drs. A. R. Todd and G. Kenner.

All solvents were reagent grade commercial products and were used without further purification. Phenol of the required high purity was Merck reagent grade.

Methods.—Paper chromatography was carried out on 28 × 42 cm. sheets of Whatman #1 paper. Spots of approximately 4 mm. diameter were applied at the starting line, and the papers developed either ascending in 15 × 45 cm. cylindrical jars or descending in a Chromatocab. These operations were carried out in very dim light in order to minimize photodegradation of the flavins to LF or LC. An equilibration period of 3 hours was required for all organic systems, but not for aqueous systems.

As little as 0.01 μg. of flavin can be detected by means of its fluorescence under the Mineralight ultraviolet lamp, Model RB-50. When it was desired to locate, in addition, other nucleotides by their dark blue "quenching" spots, the shorter wave length Mineralight lamp, Model V41, was employed. Larger amounts of the dinucleotides, such as FAD, must be used in comparison to Rb or FMN, since the molar fluorescence of FAD is only 10–15% of that of the other two compounds at neutral *p*H.[18] In addition, considerable quenching of the fluorescence of all the flavins is caused by the presence of many organic compounds and metal ions.[19]

Due to the great sensitivity of detection by means of fluorescence, the usual spray reagents are largely unnecessary, and, in fact, are somewhat interfered with by the yellow color of the flavins. Thus, the phosphate reagent of Bandurski and Axelrod[20] yields spots of a greenish shade rather than blue. It is possible by spraying with an alkaline hydrosulfite reagent to bleach temporarily the yellow color of flavins, which are then re-oxidized by air. This serves to distinguish flavins from many other colored materials.

A semi-quantitative estimate of the amount of each flavin on a paper chromatogram may be obtained by photographing the flavins by their own fluorescence, and subsequently analyzing the negative with a Photovolt Model 501A densitometer.[21] The photography is accomplished by illuminating the paper evenly with the ultraviolet light source and using a red (*e.g.*, Wratten A) filter at the camera with Contrast Process Panchromatic Sheet film (Eastman). The picture also provides a permanent record of the chromatogram. An alternate method for obtaining quantitative data consists of treating the paper strip with a light Mineral oil, passing it through a Beckman Model DU spectrophotometer equipped with a paper-strip scanner,[22] Model 2001, and taking optical density readings at 450 mμ.

Results and Discussion

R_f Values and Solvent Systems.—Table I lists a series of acidic, basic and neutral solvents which have been found to be most suitable for the separation and identification of flavins. It is seen that essentially all of the systems readily separate the four *classes* of flavins: (a) degradation products, LC and LF; (b) nucleosides, Rb, Lx, GalF, IsoRb and RbG; (c) mononucleotides, FMN and cyc-FMN; and (d) dinucleotides, FAD and FAD-X. Within a given class, the individual members are usually separable, with the exception of Rb and Lx for which no separation has been devised.[23]

TABLE I

PAPER CHROMATOGRAPHY OF FLAVINS

Substance	R_f Values × 100 in various solvent systems[a] 1	2	3	4	5	6	7	8	9
Dinucleotides									
FAD	5	36	38	20	17	8	4	24	14
FAD-X	16	37	38	41	30	28	20	29	30
Mononucleotides									
FMN	10	33	50	17	4	17	4	17	14
cyc-FMN	13	27	36	49	15	29	12	29	23
Nucleosides

Lx	32	55	30	77	64	34	40	32	38
IsoRb	33	55	27	80	74	45	46	35	42
GalF	30	51	41	73	57	37	41	32	39
RbG	23	42	43	59	50	34	35	31	36
Degradation Products									
LF	47	67	18	94	68	34	43	34	44
LC	68	75	7	88	72	61	73	53	58

[a] Composition of solvent systems: 1, *n*-butanol:acetic acid:H_2O (40:10:50)—use organic phase; 2, isobutyric acid:NH_4OH:H_2O (66:1:33); 3, $Na_2HPO_4 \cdot 7H_2O$ (5% in H_2O); 4, phenol:*n*-butanol:H_2O—160 g. of phenol is dissolved with warming in 30 ml. of *n*-butanol. The resulting solution is cooled to room temperature, shaken with 100 ml. of water and the organic phase used. 5, collidine—saturate with H_2O and use organic phase; 6, *t*-butyl alcohol:H_2O (60:40); 7, *t*-butyl alcohol:pyridine:H_2O (60:15:25); 8, *t*-butyl alcohol:NH_4OH:H_2O (60:5:35); 9, *n*-propanol:NH_4OH:H_2O (60:30:10). After being run in solvent system 4 and 5, the dried papers must be washed repeatedly in $CHCl_3$ before the fluorescent spots can be seen.

Solvent system 3, and similar ones employing aqueous buffered solutions, are susceptible to extreme variation in R_f values depending upon both the *p*H and the buffer concentration. The R_f values (× 100) for Rb, FMN and FAD vary with the molar concentration of 1.0, 0.1, 0.01 and 0.001 *M* phosphate buffer, *p*H 8.0, as follows: Rb—19, 32, 34, 32; FMN—40, 75, 76, 89; and FAD—24, 62, 74, 79. The relative order of the compounds does not change in spite of wide variations in their relative separation. This latter finding is not the case, however, when the *p*H is varied using different buffers, but with the buffer concentration held at 0.1 *M*. The R_f of Rb is not greatly influenced from *p*H 2 to 10, while FAD precedes FMN at *p*H values below 5.5, and follows FMN at *p*H values above that. Maximum separation may be ob-

tained for a mixture of all three components in the *p*H range of 7.0–8.0.

It is possible also in aqueous solvent systems, such as No. 3, to observe a linear relationship, as shown in Fig. 1, between the R_f value of a flavin

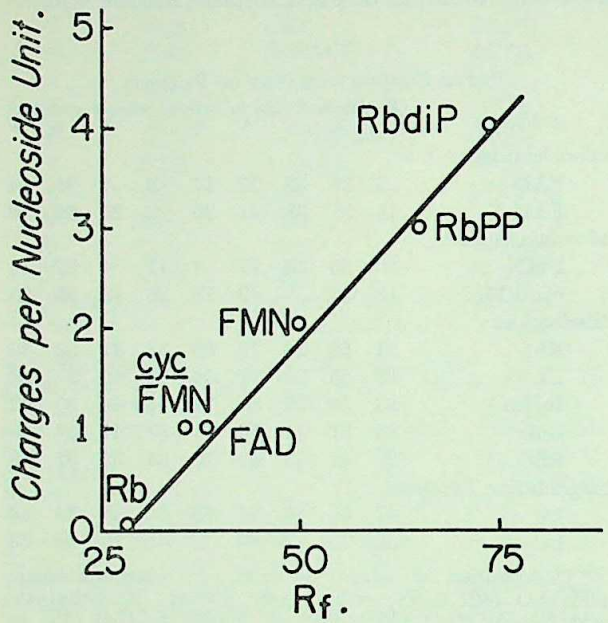

Fig. 1.—R_f value as a function of charge per nucleoside.

and its "charge per nucleoside" ratio. This latter quantity is obtained by dividing the number of negative charges, due to ionization of the phosphate groups, by the total number of nucleoside residues in the molecule. At *p*H 8, these values are 0, 1 and 2, respectively, for Rb, FAD and FMN.

The acidic solvents in Table I have been chosen partially because of the relative stability of sensitive dinucleotides, such as FAD, in these systems. The basic solvents, especially those containing ammonia, all have shown a tendency to cause cyclization of the flavin nucleotides.

Identification of Unknown Flavin Nucleotides.—Considerable information concerning the structure of a flavin prosthetic group or synthetic flavin may be obtained on small amounts of material by the above techniques. All flavoproteins, with the exception of succinic dehydrogenase,[24] have their prosthetic groups readily detached by heat denaturation or treatment in the cold with 10% trichloroacetic or perchloric acid. Heat is preferable both because it minimizes breakdown and because it avoids the addition of extraneous materials. Excess of the two precipitating agents should be removed, however, by ether extraction or neutralization with KOH, respectively. Prior to examination by paper chromatography, the flavins may be concentrated by methods described previously, or by adaptation of paper chromatographic methods, wherein the flavins are run as streaks and eluted with minimum volumes of water. It should be noted that acids, bases, light and some organic solvents, (*e.g.*, acetone and ethyl alcohol), tend to degrade flavins and should be avoided during the concentration procedures.

In addition to obtaining information from chromatography of the intact flavin, it is possible to degrade the material by means of treatment with acid, base or enzymes, and to compare the breakdown products with known standards. For example, after spotting the flavin at the origin, the paper may be exposed to HCl or NH_3 vapors for 1 hour in the dark, and then aerated in a hood for a few minutes before being placed in the solvent. Similarly, the spot may be overlaid with a concentrated solution of intestinal phosphatase or nucleotide pyrophosphatase and the paper suspended in a moist tank for an hour prior to running the chromatogram. Such techniques have been employed previously for establishing the structure of FAD-X.[15]

Acknowledgment.—The authors are indebted to Mrs. Enid Vercamer for her assistance in this problem.

Chemical Synthesis of Riboflavin 5′-Pyrophosphate[1,2]

BY G. L. KILGOUR[3] AND F. M. HUENNEKENS

RECEIVED SEPTEMBER 19, 1956

The chemical synthesis of riboflavin 5′-pyrophosphate (RbPP) from readily available riboflavin 5′-phosphate (FMN) has been investigated, using several phosphorylating agents, the most suitable being phosphoric acid in the presence of di-*p*-tolyl carbodiimide (DPTC). By means of these reactions, and subsequent isolation of the product by large-scale, preparative paper chromatography, RbPP has been obtained and characterized.

The chemical synthesis of flavin–adenine dinucleotide (FAD[4]) was first achieved by A. R. Todd and his colleagues[5] through a route utilizing the condensation of the mono-silver salt of FMN with 2′,3′-isopropylidene adenosine-5′-benzyl phos-

phorochloridate, followed by removal of the protective groups. Subsequently, an alternate procedure was devised in this Laboratory, wherein FMN and AMP are condensed directly using di-*p*-tolyl carbodiimide as the dehydrating agent.[6] Other projected pathways to FAD, not requiring protective groups, would envision either (a) the condensation of RbI with mono-silver ADP, or (b) mono-silver RbPP with AdI.[7] The present communication describes briefly the attempted preparation of RbI and, in more detail, the successful synthesis of RbPP.

Synthesis of RbI would be expected to proceed through replacement of the primary tosyl group, at the 5′-position of riboflavin, with iodine.[8] Preliminary experiments, however, confirmed the finding of Forrest, *et al.*,[9] that neither the 5′-tosyl nor the 5′-mesyl ester of riboflavin could be obtained, even with wide variation in reaction conditions. Attempts to halogenate the 5′-position directly with ICl were likewise unproductive; accordingly the first route was not explored further.

The preparation of RbPP was approached in several ways. It was decided first to attempt the condensation of the silver salt of FMN with $POCl_3$ at temperatures below 0° in anhydrous dimethylformamide. Upon chromatographing an aliquot of the resulting solution in 5% Na_2HPO_4 and determining the amount of each component by quantitative densitometry,[1] three products were found in addition to unreacted FMN (R_f = 0.57, 18% yield) and large quantities of cyc-FMN (R_f = 0.36, 63% yield). Following purification by means of large-scale paper chromatography, one product (R_f = 0.66, 6% yield) was identified as RbPP. It was found to exhibit a P_7:P_{tot}:flavin ratio[10] of 1:2:1, and upon treatment with dilute H^+, NH_3 or Ba^{++}, was hydrolyzed to FMN (with NH_3, some cyc-FMN was formed also). The second flavin product (R_f = 0.73, 8% yield) is believed to be riboflavin-4′,5′diphosphate by the P_{tot}:flavin ratio of 2:1, the absence of any acid-labile phosphate, and the positive periodate reaction.[11] This second compound has been detected also in small amounts (*ca.* 3–6%) by paper chromatography of commercial FMN. The third flavin (R_f = 0.60, 5% yield) has been designated tentatively as Rb-4′,5′-cyc-diphosphate because of its chromatographic behavior, ease of hydrolysis in dilute acids to yield Rb-4′,5′-diphosphate, and positive reaction to the periodate reagent.

The yield of RbPP could not be increased, nor could the amount of unwanted cyc-FMN be decreased, by substituting monochlorophosphoric acid[12] or diphenylphosphoryl chloride for $POCl_3$.

The synthesis of ATP and ADP from AMP and H_3PO_4 using dicyclohexyl carbodiimide[13] suggested the possibility of RbPP synthesis from FMN and H_3PO_4 by this method. However, DCC reacted rapidly and completely with FMN to give only cyc-FMN. When the less reactive DPTC was substituted for the dicyclohexyl derivative, the reduced reaction rate permitted the hydroxyl group of the entering phosphate to compete with the sterically preferred 4′-hydroxyl of FMN. In addition to FMN and cyc-FMN, the products included one compound chromatographically and chemically indistinguishable from the RbPP prepared previously by condensation of Ag_2FMN and $POCl_3$. Several other flavins obtained in lower yield appeared to be, on the basis of R_f values and acid hydrolysis to FMN, higher polyphosphates of riboflavin, Rb(P)x, analogous to the ATP and adenosine tetraphosphate obtained by Khorana[13] in the synthesis of ADP.

Experimental

Materials and Methods.—Commercial chemicals used in this investigation were obtained from the following sources: monosodium FMN, Hoffman–LaRoche, Inc.; Rb, Nutritional Biochemical Co.; DCC, Dajac Laboratories; Florisil, Floridin Company; ICl, Eastman Kodak Co. DPTC was prepared by the method of Khorana.[14] Cyc-FMN was prepared by the method of Forrest and Todd.[15]

Paper chromatography was carried out as described previously.[1]

Preparation of Disilver FMN.—NaFMN (1.0 g., 2.1 mmoles) was dissolved in 10 ml. of water and a solution of 1.0 g. (6.0 mmoles) of $AgNO_3$ in 10 ml. of water added. To the resultant bright red solution was added 10 ml. of absolute methanol. At this point a flocculent red precipitate formed and was centrifuged readily from the pale yellow supernatant solution. The precipitate was washed twice with absolute methanol, twice with dry ether, and dried under vacuum at room temperature to yield 1.080 g. of a fine, red powder. Found: Ag = 33.17%; Calcd. for AgFMN, Ag = 19.04%; for Ag_2 FMN, Ag = 31.73%; for Ag_3FMN, Ag = 41.70%.

Synthesis of RbPP Using H_3PO_4 and Carbodiimide.—Ten mg. of NaFMN was dissolved in 0.1 ml. of water and 0.5 ml. of pyridine was added. To this was added a solution of 500 mg. of DPTC in 0.5 ml. of pyridine. Finally, 0.25 ml. of 85% H_3PO_4 was added with shaking, and the final mixture was shaken mechanically in the dark at room temperature for 24 hours. Addition of water (*ca.* 2 ml.) to the mixture caused precipitation of unreacted DPTC and the by-product, di-*p*-tolylurea. These materials were removed by filtration and the resulting clear solution analyzed by paper chromatography in order to ascertain the amount of RbPP present. Quantitative densitometry of the paper chromatograms revealed that 17% of the total flavin was RbPP. Decreasing the amount of H_3PO_4 or water, increasing the amount of pyridine (to 3.0 ml.), or substitution of FMN (free acid) for NaFMN, greatly diminished the yield of RbPP, while increasing the time beyond 24 hours appeared to have no significant effect. Shorter times were found to result in increased amounts of unreacted FMN.

(7) Since the difficulties of preparing AdI by the conventional route through the condensation of 2′,3′-isopropylidene-5′-tosyladenosine with NaI are well recognized (J. Baddiley, *J. Chem. Soc.*, 1349 (1951); V. M. Clark, A. R. Todd and V. Zussman, *ibid.*, 2952 (1951)), this pathway would be useful only if an alternate route to AdI were available. The analog, flavin-inosine dinucleotide, previously synthesized by another route,[8] could be prepared, however, in this manner, since the synthesis of inosine-5′-iodide is reported to proceed smoothly by NaI treatment of the tosyl intermediate.

RbPP was isolated from the above mixture of flavins by the following procedure. The solution was diluted to 50 ml. with water and was shaken three times with four volumes of $CHCl_3$ in order to remove most of the pyridine. Removal of inorganic impurities was carried out by adsorption of the flavins on a Florisil column. The solution was acidified to *p*H 5 with acetic acid and passed through a washed column of Florisil (*ca.* 10 × 30 cm.). The column was washed with acetic acid, water and pyridine, as described previously,[16] and the flavins removed by elution with 5% pyridine. Pyridine was removed by shaking with $CHCl_3$, giving a clear yellow solution of the flavins.

The solution was concentrated to a small volume by lyophilization. Bulk separation of the flavins was achieved by applying the concentrated flavin solution to the starting line of Munktell's Cremer–Tiselius paper[6] (*ca.* 50 mg. per sheet) and developing the chromatogram in 5% Na_2HPO_4. The separate bands were located by inspection under a Mineralite, cut out, and eluted with water. Inorganic phosphate was removed from each fraction as follows. First, the solutions were stored at 0–5° for several days in order to crystallize out excess phosphate. Silver nitrate was then added in slight excess, with stirring, and the solution was adjusted with dilute acetic acid until the flavin went back into solution as a red complex. The residual silver phosphate was removed by centrifugation and the red supernatant solution passed through a short, chilled column of IR-120(H^+) cation exchange resin to remove silver. The effluent was collected in a tube immersed in a bath of acetone and Dry Ice and was thus frozen immediately. The solution was later thawed and adjusted immediately to *p*H 7 with dilute NaOH. Large-scale paper chromatography was repeated as above but employing *t*-BuOH:water (60:40) as the solvent system.[6] The pure components thus obtained, with the exception of FMN and cyc-FMN, were present in amounts too small to handle conveniently in the dry state, and the analyses and characterization were carried out using concentrated solutions. At this point, all of the flavins including RbPP behaved chromatographically as single components having the R_f values given previously. RbPP was obtained after purification in *ca.* 5% over-all yield, based upon the original NaFMN. The P_i:$P_{tot.}$: flavin ratio was 1.13:2.07:1 and 1.09:2.17:1 in duplicate analyses, and upon gentle acid hydrolysis there was quantitative conversion to FMN.

Lyxoflavin Nucleotides[1,2]

BY F. M. HUENNEKENS, S. P. FELTON AND ESMOND E. SNELL

RECEIVED OCTOBER 26, 1956

L. lactis cells, grown on lyxoflavin, incorporate the vitamin into lyxoflavin mononucleotide (LMN) and dinucleotide (LAD), which can be isolated by means of chromatography on Florisil and paper columns. LMN and LAD can be distinguished from their riboflavin analogs by means of a differential microbiological assay using *L. lactis* and *L. casei*. They cannot be distinguished, however, by means of paper chromatography. In TPNH cytochrome c apo-reductase from yeast FMN is utilized preferentially to LMN, although the latter exhibits appreciable activity. In a D-amino acid apo-oxidase from pig kidney, FAD is utilized preferentially to LAD.

In 1949 Pallares and Garza[3] reported the isolation of L-lyxoflavin from human cardiac muscle. The proof of its structure, and its non-identity with D-riboflavin, rested principally upon the preparation of the tetraacetyl derivative, whose melting point agreed with that of Lx,[4] but not Rb. Synthetic Lx was first prepared by these authors, using a modification of the Karrer procedure[5] and, subsequently, by other independent routes.

The failure of other workers[6,7] to find Lx in a variety of animal tissues has cast doubt as to the natural occurrence of this substance. In addition, Gardner, *et al.*,[7] have pointed out the difficulty in distinguishing Lx and Rb on the basis of a single derivative.

In spite of the doubtful natural occurrence of Lx, other investigations have been carried out with the synthetic material. The addition of Lx to experimental rations increased the growth of rats,[8,9] chicks[9,10] and pigs.[11] Snell, *et al.*,[6] have shown that Lx does not support growth of *Lactobacillus casei* in the absence of Rb, but that low concentrations of Lx increase the growth response to limiting amounts of Rb. Under the latter conditions it was shown that Lx was not deposited in cells of *L. casei*, and that it actually decreased the concentration of Rb deposited in such cells. In contrast, the similar organism, *Lactobacillus lactis*, grew in the absence of Rb when Lx was supplied to the medium.[6,12] In this case, cells grown with Lx contain no Rb, but do contain Lx; *i.e.*, Lx apparently can fulfill the essential metabolic roles normally played by Rb. The growth requirements of these two organisms made it possible to determine Lx and Rb by means of a differential microbiological assay.[6]

Since it had been established that *L. lactis* utilized Lx directly for growth, it seemed possible that the Lx was being incorporated into the cellular flavin nucleotides. In the present study, the

flavin nucleotides have been isolated from *L. lactis* cells grown on Lx, and shown to be the corresponding counterparts of FMN and FAD. Although the Lx and Rb nucleotides are similar in many chemical aspects, including migration on paper in various solvent systems, they can be distinguished by their behavior as coenzymes in enzymatic assay systems.

Experimental

Materials.—Lx was generously provided by Drs. Karl Folkers and J. M. Cooperman. FAD was prepared by the method of Dimant, *et al.*,[13] FMN was obtained from Hoffmann-LaRoche, Inc., and was recrystallized from an acidic aqueous solution. Cytochrome-c and TPN were obtained from the Sigma Chemical Company. TPNH was prepared by the enzymatic reduction of TPN using the glucose 6-phosphate dehydrogenase system.

Synthetic LMN was prepared as follows[14]: 5 mg. of Lx was added to a mixture of 0.15 ml. of $POCl_3$ and 0.01 ml. of water at room temperature. After 20 minutes the solid had dissolved to yield a dark red-brown solution. Twenty ml. of ether was then added and the resulting precipitate was recovered by centrifugation, washed twice with ether and dried *in vacuo*. The solid was dissolved in 1.5 ml. of water, neutralized with NaOH and subjected to large-scale paper chromatography, using 5% aqueous Na_2HPO_4 as the solvent system. The LMN band, which separated cleanly, was cut out, eluted and standardized spectrophotometrically in solution[15]; yield, *ca.* 25% of theory. The molal extinction coefficient, ϵ, for LMN is assumed to be the same as for FMN,[16] *i.e.*, 12.2×10^6 cm.^{2}/mole.

D-Amino acid apo-oxidase and TPNH-cytochrome-*c* apo-reductase were prepared from pig kidney and baker's yeast, respectively.[17] The growth media for both *L. casei* and *L. lactis* has been described previously by Snell, *et al.*[6]

Methods.—Absorption spectra were determined with a Beckman spectrophotometer, Model DU. Enzymatic assays[17] for FAD and FMN and the differential microbiological assay[6] for Rb and Lx have been described previously.

Using a great variety of solvent systems, or even borate-treated papers, it has not been possible to effect a satisfactory separation of Rb and Lx, or the corresponding nucleotides, by means of paper chromatography.[18]

The isolation of the flavin nucleotide fraction from *L. lactis* cells by means of chromatography on Florisil was carried out as follows: 10 g. of washed, harvested and lyophilized cells were mixed with 30 ml. of water and 4.7 ml. of 50% trichloroacetic acid and homogenized for 1 minute in a Waring blendor. The slurry was centrifuged for 5 minutes at 2300 × *g* in the cold, and the supernatant fluid was removed by decantation. The residue was homogenized twice with 35 ml. of 6.7% trichloroacetic acid, and the supernatant fluids separated by centrifugation. The combined supernatant fluids (77 ml.) exhibited optical density values of log I_0/I = 0.195 at 450 mμ and 1.095 at 260 mμ. The trichloroacetic acid extract was passed through a Florisil column (3.4 × 14.5 cm.), and, after adsorption of the flavins at the top, the column was washed, in turn, with 1 l. of 2% acetic acid, 2 l. of water and one l. of 0.5% pyridine. The flavins were then eluted with 200 ml. of 5% pyridine. After removal of the pyridine by extraction with chloroform, there remained a volume of 160 ml. which had optical density values of 0.035 at 450 mμ and 0.565 at 260 mμ. This would correspond to 5.0×10^{-4} mmole of flavin, or a recovery of about 38% of that originally placed on the column. The solution was then lyophilized to yield a light yellow powder weighing 35 mg.

Separation of the Lx nucleotides was effected by means of adsorption chromatography on a paper pulp column. Solka-floc[19] was slurried in acetone and packed into a column (1.1 × 23 cm.) under gentle air pressure. The column was washed with 0.05 *M* phosphate buffer (*p*H 8.0) until all of the acetone had been removed, and the column was completely equilibrated with the buffer. The column was taken to incipient dryness and the above lyophilized flavin material, dissolved in 1.5 ml. of water, was added to the top of the column. Separation of the flavins was achieved by developing the column with phosphate buffer. The flow rate was about 2 drops per minute, and the effluent was collected in an automatic fraction collector. The contents of each tube was diluted up to 3 ml. with water and the optical density determined at 450 mμ. The resulting column profile is shown in Fig. 1.

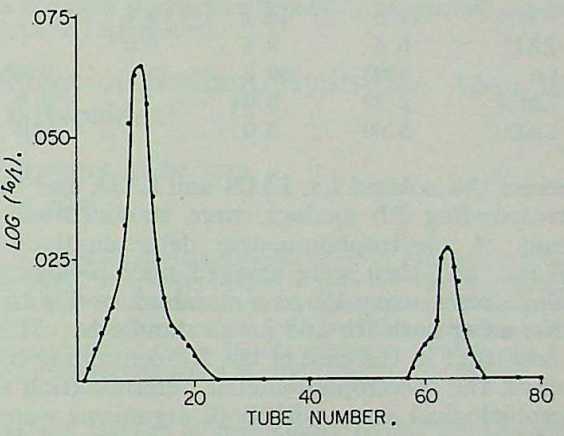

Fig. 1.—Separation of flavins on Solka-floc column. Column effluent was collected in test-tubes using a Technicon Time-Flow Automatic fraction collector, pre-set for 5 drops per tube from 1–56 and 10 drops per tube from 57–80. The contents of each tube was diluted to 3.0 ml. with water and the light absorption log (I_0/I) determined at 450 mμ.

Paper chromatography[15] revealed that tubes 8–13 contained only LMN, whereas tubes 14–19 contained both LMN and LAD. The latter group were pooled, lyophilized to dryness, and the material chromatographed on sheets of No. 1 Whatman paper using 5% $NaHPO_4$ as the solvent system. The separated bands of LMN and LAD were cut out, eluted, and the LMN fraction combined with the contents of tubes 8–13. Assayed spectrophotometrically, the amounts of lyxoflavin-containing materials were: Lx, 0.44 × 10^{-4} mmole; LMN, 1.21 × 10^{-4} mmole; and LAD, 0.14 × 10^{-4} mmole; total, 1.79 × 10^{-4} mmole; recovery, 36%. About 75% of the flavin is in the mono- or dinucleotide form, the remaining 25% being the free vitamin concentrated within the cell. In animal tissues essentially all of the flavin is distributed between the nucleotide forms.[13]

Results and Discussion

Isolation of Lx Nucleotides.—The total amount of flavin contained in cells of *L. lactis* grown on Lx may be calculated from the data obtained in the Florisil chromatography step. In the pyridine eluate fraction about 230 μg. of flavin was obtained from 10 g. of dried cells, or about 23 mg. of flavin per kg. of dried cells. For pig liver or yeast the value is about 200 mg. per kg.[12] It is probable that the amount of flavin calculated from the pyridine eluate is more accurate than that obtained on the original trichloroacetic acid extract, since the original extract may have contained substances

other than flavin capable of absorbing light at 450 mμ.

Microbiological Assay of Lyxoflavin Nucleotides.—It was of interest to carry out on the isolated Lx nucleotides a differential microbiological assay similar to that which had been done previously on the total Lx-containing compounds in *L. lactis* cells.[6] Table I contains the results of the assay,

TABLE I

FLAVIN CONTENT BY SPECTROPHOTOMETRIC AND MICROBIOLOGICAL ASSAY

Compound	Spectrophotometric assay, μg./ml.	Microbiological assay, μg./ml. *L. casei* Rb Std.	*L. lactis* Rb Std.	*L. lactis* Lx Std.
Rb	19.4	18.4	18.0	
FMN	14.9	14.1	15.9	
FAD	9.5	9.6	8.0	
Lx	0.92	0.0		0.42
LMN	2.22	0.04		2.0
LAD	3.60	0.0		0.0

wherein the isolated Lx, LMN and LAD, and their corresponding Rb analogs, were standardized by means of spectrophotometric determinations at 450 mμ, and then were assayed microbiologically with *L. casei*, using Rb as a standard, and with *L. lactis*, using both Rb and Lx as standards. It can be seen that in the case of the Rb-containing compounds, the spectrophotometric determination and microbiological assay with both organisms were in good agreement. In the case of the Lx analogs, however, there was no apparent response in the *L. casei* assay. Of interest also is the fact that the Lx materials did not function equally well in the microbiological assay with *L. lactis*. Both Lx and LMN showed agreement between the microbiological and spectrophotometric assays, but LAD gave no response in the microbiological assay.

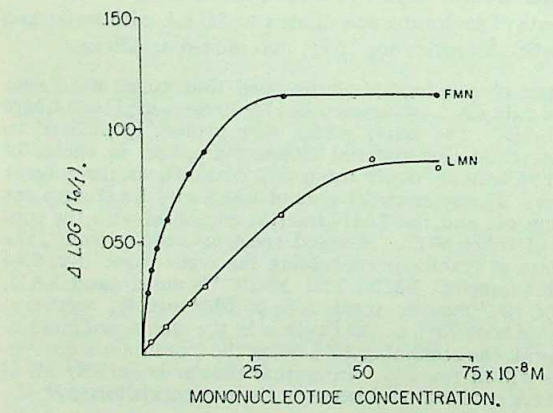

Fig. 2.—Comparison of FMN and LMN as coenzymes for TPNH-cytochrome-C reductase. The following components were added to a Corex cuvette having a light path of 1 cm.: 20 μmoles of phosphate buffer, *p*H 7.3, 0.08 μmole of cytochrome-c, 0.05 μmole of TPNH, the indicated amount of FMN (⊙) or LMN (△) and water to make 2.9 ml. The blank cell was identical except for the omission of cytochrome-c. After taking an initial reading at 550 mμ, 0.1 ml. of the apo-reductase was added to both cuvettes and the readings taken at 1-min. intervals for 6 min. Since the change in optical density was linear over the entire period, the total change, expressed as log (I_0/I) for 6 min., is plotted on the ordinate. All experimental values have been corrected for an additional blank wherein no FMN was added. This value, representing the residual, conjugated enzyme in the preparation, was about one-fourth the experimental value.

Enzymatic Activity of LMN.—The dissociated TPNH-cytochrome-*c* reductase from baker's yeast was chosen as a suitable test system for examining the relative coenzymatic activity of the two mononucleotides. As shown in Fig. 2, FMN restored full activity to the enzyme at a level of about 150 μg. per ml., and has a Michaelis constant K_m, of 5.2×10^{-8} *M*. LMN was less effective than FMN, but at high concentrations it reached a maximum activity about 75% of that shown by FMN. The K_m value for LMN was 6.4×10^{-7} *M*. Further evidence that the isolated LMN is, in fact, the 5′-phosphate derivative of Lx, was afforded by an experiment wherein a synthetic sample of LMN, prepared by the direct phosphorylation of Lx in the 5′-position, was assayed in the above enzymatic system. A K_m value of 8.8×10^{-7} *M* was obtained. The somewhat higher value for the synthetic LMN may have been due to the presence of inhibitory substances carried along from the synthetic reaction mixture.

Enzymatic Activity of LAD.—The D-amino acid oxidase of pig kidney was chosen for a comparison of FAD and LAD. Using the customary manometric assay, the effect of FAD concentration upon activity is shown in Fig. 3. The Michaelis

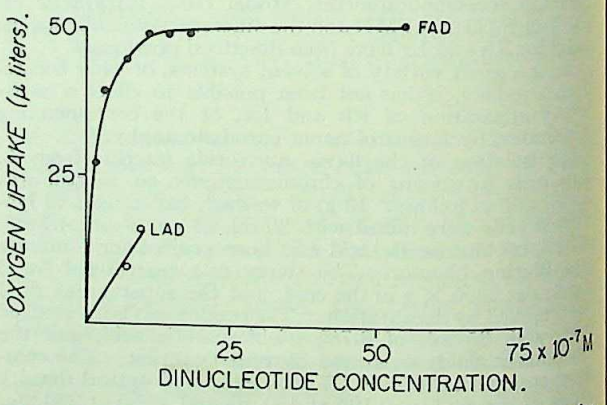

Fig. 3.—Comparison of FAD and LAD as coenzymes for D-amino acid oxidase. The manometer cups contained 25 μmoles of pyrophosphate buffer, *p*H 8.3, 100 μmoles of DL-alanine, *p*H 8.3, 0.5 ml. of D-amino acid apo-oxidase, FAD (⊙) or LAD (△) at the indicated concentration, and water to make 2.8 ml. The center well contained 0.2 ml. of 6 *N* NaOH. The blank cups were identical except for the omission of alanine. The cups were gassed with oxygen and equilibrated for 10 min. with the stopcocks open. Oxygen uptake values are expressed as μliters for the first 10-min. period after the stopcocks were closed. All values are corrected for the blanks without substrate and without added FAD. The blank was about 20% of the experimental values; bath temperature, 30°.

constant, K_m, is calculated to be 1.6×10^{-7} *M*. LAD, on the other hand, was quite inactive in this system at concentrations where FAD had saturated the enzyme, although there was a progressive increase in activity as the concentration was in-

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

creased. The small amount of LAD available for this study made it impossible to test the activity at higher concentrations.[20]

The results with both enzymatic assay systems give further convincing evidence of the remarkable ability of enzyme systems to distinguish between closely related substances. In this respect, it would be of interest to isolate typical flavoprotein enzymes from *L. lactis* cells, and to determine the relative efficiency of Rb and Lx nucleotides in these systems. Since Lx nucleotides satisfy the requirements of all of the flavoprotein enzymes of this organism that are essential for its growth, they may approach their Rb counterparts more closely in activity. Even in this organism Rb promotes growth at substantially lower concentrations than Lx,[6] and it is unlikely that the Lx coenzymes function as efficiently as the Rb coenzymes.

(20) The present evidence does not constitute unequivocal proof that the material in question is actually lyxoflavin–*adenine* dinucleotide. By all criteria of paper and column chromatography, the material is clearly a lyxoflavin *dinucleotide*. After acid degradation, LMN could be identified by paper chromatography, but the equally minute amount of purine mononucleotide could not be located on the paper chromatograms.

The Shape of Pyranoside Rings. II. The Effect of Sodium Hydroxide upon the Optical Rotation of Glycosides[1]

BY RICHARD E. REEVES AND FLORINE A. BLOUIN

RECEIVED OCTOBER 25, 1956

The optical rotation of many glycosides is essentially the same in neutral aqueous solution or in *N* sodium hydroxide solution. However, there are some glycosides which show relatively large, reversible changes in optical rotation at sodium hydroxide concentrations greater than approximately 0.01 *N*. The observation that these changes are reversible argues against their being due to hydrolysis or to degradation reactions. The possibility is considered that these alkali-sensitive substances might undergo an alteration in the fine structure (conformation) of the molecules arising as a result of a tendency of axially oriented hydroxyl groups to shift toward an equatorial orientation under strongly alkaline conditions.

In a continuing search for an understanding of the effect of alkali upon the optical rotation of amylose,[2] we have been led to a general investigation of the effect of alkali upon the rotation of simple glycosides. The literature contains few observations of an effect of alkali upon the rotation of "alkali-stable" sugar derivatives, and no survey of this effect seems to have been reported. An unusual temperature dependence of optical rotation has been noted for a class of glycosides, the acylated *o*-nitrophenyl glycosides, and this had led to the development of ideas regarding the fine structure of these substances.[3] However, no significance has hitherto been attached to the fact that some glycosides are quite alkali-sensitive while others are not.

Experimental

The glycosides employed in this work possessed melting points and specific rotations in close agreement with the best values reported in the literature.

To avoid the possibility that the different optical rotations observed for neutral and alkaline aqueous solutions might be due to ionic strength differences, we have observed optical rotations in molar sodium chloride and in normal sodium hydroxide. When a substance with different rotations in water and in alkali was encountered, solutions of equal concentration were prepared in molar saline and in normal sodium hydroxide, and the solutions were mixed in various proportions in a sealed-end polarimeter tube made with a side-arm bulb to allow for mixing. Additive volumes were assumed for these solutions. In some instances observations were made at alkali concentrations greater than normal and these solutions were separately prepared in volumetric flasks. The reversibility of the alkali-induced shifts in rotation was checked by neutralizing normal or half-normal sodium hydroxide solutions with hydrochloric acid and observing the rotations of the neutralized solutions.

The observations were made with the sodium D-line at 27.5 ± 2.5° using either a 1- or a 2-dm. polarimeter cell. Because of the fixed volume requirements of the cells and the widely different availability of pure samples of the substances employed, the measurements are not uniformly precise. However, it seems to us that the greatest uncertainty due to experimental error in the difference between specific rotation in saline and in normal sodium hydroxide should not exceed 1°.

In the preparation of a solution of methyl β-D-altropyranoside the crystalline tetraacetate was dissolved in an excess of aqueous sodium hydroxide at room temperature. Back titration with standard hydrochloric acid provided assurance that all four acetate groups had been saponified. The saline and alkaline solutions were prepared from this neutralized stock solution and contained 0.53 *M* sodium acetate in addition to the sodium chloride and sodium hydroxide.

Results

The simple glycopyranosides so far examined in saline and in normal sodium hydroxide solution have fallen into two classes: those which show differences in specific rotations amounting to less than 2.5° and those which show differences greater than 7.0°. These substances are listed in Table I together with the approximate concentrations employed, their observed rotations in molar sodium chloride solution, in normal sodium hydroxide solution and the difference, sp. rot. (NaCl) minus sp. rot. (NaOH). For the first class of substances some of the differences are within the experimental error of the observations, but others, for example that of methyl β-D-glucoside, appear to lie slightly outside the experimental error. Almost an order of magnitude greater are the differences attributed to the second class of substances, described as being alkali-sensitive. These five substances have spe-

cific rotations which are appreciably altered by the presence of alkali. Upon neutralization each of these specific rotations in alkali returned to the value characteristic of a directly prepared neutral solution. Observations on the disaccharides sucrose[4] and trehalose are included in the table for comparison with the simple glycosides. An interesting aspect of the rotation of sucrose in alkaline solution will be considered below.

In Fig. 1 is plotted the change in specific rotation *versus* the log sodium hydroxide concentration for

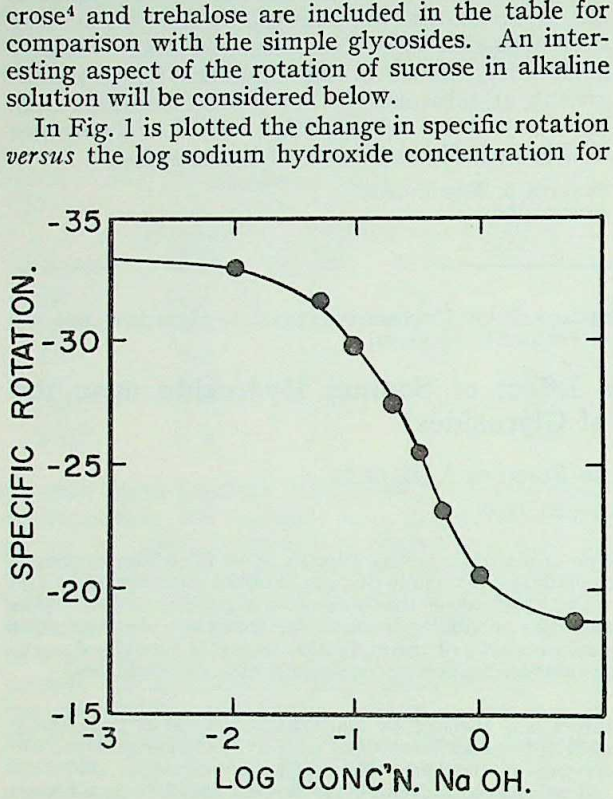

Fig. 1.—The effect of sodium hydroxide upon the optical rotation of methyl β-D-altropyranoside.

methyl β-D-altropyranoside, a member of the group possessing alkali-sensitive rotations. All observations save the one at the highest alkali concentration were made at constant ionic strength. The point of inflection of this curve lies in the vicinity of log *N* NaOH, −0.4. All other members of this group gave curves of similar shape and location on the *x*-axis.

In Fig. 2 is plotted the change in specific rotation *versus* the log sodium hydroxide concentration for sucrose. The solid circles represent observations made in the present work, at unit ionic strength up to the normal sodium hydroxide concentration. The triangles represent data reported by Thomsen in 1881.[5] Although Thomsen did not comment upon the fact, his data clearly showed the minimum occurring at 1.57 *N* alkali concentration. The highest alkali concentration employed by this worker was 2.14 *N*, and at this point the specific rotation had risen only 0.1° above the minimum; the pronounced rise at still higher alkali concentrations apparently was not observed. Thomsen did note an evolution of heat when sucrose was added to sodium hydroxide solution.

(4) It is noted that the specific rotation of 10% sucrose in molar sodium chloride is one degree lower than its rotation in water as required by the formula proposed by Brown, *Ind. Eng. Chem.*, **17**, 39 (1925).

(5) Th. Thomsen, *Ber.*, **14**, 1647 (1881).

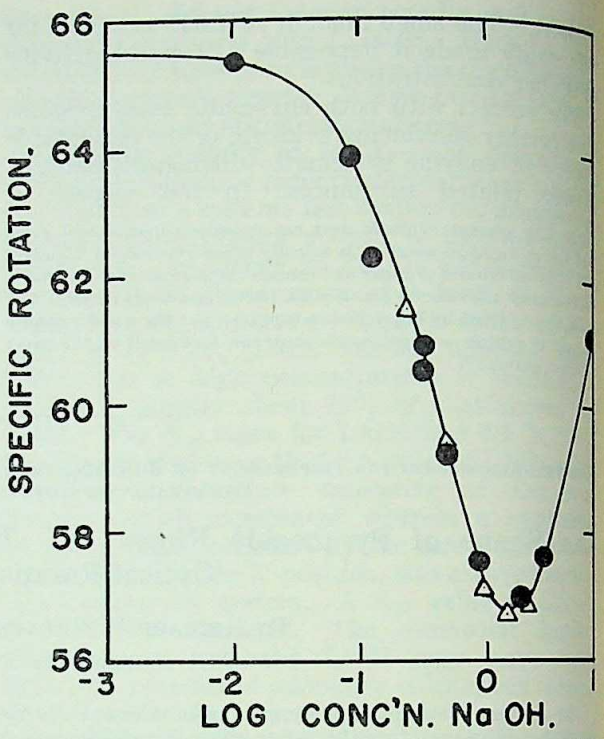

Fig. 2.—The effect of sodium hydroxide upon the optical rotation of sucrose; triangles represent observations made by Thomsen.[5]

Discussion

The position on the alkalinity scale and the general shape of the curves of alkali-sensitive substances suggest the possibility that the ionization of hydroxyl groups may be involved in these rotational shifts. Yet there are closely related glyco-

TABLE I

OPTICAL ROTATIONS OF GLYCOSIDES IN NEUTRAL AND ALKALINE SOLUTIONS

Substance	Approx. concn., %	Specific rotation, degrees *M* NaCl	*N* NaOH	Diff.

sides which are not alkali-sensitive. In searching for an explanation for the difference between the two classes of glycosides, it was considered possible that axially oriented hydroxyl groups might tend to produce a ring strain or a conformation shift at high alkali concentrations. Since charged RO^- groups would be more strongly solvated and have a greater effective volume than neutral ROH groups, it might be supposed that under ionizing conditions there would be a tendency for the ring to adopt a shape placing as many as possible of the ring hydroxyls in the equatorial positions where there is less steric hindrance than is afforded by the axial positions. We have chosen to accept the hypothesis that hydroxyl groups which are axially oriented in neutral solution may produce reversible rotational changes due to their tendency to move to equatorial positions at high alkalinity and to examine the implications of this hypothesis in the light of the present observations.

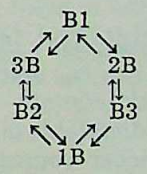
Except for the α-1,4-linked glucose polysaccharides, there is no reason to doubt that the C1 conformation is the favored shape of the D-glucopyranoside ring. In this conformation there are no axially oriented hydroxyl groups and, in agreement with the hypothesis, all the simple glucosides (and xylosides) yet examined have exhibited optical rotations which were similar in neutral and alkaline solution.

In the D-galactose (L-arabinose) series the favored conformation again appears to be C1,[6] but in this series there is an axial hydroxyl group at carbon atom 4. Both α- and β-galactosides and the arabinoside were alkali-sensitive. In agreement with the hypothesis this might be due to a strain imposed upon the C1 ring, or to displacement of an equilibrium in the direction of a form possessing fewer axial hydroxyl groups. In the latter event the effect produced by alkali might be to shift a C1 $\rightleftarrows$ B2 equilibrium to the right. In the B2 conformation the hydroxyl groups at carbon atoms 2, 3 and 4 are equatorial in the D-galactose series.

It is observed that the methyl α-pyranosides of D-mannose, D-altrose, D-lyxose and L-rhamnose fall into the alkali-stable class. Each of these configurations would possess one or more axial hydroxyl groups if it existed in a chair form. But for each of these α-anomers there is a boat-form conformation with *no* axial substituents: D-mannose and D-lyxose, B1; D-altrose, 2B; and L-rhamnose, 1B. These forms may be reconciled with the cuprammonium-complexing behavior of these glycosides as well as the previously suggested chair forms.[7]

To argue, as the present hypothesis appears to require, that boat-form rings represent the lowest energy state for some pyranosides brings into question a previous hypothesis that "Pyranose rings assume a chair form in preference to any boat form whenever both are structurally possible."[7] It may be the case that although chair forms are generally of lower energy than boat forms, the difference is more than offset when a boat form allows *all* ring substituents (other than hydrogen) to be equatorial. It should be remarked that in simple pyranosides geometrically regular boat forms are unlikely because of the high energy resulting from the eclipsed valence angles on some of the adjacent atoms. Therefore, the suggestion that methyl α-D-mannoside may prefer the B1 conformation should be construed to mean that it may take a shape approximating that of the pure B1 form but distorted into the region where the tendency of the large groups to move into the equatorial plane is balanced by the repulsion brought about by approaching the eclipsed valence position. There is already experimental evidence that some of these glucosides do not take a pure boat form, for to do so would place two adjacent hydroxyl groups in the true *cis* position where they should be almost instantly cleaved (titratable) with lead tetraacetate. It has been shown that this does not occur in the case of methyl α-D-mannoside, α-D-lyxoside or α-D-altroside.[7]

Boat-form rings are unlike chair forms in possessing a flexibility so that positions intermediate between Reeves' designated forms can occur without greatly increased ring strain. There is a sequence in which one boat form may be changed into another, as is shown in the following diagram. Unless certain of the forms are prohibited by steric interference of the substituents, boat forms may shift in either direction around the ring shown in the diagram.



Faced with increasing evidence that boat-form rings may have an important role in carbohydrate chemistry, it would be desirable to give further consideration to the problem of designating the various ring shapes. It now seems clear that Reeves' designations B1, 1B, etc., will not be sufficiently precise. However, until a better system is devised it is proposed to describe the boat forms as *e.g.* "approximating" a particular conformation; or as intermediate between B1 and 3B, or between such other forms as are adjacent to each other in the above diagram.

The β-mannose and β-altrose configurations differ from their anomers in having no conformation which places all ring substituents in the equatorial position. Without attempting, for the present, to assign most stable ring conformations to these substances, it would appear that neutral aqueous solutions might contain some finite proportion of axial hydroxyl groups and that this proportion might be reduced by ring shifts at high alkali concentrations.

The alkali-stability of the optical rotation of methyl α-D-guloside presents some unusual aspects. Any of the conformations compatible with the cuprammonium complexing behavior of this substance[7] require at least one axial hydroxyl group. As far as the hitherto recognized factors governing ring stability are concerned, the guloside could as well shift from C1 toward 1B under the influence of alkali as the galactosides might shift from C1 toward B2. However, inspection of scale

models of α-D-hexosides reveals extensive interference between the hydrogen atom of carbon 4 and the oxygen atom at carbon 1 in the 1B conformation, an interference not present in the proposed galactoside shift C1 ⇄ B2. It may be that the 1B conformation is prohibited for steric reasons in the α-D-hexose (and pentose) series, or its energy level is so much greater than that of the other forms that it cannot be overcome by the tendency of a charged axial hydroxyl group to move to the equatorial position. It is noted that methyl β-D-guloside might be expected to show an alkali-sensitive rotation due to the shift of a C1 ⇄ 1B equilibrium.

The hypothesis that hydroxyl groups which are axially oriented in neutral solution move to equatorial positions under conditions of high alkalinity requires further confirmation. Work to prove or disprove the concept is in progress. No attempt will be made at this time to interpret the alkali-sensitive behavior of the disaccharide sucrose, beyond observing that since the simple α-glucopyranosides (and trehalose) fail to show the same type of behavior, it would be logical to attribute the observed effect to changes in the fructofuranoside portion of the sucrose molecule.

Acknowledgment.—Some of the glycosides employed in this work were supplied by Drs. N. K. Richtmyer and H. S. Isbell.

4-Allylveratrole from *Anemopsis californica*

BY W. J. HORTON AND E. G. PAUL

RECEIVED NOVEMBER 5, 1956

The steam distillable oil from rhizomes of *Anemopsis californica* contains 4-allylveratrole which contributes the pungency to the odor of the oil. A second compound of unknown nature greatly masks the spice-like odor. A number of 4-alkylveratroles and their 5-sulfonamides were prepared in an effort to identify the sulfonamide (2-propyl-4,5-dimethoxybenzenesulfonamide) derived from the natural oil.

Anemopsis californica has a distinctive odor with a faint undertone of a spicy material. Both leaves and rootstock contain the odorant which resides in the steam distillable oil. Since the woody rhizome was the richer source, oil was obtained from this portion of the plant and submitted to fractional distillation using a small Vigreux column. A redistilled sample gave analytical data in excellent agreement with $C_{12}H_{16}O_2$. Catalytic hydrogenation indicated a single olefinic bond and oxidation produced veratric acid which was confirmed by the preparation of veratramide. The ultraviolet absorption also suggested the veratryl ring[1] with the olefinic bond in a non-conjugated position. Synthetic work was therefore designed so as to determine the nature of the butyl group in hydrogenated *Anemopsis* oil. A comparison of synthetic 4-butylveratroles (Table II) with the alkylveratrole derived from the oil was facilitated by the preparation of a crystalline sulfonamide from the hydrogenated oil. However, re-examination of the original analysis became necessary when none of the synthetic 4-butylveratroles nor isoamylveratrole gave a sulfonamide identical to the unknown sulfonamide (Table III). Furthermore the analytical values obtained from the unknown sulfonamide indicated a propyl group rather than a butyl group. Subsequent samples of the oil submitted to analysis pointed to contamination in the original oil by compounds of higher carbon content so as to make the excellent agreement with the formula $C_{12}H_{16}O_2$ fortuitous. The preparation of 4-propylveratrole (Table II) and its sulfonamide together with the ultraviolet spectra identify this part of the original oil as 4-allylveratrole.

The acyl-3,4-dimethoxyphenones were prepared by the excellent procedure of Gardner[2] and are collected in Table I. Clemmensen reduction gave the corresponding 4-alkylveratroles (Table II) whose sulfonamides are presented in Table III.

We are greatly indebted to Prof. Walter P. Cottom of our Department of Botany for discussions and to Mr. L. Woodbury at Dixie College, St. George, Utah, who so kindly provided the plant material.

Experimental[3]

The plant material collected in the vicinity of St. George, Utah, was divided into rhizomes and stems, the rhizomes were washed in water to remove adhering soil and thoroughly air-dried. They were then passed through a food chopper to produce material of the appearance of a brown sawdust. A 200-g. portion was steam distilled until 6 l. of distillate was obtained. The distillate was saturated with sodium chloride and extracted with ether. The residual oil on distillation of the dried ether extract weighed 17.4 g. (8.7%). This oil was divided into three fractions by distillation: (a) 6.22 g. of pale yellow, b.p. 137–141° (23 mm.); (b) 5.38 g. of yellow green, b.p. 141–146° (23 mm.); and (c) 2.44 g. of green, b.p. 147–155° (23 mm.). All fractions gave a brown color with tetranitromethane and a negative test with ferric chloride except (c) which was dubious. Fraction (a) gave a red complex with picric acid but a solid picrate could not be obtained.

In a similar manner from 500 g. of rhizomes the following fractions were collected by distillation at 23 mm. through a 25-cm. Vigreux column: 0.40 g., 90–106°; 16.16 g., 135–141.5°; "Fraction C" 8.09 g., 141–143°; 11.67 g., 144–151° (total yield 7.3%).

By distillation of fraction b above, a sample was obtained for analysis.

Anal. Calcd. for $C_{12}H_{16}O_2$: C, 74.96; H, 8.39; O, 16.64. Found: C, 74.89; H, 8.34; O, 17.0.

The fraction b.p. 144–151° (23 mm.) was redistilled collecting a portion, b.p. 129–130° (14 mm.). From the latter a cut, b.p. 146.5° (29 mm.), was analyzed; $n^{25}D$ 1.52925, d^{25}_4 1.028; $\lambda_{max}^{ethanol}$ 230 mμ (log ε 3.83), 280 mμ (log ε 3.39).

Anal. Calcd. for $C_{11}H_{14}O_2$: C, 74.13; H, 7.92; O, 17.95. Found: C, 74.66; H, 8.22; O, 17.4.

Catalytic Hydrogenation of "Fraction C."—A redistilled portion (7.55 g.) of the 8.09-g. middle cut above with 60 ml. of absolute ethanol and 300 mg. of platinum oxide was shaken with hydrogen at slightly above atmospheric pressure. After absorption of one mole of gas, the reaction stopped. The catalyst was removed by filtration, and the alcohol was distilled *in vacuo*. Distillation of the residue gave a middle cut, b.p. 164–164.5° (66 mm.), $n^{25}D$ 1.5131.

Anal. Calcd. for $C_{12}H_{18}O_2$: C, 74.19; H, 9.34; O, 16.47. Found: C, 74.92; H, 9.31; O, 16.0.

The residual material boiled at 144–145° (29 mm.) and was later redistilled for analysis, b.p. 143–144° (29.5 mm.), $n^{25}D$ 1.5125, d^{25}_4 0.9969, $\lambda_{max}^{ethanol}$ 278 mμ (log ε 3.62), 228 mμ (log ε 4.05).

Anal. Calcd. for $C_{11}H_{16}O_2$: C, 73.30; H, 8.95; O, 17.75. Found: C, 74.64; H, 9.07; O, 16.6.

Oxidation with Permanganate.—The reaction of 3.84 g. of the original oil with powdered potassium permanganate in aqueous pyridine[4] gave 1.5 g. of acid, m.p. 172–178°. The neutral equivalent was 177; for veratric acid, 182. After sublimation (0.17 mm.) and crystallization from benzene, it melted at 171.5–179.5°. On mixing with veratric acid from authentic veratraldehyde (m.p. 176.5–180°), the melting point was 176–181.5°.

The amide prepared from the acid melted at 162.5–167° and mixed with authentic veratramide (m.p. 162–165°) melted at 161–164°.

2-(3,4-Dimethoxyphenyl)-2-butene.—Methylmagnesium iodide from 5.62 g. (0.231 mole) of magnesium in 150 ml. of ether was allowed to react with 15 g. (0.0774 mole) of 3,4-dimethoxypropiophenone dissolved in 70 ml. of

2-Pyrones. XXVI. Alkylidene Methylglutaconic Acids and 3,6-Dialkyl-5-carboxy-5,6-dihydro-2-pyrones from Methyl β-Methylglutaconate and Ethyl Isodehydroacetate and their Isomerization and Decarboxylation

BY RICHARD H. WILEY AND H. G. ELLERT

RECEIVED NOVEMBER 1, 1956

The condensation of aliphatic aldehydes with methyl β-methylglutaconate gives alkylidene glutaconic acids (III) and carboxy-δ-lactones (IV). Comparable yields are obtained using ethyl isodehydroacetate in place of the glutaconate. Short-chain and branched-chain aldehydes give diacids (III); longer chain and unbranched aldehydes give carboxylactones (IV). Decarboxylation of these products gives the dienonoic acids VI and δ-lactones V. The lactones can be hydrolyzed to the corresponding acids and the preferred route to the isoprenoid acid, 3,7-dimethyl-2,4-octadienoic acid, is *via* decarboxylation of the dipotassium salt to the lactone which is then hydrolyzed. The carboxy isoprenoid acid, γ-isoamylidene-β-methylglutaconic acid, has been obtained in three forms, m.p. 149–150, 163° and 181–184°. The isomer m.p. 149–150° has been assigned the 4-*cis*-2-*trans* structure; the isomer m.p. 181–184° has been assigned the 2-*trans*-4-*trans* structure on the basis of comparisons of their infrared spectra with those of *cis* and *trans* β-methylglutaconic acid. The δ-lactone structure has been established by conversion to the tetrahydro-2-pyrone structure with properties similar to those of other known tetrahydro-2-pyrones.

One of the few known methods for adding an isoprenoid unit to an organic structure involves the base-catalyzed condensation of dimethyl β-methylglutaconate (II) with an aldehyde[1–4] to give γ-arylidene or alkylidene-β-methylglutaconic acids (III). Although previously utilized principally for the synthesis of vitamin A, this method also makes possible the synthesis of acyclic isoprenoid acids of 10 or 15 carbons, which are of current interest as possible intermediates in the biosynthesis of cholesterol[5–8] with varying substituents, notably a 4-carboxyl group. Since previous studies of the reaction have not included comprehensive studies of the scope of the reaction using aliphatic aldehydes, we have undertaken a study of such reactions which we wish to record here along with our observations on the previously unreported accompanying cyclization to lactones (IV), the decarboxylation, and the geometrical isomerism of the γ-alkylidene-β-methylglutaconic acids (III). Particular attention has been directed to 3,7-dimethyl-2,4-octadienoic acid—an isomer of geranic acid and its 4-carboxy derivative.

The condensation reaction previously has been conducted using the aldehyde and dimethyl β-methylglutaconate (II) in methanolic potassium hydroxide. With aliphatic aldehydes the reaction is exothermic and the crystalline potassium salt of the product begins to precipitate shortly after mixing the reactants. The products from aliphatic aldehydes have been isolated in 51–91% yields (Table I). Since the β-methylglutaconate itself is formed readily from ethyl isodehydroacetate (I) by the action of methanolic potassium hydroxide, the utilization of the latter in place of the β-methylglutaconate to give the products directly in one step has been examined and found to be satisfactory. The products obtained by the two processes are comparable in all respects observed. This reaction is also exothermic and gives comparable yields with hexaldehyde (55 as compared to 58%), heptaldehyde (48 as compared to 51%), and pelargonaldehyde (61 as compared to 76%). With isobutyraldehyde (59 as compared to 91%) and isovaleraldehyde (43 as compared to 84%), the yield is noticeably poorer. Allowance for a 75% yield from isodehydroacetate to β-methylglutaconate indicates that the one-step process gives comparable yields with considerable saving of effort by avoiding isolation of the intermediate ester. The combined one-step process has been used with several other aliphatic and aromatic aldehydes listed in Table II. β-Ethoxypropionaldehyde, tiglic aldehyde and acetaldehyde failed to give characterizable products.

A unique feature of this reaction, which has not been recognized previously, is that not only diacids IV but also the isomeric carboxylactones IV are

[a] Recrystallized from A, methanol–water; B, methanol; C, ethyl acetate; E, petroleum ether–ether; P, ethyl acetate–petroleum ether. [b] Diacid III. [c] Carboxylactone IV. [d] See ref. 4. [e] In cm.$^{-1}$.

formed. It appears that the short chain and branched-chain aliphatic aldehydes and aromatic aldehydes give exclusively the diacid products III and that the longer chain, unbranched aldehydes give principally the carboxylactones IV as products. The contrast in behavior in this respect between valeraldehyde and isovaleraldehyde and between *n*-octaldehyde and 2-ethylhexaldehyde is striking. Assuming that the 2-*cis* form is needed for cyclization and that the 2-*trans* form is customarily obtained[4] in this reaction, isomerization and subsequent lactonization must take place more readily under the conditions used in the reaction with the unbranched types. It is difficult to assign a reason for this in the absence of additional data about the conditions required for geometrical isomerization of these structures. With some of these materials it is possible to lactonize the dibasic acids, although in low yield. Thus, γ-isoamylidene-β-methylglutaconic acid (III, R = isobutyl) is lactonized in 16% yield by treatment with acid. With others it is possible to obtain mixtures of both isomers. Thus, the potassium salt obtained from the hexaldehyde reaction (III, R = *n*-amyl) gives a mixture of the lactone IV and the dibasic acid III when exactly neutralized at 0°. The two types of products formed in this reaction are readily distinguished by their neutral equivalents. The infrared absorption characteristics of the dibasic acids show typical carboxyl carbonyl absorption bands at 1690–1680, at 1455–1445, 1430–1425 and at 950–935 cm.$^{-1}$. The lactones show a strong carbonyl absorption at 1730–1725 cm.$^{-1}$ typical of δ-lactones. The δ-lactone structure is further confirmed by the conversion described in following paragraphs of one derivative to a similar tetrahydro-2-pyrone obtained by another synthetic route. These considerations eliminate the alternative γ-lactone structure.

During the process of decarboxylation the dibasic acids and the carboxylactones give either acids such as VI or lactones (5,6-dihydro-2-pyrones) such as V. The dibasic acids (R = isopropyl, isobutyl) decarboxylate in 10–12% yields using 2,4-lutidine and cupric acetate as the catalyst. These products are assumed to have lost the carboxyl groups on the 4-carbon atom, by analogy with previously reported data,[9] to give dienoic acids. These acids are unstable toward oxygen and readily form peroxides. Their purification is difficult and this accounts in part for the low yields in the decarboxylation. Although reactions of these acids with bromine and with maleic anhydride have not given readily characterizable derivatives, the benzylthiuronium salts readily are formed and crystallize nicely.

When the crude dipotassium salts are heated in glacial acetic acid, decarboxylation occurs and the product is the lactone (V, R = isobutyl, *n*-amyl or 2′,6′-dimethyl-5′-heptenyl). Using lutidine and cupric acetate for the decarboxylation, a mixture of lactone V and acid VI results from other dibasic acids (R = propyl, 1′-ethylamyl) and from the carboxylactone (IV, R = butyl). Two of the lactones obtained by decarboxylation (V, R = isobutyl, propyl) have been converted to the open-chain acids by hydrolysis with alcoholic potassium hydroxide. This hydrolysis gave 38% of 3,7-dimethyl-2,4-octadienoic acid (VI, R = isobutyl) and this route *via* dibasic acid salt, decarboxylation to the lactone (71%) and hydrolysis (38%) is pre-

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

ferred to that *via* the decarboxylation of the dibasic acid (12%) since the yield is better and the isolation of the dicarboxylic acid is avoided.

The lactone or 5,6-dihydro-2-pyrone structure assigned to the compounds IV and V has been confirmed by catalytic reduction of 6-butyl-4-methyl-5,6-dihydro-2-pyrone to 6-butyl-4-methyltetrahydro-2-pyrone with infrared absorption characteristics identical in all significant respects with that of 4,6-dimethyltetrahydro-2-pyrone prepared previously.[10] Carbon–hydrogen absorption at 2960 cm.$^{-1}$, a carbonyl doublet at 1735–1710 cm.$^{-1}$ and the ester carbon–oxygen absorption at 1240 cm.$^{-1}$ are the most prominent bands and are at the same location in the spectra of both of these compounds.

The geometric isomerism of acids such as γ-isoamylidene-β-methylglutaconic acid is of considerable significance. This acid is a carboxy isoprenoid acid which by virtue of its structural relation to β-methylglutaconic acid is of interest as a possible intermediate in the biosynthesis of cholesterol. The fact that only *trans*-, not *cis*-, β-methylglutaconic acid is an effective intermediate in this process and that squalene, another apparent intermediate, is of the *trans* configuration, suggest that geometric isomers of the acid should be available for biosynthetic examination.

Attempts to isomerize the acids, m.p. 149–150°, with iodine and ultraviolet light gave an isomer, m.p. 163°, which was also obtained by slow recrystallization of the acid, m.p. 149–150°, from ether–ligroin. The facts that no depression of the melting point of the acid, m.p. 149–150°, is observed with mixtures of the two and that the infrared spectra of the two materials are apparently identical indicates that these two forms may be isomorphic. This does not eliminate the possibility that they are geometric isomers or mixtures thereof.

An isomer of γ-isoamylidene-β-methylglutaconic acid has been obtained by altering the conditions used in the preparation of this acid from methyl β-methylglutaconate. If double the amount of potassium hydroxide is used in a procedure otherwise similar, a product is obtained which melts at 181–184°. This gives a mixed m.p. of 144–151° with the isomer, m.p. 150°. The infrared spectra of the two (Fig. 1) are substantially identical except in the 1285 cm.$^{-1}$ (C–O stretching or O–H deformation) and 1175 cm.$^{-1}$ (band progression) regions where certain minor differences can be correlated with differences in the infrared spectra for *cis*- and *trans*-β-methylglutaconic acid (Fig. 2). There is no substantial difference in the C–H out-of-plane deformation region where disubstituted *cis–trans*-ethylenes show marked differences,[11] but it has previously been noted[12] that trisubstituted ethylenes do not show such differences. *cis*-β-Methylglutaconic acid shows maxima at 1277 and 1148 cm.$^{-1}$ shifted to 1264 and 1167 cm.$^{-1}$, with a shoulder at 1152 cm.$^{-1}$ in the *trans*-acid. The isomer, m.p. 150°, shows maxima at 1289 cm.$^{-1}$ shifted to 1284 cm.$^{-1}$ with shoulders at 1295 and 1310 cm.$^{-1}$ and a new band at 1263 cm.$^{-1}$

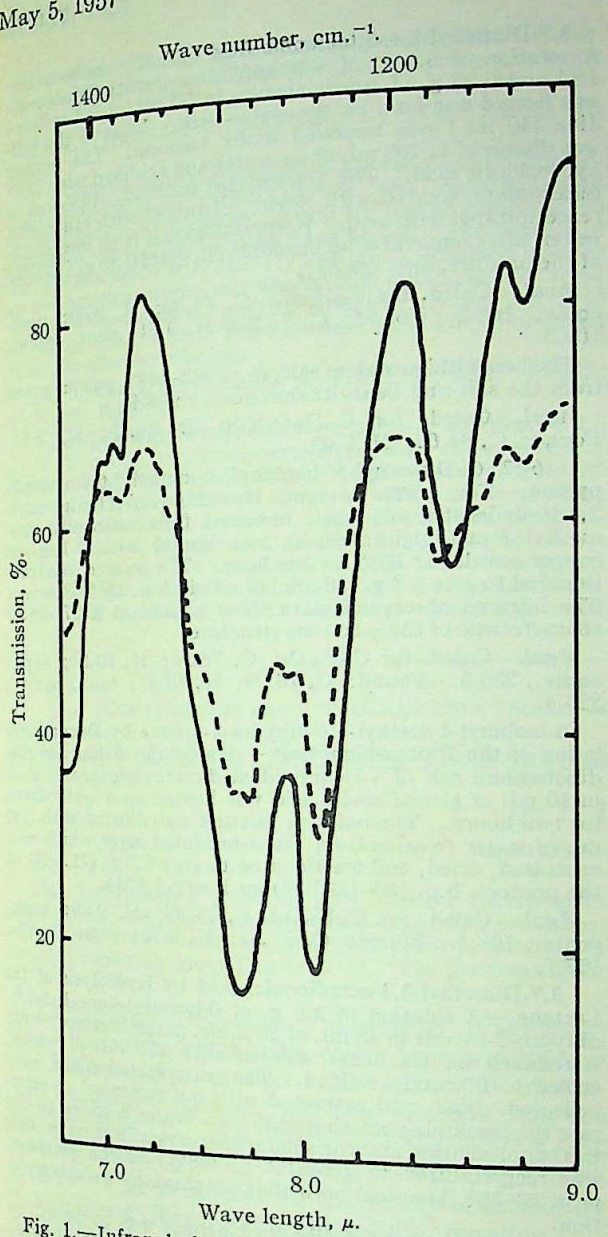

Fig. 1.—Infrared absorption of γ-isoamylidene-β-methylglutaconic acids: m.p. 149–150° (——); m.p. 181–184° (- - - -).

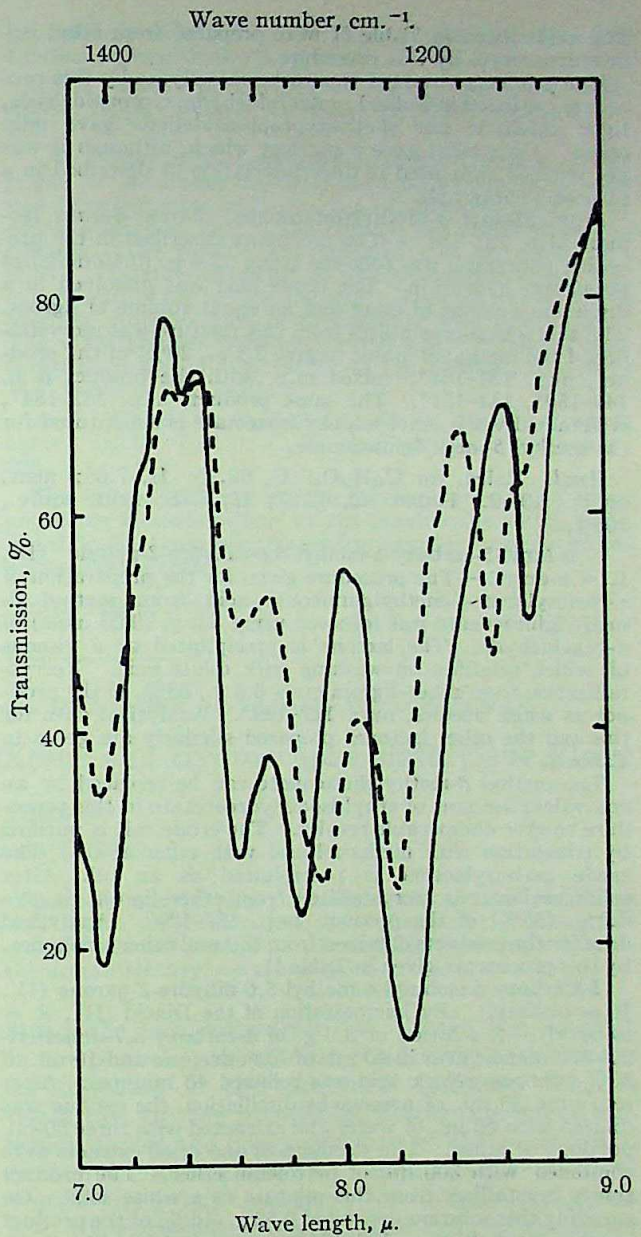

Fig. 2.—Infrared absorption of *cis*- (——) and *trans*- (- - - -) β-methylglutaconic acids.

support a tentative assignment of the *trans–trans* structure to the isomer, m.p. 181–184°, on the basis that the *cis–cis* structure would have undergone lactonization. The 4-*cis*-2-*trans* structure may be tentatively assigned to the isomer, m.p. 150°, on the basis of reasons previously analyzed.[4,9]

Acknowledgment.—The authors wish to acknowledge with appreciation partial support of this research by a grant (NSF-G1918) from the National Science Foundation.

Experimental[13]

The ethyl isodehydroacetate,[14] b.p. 139–142° (5 mm.), and the methyl β-methylglutaconate,[15] b.p. 142° (30 mm.), used in these studies were prepared by the methods previously given. The authors are indebted to the Tennessee Eastman Co. for additional supplies of ethyl isodehydroacetate. The aldehydes were commercial samples and were distilled prior to use. Details of typical reactions will be given. Data on other reactions and characterization of the products are presented in the Tables.

γ-Isoamylidene-β-methylglutaconic Acid (III, R = isobutyl). **From Methyl β-Methylglutaconate. 4-*cis*-2-*trans* Isomer, M.p. 149–150°.**—To a solution of 4.3 g. (0.05 mole) of freshly distilled isovaleraldehyde and 8.6 g. (0.05 mole) of methyl β-methylglutaconate in 10 ml. of methanol was added a filtered solution of 11.2 g. (0.2 mole) of potassium hydroxide in 30 ml of methanol. An immediate exothermic reaction was followed by precipitation of the dipotassium salt of the acid. After six hours the mixture was cooled to 0° and filtered. The salt was washed with cold methanol, dried, and dissolved in water. Acidification with concd. hydrochloric acid precipitated the crude product. Recrystallization from methanol–water gave 8.9 g., 84.6%, of the product, m.p. 149–150°. Analytical data are given in Table I. Slow recrystallization from ether–ligroin gives the acid in a form which has m.p. 163°.

The methyl β-methylglutaconate can be replaced with an equivalent amount of ethyl isodehydroacetate. The crude salt is triturated at 0° first with methanol then with ether before conversion to the acid. Recrystallization of the acid gives 6 g. (43.3%) of the product, m.p. 149–150°.

(13) Analysis by Micro Tech Laboratories, Skokie, Ill., m.p.'s are uncorrected.

The acids listed in Table II were prepared from ethyl isodehydroacetate by this procedure.

The products obtained from other aldehydes by this procedure are listed in Table I. Acetaldehyde, crotonaldehyde, tiglic aldehyde and β-ethoxypropionaldehyde gave only resins. Citronellal gave a product which, although it was not purified, was used in decarboxylation as described in a following paragraph.

From Methyl β-Methylglutaconate. 2-*trans*-4-*trans* Isomer, M.p. 181–184°.—The procedure described in the preceding paragraph was followed using 22.4 g. (0.40 mole) of potassium hydroxide. The crude acid was dissolved in a minimum amount of ether and an equal volume of ligroin. The acid which crystallizes from this mixture was recrystallized from methanol–water to give 2.1 g., 20%, of the product, m.p. 181–184°; mixed m.p. with the product m.p. 149–150°, 144–151°. The same product, m.p. 181–184°, is obtained when ethyl isodehydroacetate is substituted for the methyl β-methylglutaconate.

Anal. Calcd. for $C_{11}H_{16}O_4$: C, 62.25; H, 7.60; neut. equiv., 106.2. Found: C, 62.27; H, 7.75; neut. equiv., 106.1.

6-Amyl-5-carboxy-4-methyl-5,6-dihydro-2-pyrone (IV, R = *n*-amyl).—The procedure given for the preparation of γ-isoamylidene-β-methylglutaconic acid from methyl β-methylglutaconate was followed using 5.0 g. (0.05 mole) of *n*-hexaldehyde. The lactone is precipitated as a viscous oil which solidifies on washing with dilute acid. Recrystallization from ether–ligroin gives 6.5 g., 58%, of the product as white needles, m.p. 127–129°. Analytical data for this and the other lactones prepared similarly are given in Table I.

The methyl β-methylglutaconate can be replaced by an equivalent amount of ethyl isodehydroacetate in this procedure to give comparable results. The crude salt is purified by trituration with methanol and with ether at 0°. The crude carboxylactone is precipitated as an oil. After solidification it is recrystallized from ether–ligroin to give 6.2 g. (55%) of the product, m.p. 127–129°. Analytical data for the products obtained from this and other aldehydes, by this process are given in Table II.

5-Carboxy-6-isobutyl-4-methyl-5,6-dihydro-2-pyrone (IV, R = isobutyl). **By Lactonization of the Diacid** (III, R = isobutyl).—A solution of 2.0 g. of 4-carboxy-3,7-dimethyl-2,4-octadienoic acid in 40 ml. of C.P. acetone and 10 ml. of 50% aqueous sulfuric acid was refluxed 45 minutes. After removing 30 ml. of acetone by distillation, the residue was diluted with 50 ml. of water and extracted with three 50-ml. portions of ether. The decolorized and dried extracts were combined with 300 ml. of petroleum ether. The product slowly crystallizes from this mixture as a white solid. On standing this solution deposited 0.32 g. (16%) of the product as white crystals, m.p. 133–134°.

Anal. Calcd. for $C_{11}H_{16}O_4$: C, 62.25; H, 7.60; neut. equiv., 212.2. Found: C, 62.75; H, 7.93; neut. equiv., 212.5.

γ-Hexylidene-β-methylglutaconic Acid (III, R = *n*-amyl).—This acid was obtained by careful acidification of the crude salt obtained in the reaction of *n*-hexaldehyde with ethyl isodehydroacetate as described above. The neutralization of the salt is carried out by the dropwise addition of the calculated amount of 0.1 *N* hydrochloric acid. The precipitated product is a mixture of the carboxylactone and dicarboxylic acid. Fractional recrystallization from ether–ligroin gives 27% of the dibasic acid, m.p. 110–112°, as the less soluble fraction.

Anal. Calcd. for $C_{12}H_{18}O_4$: C, 63.70; H, 8.02; neut. equiv., 113.1. Found: C, 63.74; H, 8.07; neut. equiv., 115.6.

3,6-Dimethyl-2,4-heptadienoic Acid (VI, R = isopropyl).—A solution of 5.0 g. of γ-isobutylidene-β-methylglutaconic acid and 0.125 g. of cupric acetate in 25 g. of 2,4-lutidine was heated in a water-bath for one hour. The lutidine was removed under vacuum. Dilution of the residue with 25 ml. of water followed by acidification precipitated the crude acid in 68% yield. Recrystallization gave 0.40 g. (10.4%) of the product, m.p. 82–86°.

Anal. Calcd. for $C_9H_{14}O_2$: C, 70.10; H, 9.15; neut. equiv., 154.2. Found: C, 70.07; H, 9.19; neut. equiv., 157.3.

3,7-Dimethyl-2,4-octadienoic Acid (VI, R = isobutyl).—A solution of 8.0 g. of γ-isoamylidene-β-methylglutaconic acid and 0.25 g. of cupric acetate in 50 ml. of 2,4-lutidine was heated one hour on the water-bath. Most of the lutidine (40 ml.) was removed under vacuum. The residue was dissolved in 100 ml. of ice-water and acidified with 12 *N* hydrochloric acid. The precipitated solid was dissolved in bicarbonate, treated with Norite, extracted with ether, and reprecipitated with acid. Recrystallization from methanol-water, after removal of an insoluble oil, gives 0.80 g. (12.6%) of the product, m.p. 50–53°.

Anal. Calcd. for $C_{10}H_{16}O_2$: C, 71.39; H, 9.59; neut. equiv., 168.2. Found: C, 71.26; H, 9.71; neut. equiv., 169.2.

The benzylthiouronium salt, m.p. 143–144°, was prepared from the salt and benzylthiouronium chloride.

Anal. Calcd. for $C_{18}H_{26}O_2N_2S$: C, 64.65; H, 7.81. Found: C, 64.62; H, 7.92.

6-(2′,6′-Dimethyl-5′-heptenyl)-4-methyl-5,6-dihydro-2-pyrone.—Ten grams of crude 4-carboxy-3,7,11-trimethyl-2,4,10-dodecatrienoic acid, obtained from citronellal and methyl β-methylglutaconate, was heated with 0.1 g. of copper powder at 165° for one hour. The residue was fractionated to give 3.2 g. (38.2%) of an oil, b.p. 155° (3 mm.). The infrared absorption data show a band at 1727 cm.$^{-1}$ characteristic of the γ-lactone structure.

Anal. Calcd. for $C_{15}H_{24}O_2$: C, 76.22; H, 10.24; sapn. equiv., 236.3. Found: C, 76.09; H, 10.41; sapn. equiv., 226.4.

6-Isobutyl-4-methyl-5,6-dihydro-2-pyrone by Decarboxylation of the Dipotassium Salt.—A solution of 10 g. of the dipotassium salt of γ-isoamylidene-β-methylglutaconic acid in 10 ml. of glacial acetic acid was heated on a water-bath for two hours. The reaction mixture was diluted with 300 ml. of water to separate a water-insoluble layer which was separated, dried, and fractionated to give 4.3 g. (71.5%) of the product, b.p. 130–133° (8 mm.), $n^{26}D$ 1.4754.

Anal. Calcd. for $C_{10}H_{16}O_2$: C, 71.39; H, 9.59; sapn. equiv., 168.1. Found: C, 71.27; H, 9.71; sapn. equiv., 167.7.

3,7-Dimethyl-2,4-octadienoic Acid by Hydrolysis of Its Lactone.—A solution of 3.0 g. of 6-isobutyl-4-methyl-5,6-dihydro-2-pyrone in 45 ml. of 20% alc. potassium hydroxide is refluxed for six hours, diluted with 100 ml. of water, cooled to 0°, and acidified. The precipitated solids were collected, dried, and extracted with hot methanol to separate the insoluble potassium sulfate. Water is added to the methanol solution and the solid which crystallizes on cooling was recrystallized to give 1.1 g. (38%) of the product, m.p. 50–53°, identical with that obtained by decarboxylation.

6-Amyl-4-methyl-5,6-dihydro-2-pyrone was prepared by the process given above for the 6-isobutyl analog. Fractionation gave 66.7% of the product, b.p. 134° (5 mm.), $n^{25}D$ 1.4705.

Anal. Calcd. for $C_{11}H_{18}O_2$: C, 72.49; H, 9.96; sapn. equiv., 182.2. Found: C, 72.30; H, 10.16; sapn. equiv., 176.

4-Methyl-6-propyl-5,6-dihydro-2-pyrone.—A solution of 20 g. of γ-butylidene-β-methylglutaconic acid and 0.25 g. of cupric acetate in 45 ml. of 2,4-lutidine was heated at 100° for 45 minutes. Addition of ice and acidification precipitates an oil which was taken up in ether. The crude product obtained from these ether extracts was fractionated to give 7.5 g. of material, b.p. 112–135° (6 mm.), which showed the infrared carbonyl absorption characteristics of a mixture of the δ-lactone and unsaturated acid (1738 and 1680 cm.$^{-1}$). The mixture was dissolved in water, neutralized, and extracted with ether to obtain 2.1 g. (13.5%) of the pure 2-pyrone, b.p. 124° (7 mm.), $n^{30}D$ 1.4821.

Anal. Calcd. for $C_9H_{14}O_2$: C, 70.09; H, 9.15; sapn. equiv., 154.2. Found: C, 70.05; H, 9.23; sapn. equiv., 154.

3-Methyl-2,4-octadienoic Acid Benzylthiouronium Salt.—A solution of 0.5 g. of 4-methyl-6-propyl-5,6-dihydro-2-pyrone in 10 ml. of methanol is refluxed for one hour with a solution of 0.2 g. of potassium hydroxide in 5 ml. of water. Neutralization precipitated the 3-methyl-2,4-octadienoic acid as a crude oil which could not be purified by crystallization or distillation. Addition of a slight excess of benzyl-

thiouronium chloride in methanol precipitated the salt. Recrystallization gave 0.75 g. (68%) of the product as white needles, m.p. 150°.

Anal. Calcd. for $C_{17}H_{24}O_2N_2S$: N, 8.74. Found: N, 8.98.

6-Butyl-4-methyl-5,6-dihydro-2-pyrone.—5-Carboxy-6-butyl-4-methyl-5,6-dihydro-2-pyrone was decarboxylated in 2,4-lutidine with cupric acetate by the procedure given above for the 6-propyl analog given above. The mixture of lactone and acid, b.p. 115–117° (4 mm.), obtained from 20 g. of starting material was dissolved in alkali and extracted with ether to obtain 6.7 g. (42.5%) of the product, b.p. 124° (4 mm.), $n^{11}D$ 1.4935. The pure acid could not be obtained from the alkaline solution.

Anal. Calcd. for $C_{10}H_{16}O_2$: C, 71.39; H, 9.59. Found: C, 70.88; H, 9.73.

6-Butyl-4-methyltetrahydro-2-pyrone.—A solution of 4.5 g. of the crude dihydro-2-pyrone obtained as described in the preceding paragraph in 50 ml. of ether was hydrogenated over palladium-on-charcoal catalyst. The crude product was neutralized and extracted with ether. The ether extracted oil was fractionated to give 1.6 g. (35%) of the product, b.p. 114° (4 mm.), $n^{10}D$ 1.4517. This compound shows infrared absorption bands in carbon tetrachloride at 2959 (C–H stretching), 1712 (carbonyl stretching), 1381 (unassigned) and 1238 cm.$^{-1}$ (C–O stretching) as does also 4,6-dimethyltetrahydro-2-pyrone.[10]

Anal. Calcd. for $C_{10}H_{18}O_2$: C, 70.54; H, 10.66; sapn. equiv., 170.2. Found: C, 70.37; H, 10.64; sapn. equiv., 169.

6-(1′-Ethylamyl)-4-methyl-5,6-dihydro-2-pyrone.—Four grams of 4-carboxy-6-ethyl-3-methyl-2,4-dodecanoic acid was decarboxylated in 10 ml. of 2,4-lutidine with 0.01 g. of cupric acetate at 100°. The lutidine was removed by distillation. The residue was acidified and extracted with ether. The ether-extracted oil on fractionation gave 2.6 g. of a mixture of the lactone and acid. The acid was extracted from an ether solution of the mixture with dilute alkali. The ether extracts were evaporated and the residue fractionated to give 1.7 g. (51%) of the product, b.p. 141–143° (5 mm.), $n^{25}D$ 1.4641.

Anal. Calcd. for $C_{13}H_{22}O_2$: C, 74.24; H, 10.54; sapn. equiv., 210.3. Found: C, 74.38; H, 10.48; sapn. equiv., 205.

The infrared absorption spectra were determined using potassium bromide pellets, except as otherwise noted, and a Baird double beam recording infrared spectrometer with sodium chloride optics.

Synthesis of Acids Containing Hydrophenanthrene and Hydroacephenanthrylene Rings

BY D. L. TURNER

RECEIVED OCTOBER 25, 1956

The Reformatsky reaction with methyl 3-carbomethoxy-2-keto-3-methyl-6-phenylcyclohexane-1-acetate yields an unsaturated acid which can be cyclized either to a keto-anhydride (IV) or to an acephenanthrylene phenol (VI). The structure of the latter was shown by an independent synthesis from the α-form of 2-methyl-2-carbomethoxy-9-methoxy-1,2,3,4-tetrahydrophenanthrene-1-acetic acid. The β-stereoisomer of the acephenanthrylene also was prepared.

The cyclic keto-ester I described previously[1] was allowed to react with ethyl bromoacetate in the Reformatsky reaction. The principal crystalline material obtained from this reaction was the lactone ester II. The presence of the lactone ring was indicated by the infrared spectrum $\lambda_{max}^{CS_2}$ 5.56, 5.75 μ. This is similar to the result obtained by Johnson and Christiansen[2] in a similar reaction.

Hydrolysis of the lactone II with alcoholic potassium bicarbonate gave the unsaturated acid III. The ultraviolet absorption spectrum of this acid showed a band at 209 mμ (ϵ 16520), supporting the structure indicated[3] containing a conjugated double bond. The infrared spectrum of the methyl ester of the acid showed a band at 5.75 μ but no absorption at 5.56 μ and a new weak band, not present in the lactone, at 6.12 μ and probably caused by the double bond. The double bond was resistant to oxidation by permanganate under the conditions described by Johnson and Hunt,[4] a method which proved successful with unhindered double bonds.[1] When III was hydrogenated in acetic acid in the presence of Adams catalyst and hydrochloric acid, a product was obtained in which the aromatic ring was reduced but not the hindered double bond.

The acid III was cyclized with polyphosphoric acid, and the product was not an ester, but instead the keto-anhydride IV. Since the product is not phenolic, the double bond must be exocyclic as indicated in the structural formula. This is confirmed by the ultraviolet absorption spectrum, which shows the characteristics of the phenyl and carbonyl chromophores in conjugation,[5,6] and deviates from the spectrum of 9-keto-1,2,3,4,4a,-9,10,10a-octahydrophenanthrene[7] only at the lower minimum where the molecular extinction is greater, reaching 21000 at 212 mμ, the limit of measurement.

The anhydride IV was recovered unchanged after boiling with alcoholic alkali and acidifying. If the double bond were in the nucleus, the substance might be expected to isomerize to a phenol under these conditions. Another substance that exists only in anhydride form and not as the free acid has been obtained in the α-amyrin series by Ruzicka's group.[8,9] It seems probable that the anhydride IV belongs to the same stereochemical series as the major products described by Johnson and Christiansen[2] and it is of interest that it would then conform to the stereochemical arrangement in the Ruzicka anhydride.

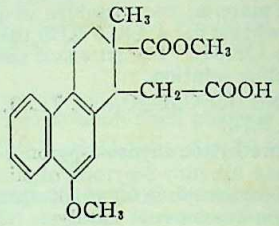
VIc, R = R′ = CH_3



VII

The carbonyl group in the anhydride IV was hydrogenated in the presence of perchloric acid[10] to form the anhydride V. This anhydride was dehydrogenated with palladium to 1,2-dimethylphenanthrene. The anhydride V shows the same resistance to reduction of the double bond exhibited by the acid III. Reduction with dissolving alkali metals[11] might be expected to succeed; perhaps it failed because of the extreme insolubility of the alkali metal salts formed from the anhydride.

When the acid III was cyclized by the Friedel–Crafts reaction, the resulting neutral product was a mixture, which was not easily separated. This mixture was hydrolyzed with alkali, producing isomers of the anhydride IV with phenolic properties. The two pure substances resulting from this reaction are assigned the structures VIa and VIb. The substance VIa could be converted to the second product VIb by esterification. These substances were soluble in alkali to give green fluorescent solutions. It was difficult to methylate the phenolic hydroxyl in VIa or VIb, and this could not be done with methyl sulfate or methyl *p*-toluenesulfonate in alkaline solution, but succeeded when diazomethane was employed in an ether–methanol solution. The methyl ether VIc was prepared by an independent method and this constitutes the proof of structure for these substances as acephenanthrylenes.

The monomethyl ester VII of Bachmann and Holmes[12] exists in two stereochemical forms α and β. Both of these were cyclized by the thionyl chloride–stannic chloride method. Since the acid chlorides were prepared at low temperature, it seems improbable that any rearrangement took place[13] and the cyclization products should be the acephenanthrylenes of structure VIc. The identity of the acephenanthrylene derived from the α-acid of Bachmann and Holmes and the product VIc from the Reformatsky acid was established by comparison of melting points and infrared spectra. Hirschmann and Johnson[14] have suggested that the α-series of Bachmann and Holmes has rings C and D fused in the *trans* configuration as in natural estrone.

The ultraviolet absorption spectrum of the methyl ether VIc shows a pronounced hypsochromic shift, when compared with that of the phenolic materials VIa and VIb, which have identical spectra. The hypsochromic shift produced by methylating the phenolic hydroxyl probably indicates chelation in the phenolic substances.[15] This effect is shown in a pronounced form by purpurogallin and its methyl ether,[16] which also has a carbonyl group adjacent to a phenolic hydroxyl. Many substances with this type of structure also show similar chemical properties, particularly characterized by difficulty in methylating the phenolic hydroxyl (quercetin[17]) and easy removal of the methyl group (purpurogallin).[18,19] It should be noted, however, that Haworth[19] ascribes the difficulty in methylating the third phenolic hydroxyl of purpurogallin to steric hindrance, rather than to the chelation effect. The easy removal of the methyl group in VIc was shown by the formation of greenish fluorescent solutions on saponification.

The infrared spectrum of VIa showed bands at 3.0 μ (hydroxyl), 5.93 μ (carboxyl carbonyl) and 6.09 μ (chelate). The band attributed to chelation agrees with the assignment of Bellamy and Beecher[20] for 1-tetralone-2-carboxylate esters. This band disappears in the methyl ether, which has a new band at about 6.2 μ possibly caused by the aromatic system.[21]

Experimental

Ultraviolet absorption spectra were determined in 95% ethanol and infrared spectra in carbon disulfide.

Lactone of Ethyl 2-Carbomethoxy-6-carboxymethyl-1-hydroxy-2-methyl-5-phenylcyclohexane-1-acetate.—A solution of 55 g. of the ester I in 500 ml. of dry ether and 450 ml. of dry benzene was treated with 70 g. of activated zinc[22] and 3 g. of iodine, while stirring and refluxing under nitrogen. Two additional portions of 50 g. of zinc and a crystal of iodine were added at two-hour periods, and the mixture was stirred for a total of six hours. The mixture was treated by the method of Bachmann, Cole and Wilds.[23] After the evaporation of the solvent from the neutral fraction, the product was crystallized from isopropyl alcohol, m.p. 125–127.5°.

Anal. Calcd. for $C_{21}H_{26}O_6$: C, 67.36; H, 7.00. Found: C, 67.76; H, 6.98.

Ethyl 2-Carbomethoxy-6-carboxymethyl-2-methyl-5-phenyl-cyclohexylidene-acetate (III) (a).—A solution of the preceding ester (3 g.) in 100 ml. of methanol was refluxed with a solution of 5 g. of potassium bicarbonate in 15 ml. of water. After one hour, the mixture was evaporated *in vacuo*, treated with water, and acidified with 10% hydrochloric acid. The acid fraction was isolated with ether, the ethereal solution was dried and the ether was removed. The residue was crystallized from benzene, giving 1.28 g., m.p. 154–155°, λ_{max} 209 mμ (log ϵ 4.22).

Anal. Calcd. for $C_{21}H_{26}O_6$: C, 67.36; H, 7.00; neut. equiv., 374. Found: C, 67.49, 67.41; H, 6.88, 6.83; neut. equiv., 375, 375.

An attempt to oxidize the material by the method of Johnson and Hunt[4] using potassium permanganate in acetone, gave a 63% recovery of the starting material.

(b).—The mother liquors from the preceding Reformatsky reaction were dissolved in 100 ml. of pyridine and refluxed for 45 minutes with 28 ml. of phosphorus oxychloride. After treating with ice and extracting with ether, the ethereal extract was washed with 10% hydrochloric acid, saturated bicarbonate and dried. The residue from the distillation of the ether was hydrolyzed with potassium bicarbonate (30 g.) in 90 ml. of water and 600 ml. of methanol. This gave 6 g. of material, m.p., alone and mixed with (a), 152–154°.

The methyl ester of the acid was made with ethereal diazomethane and crystallized from ethanol; m.p. 70–72°.

Anal. Calcd. for $C_{22}H_{28}O_6$: C, 68.02; H, 7.26. Found: C, 67.93, 68.00; H, 7.16, 7.12.

2-Carboxy-6-carboxymethyl-2-methyl-5-phenylcyclohexylideneacetic Acid.—The complete hydrolysis of the preceding acid was effected by refluxing in 5% aqueous sodium hydroxide for four hours. After cooling, it was acidified and isolated with ether in the normal manner. Crystallized from ethyl acetate it melted at 181–183°.

Anal. Calcd. for $C_{18}H_{20}O_6$: C, 65.05; H, 6.07. Found: C, 64.78; H, 6.27.

The trimethyl ester of this acid, prepared with ethereal diazomethane, was crystallized from ether–pentane; m.p. 65–66°.

Anal. Calcd. for $C_{21}H_{26}O_3$: C, 67.36; H, 7.00. Found: C, 67.29; H, 7.12.

Hydrogenation of the Reformatsky Lactone Ester. (II).—The material was recovered unchanged after attempts to hydrogenate using Adams catalyst or palladium catalysts in ethanol or acetic acid.

3-Carbomethoxy-2-keto-3-methyl-6-phenylcyclohexane-1-acetic Acid.—This was prepared for comparison with products of Reformatsky reactions by hydrolysis of the starting ester I using potassium bicarbonate in aqueous methanol as described above. It was crystallized from benzene; m.p. 147–148°.

Anal. Calcd. for $C_{17}H_{20}O_5$: C, 67.09; H, 6.63; neut. equiv., 304. Found: C, 67.15; H, 6.57; neut. equiv., 304.

Ethyl 2-Carbomethoxy-5-cyclohexyl-2-methyl-6-carboxymethylcyclohexylidene-1-acetate.—The acid from the bicarbonate hydrolysis of the Reformatsky ester (4.7 g.) was hydrogenated for 2 hours in 100 ml. of acetic acid in the presence of 1 ml. of concentrated hydrochloric acid and 0.5 g. of Adams catalyst. The acetic acid was distilled *in vacuo*, and the residue was purified by a partition chromatograph using nitroethane–heptane on silicic acid–Celite (1:3 by weight)[24] with the nitroethane as the stationary phase.[25] Early eluates gave crystals, m.p. 132–134° after recrystallization from acetone–pentane (1.4 g.).

Anal. Calcd. for $C_{21}H_{34}O_6$ (completely reduced): C, 65.94; H, 8.96; neut. equiv., 382. Calcd. for $C_{21}H_{32}O_6$ (one double bond): C, 66.29; H, 8.48; neut. equiv., 380.5. Found: C, 65.96; H, 8.33; neut. equiv., 374.

Another fraction obtained from later eluates was crystallized from acetone–pentane; m.p. 163–165°.

Anal. Calcd. for $C_{20}H_{32}O_6$ (completely reduced): C, 65.18; H, 8.73; neut. equiv. (dibasic), 246. Calcd. for $C_{20}H_{30}O_6$ (one double bond): C, 65.55; H, 8.25; neut. equiv. (dibasic), 227. Found: C, 65.60; 65.65; H, 8.31, 8.26; neut. equiv., 278.

This substance is considered to be a monoethyl ester because of the analysis and neutralization equivalent. Both of the substances from the chromatograph gave the same acid on hydrolysis.

2-Carboxy-5-cyclohexyl-2-methyl-6-carboxymethylcyclohexylidene-1-acetic Acid.—The preceding dibasic acid was refluxed in 10% aqueous sodium hydroxide solution for 4 hours. The solution was cooled, acidified, and the product filtered. After several recrystallizations from acetone–carbon tetrachloride it had m.p. 184–185.5°. A similar hydrolysis of the preceding monobasic acid gave a substance which was crystallized from acetone–carbon tetrachloride; m.p. 182–184°. The m.p. of a mixture was 182–184°. For analysis, it was crystallized from ether–pentane; m.p. 185–186°.

Anal. Calcd. for $C_{18}H_{28}O_6$: C, 63.89; H, 7.75; neut. equiv. (tribasic), 113. Found: C, 63.99; H, 7.90; neut. equiv., 114.

Anhydride of 2-Carboxy-9-keto-2-methyl-1,2,3,4,4a,9,10,10a-octahydrophenanthrylideneacetic Acid.—To 310 g. of phosphorus pentoxide was added 20 ml. of 85% phosphoric acid with cooling. After the reaction had subsided, the mixture was heated on the steam-bath for 2 hours and poured over 26 g. of the Reformatsky unsaturated acid III. The mixture was heated on the steam-bath with frequent swirling for 2 hours and then poured into ice-water. The precipitated solid was filtered, dried and crystallized from ethyl acetate, giving 9.5 g., m.p., 258–260° dec.

Anal. Calcd. for $C_{18}H_{16}O_4$: C, 72.96; H, 5.44; sapon. equiv., 148.1. Found: C, 73.07; H, 5.54; sapon. equiv., 148.

The substance did not react with diazomethane. The ultraviolet absorption spectrum showed λ_{max} 293, 247 mμ (log ϵ 3.31, 4.10); λ_{min} 275 and 226 mμ (log ϵ 3.12, 3.90). The spectrum resembled that of α-tetralone.

The semicarbazone, m.p. 300° dec., was extremely insoluble in the usual solvents. The **2,4-dinitrophenylhydrazone** was made by the method of Reich, Crane and Sanfilippo[26] and recrystallized from dimethylformamide–ethanol; m.p. 282°. It was extremely insoluble in most solvents.

Anhydride of 2-Carboxy-2-methyl-1,2,3,4,4a,9,10,10a-octahydrophenanthrylideneacetic Acid.—The unsaturated anhydride (9 g.) was hydrogenated in the presence of 3 g. of 5% palladium chloride on carbon (Wilkens–Anderson Co.) in 250 ml. of acetic acid and 10 ml. of 60% perchloric acid. The calculated amount of hydrogen was absorbed in three hours. The solution was filtered from the catalyst and poured into 100 ml. of 5% sodium carbonate solution and the product was filtered giving 4.4 g., m.p. 195–210°. This could not be purified by recrystallization. It was treated with ethereal diazomethane and the part which did not react was removed by filtration and crystallized from acetone; m.p. 208–210°, yield 3.4 g.

Anal. Calcd. for $C_{18}H_{18}O_3$: C, 76.57; H, 6.43; sapon. equiv., 141.2. Found: C, 76.52; H, 6.10; sapon. equiv., 149.

This anhydride could not be esterified by the method of Clinton and Laskowski[27] or by the sodium methylate method

of Herr and Miescher.[28] Attempts to reduce the double bond catalytically failed as with the unsaturated acid III. Sodium and *n*-butyl alcohol was not effective possibly because the anhydride gave a very insoluble sodium salt.

1,2-Dimethylphenanthrene.—The preceding anhydride of carboxy-2-methyloctahydrophenanthrylideneacetic acid (600 mg.) was heated with 1 g. of palladium chloride on Darco, a catalyst containing 5% palladium,[29] to 350° for 20 minutes. The product was dissolved in acetone and filtered from the catalyst. The acetone was evaporated and the residue was crystallized from methanol; m.p. 145°,[30] yield 300 mg.

Anal. Calcd. for $C_{16}H_{14}$: C, 93.18; H, 6.84. Found: C, 92.99; H, 6.93.

The picrate of this hydrocarbon was crystallized from ethanol; m.p. 153–154°.[31]

Cyclization of Ethyl 2-Carbomethoxy-6-carboxymethyl-2-methyl-5-phenylcyclohexylideneacetate by the Friedel-Crafts Method.—Using the method of Johnson and Glenn,[32] 23 g. of phosphorus pentachloride was added to a solution of 36.8 g. of the acid in 100 ml. of dry benzene. The acid chloride, after the removal of the solvents, was dissolved in 100 ml. of fresh benzene and the solution was added dropwise to a stirred solution of 18.5 g. of aluminum chloride in 50 ml. of benzene at a temperature below 10°. After 2 hours at this temperature and 3 hours at room temperature, the mixture was hydrolyzed with ice and hydrochloric acid, and extracted with ether. The ethereal solution was washed with hydrochloric acid, water, saturated sodium bicarbonate and dried. Partial removal of the ether gave crystals, m.p. 126–135°, yield 27 g. Because this was difficult to purify, it was hydrolyzed by refluxing in 200 ml. of methanol with 30 ml. of 15% sodium hydroxide solution. After 30 minutes, water was added, and the insoluble salt, which separated on cooling, was filtered and treated with 10% hydrochloric acid. The oily yellow crystals produced were filtered and crystallized from benzene; m.p. 159–170° dec., yield 9 g. Repeated recrystallization of this material gave VIa, better prepared by retreatment with alkali as described later.[33] The mother liquor from the benzene solution gave a second crop of 5 g., m.p. 241–248°, which was recrystallized from acetone; m.p. 252–253°. This is **3-carboxy-6-hydroxy-5-keto-3-methyl-1,2,3,3a,4,5-hexahydroacephenanthrylene (VIa).**

Anal. Calcd. for $C_{18}H_{16}O_4$: C, 72.96; H, 5.44; neut. equiv. (dibasic), 148. Found: C, 72.87; H, 5.49; neut. equiv., 149.

Alternative Preparation of 3-Carboxy-6-hydroxy-5-keto-3-methyl-1,2,3,3a,4,5-hexanydroacephenanthrylene (VIa).—The intermediate above, m.p. 159–170°, was converted to the phenol by standing in solution, or by the following treatment with alkali. The crystals (600 mg.) were heated on the steam-bath for 1 hour with 10 ml. of 10% sodium hydroxide solution. The solution was acidified with 2 *N* hydrochloric acid, and filtered, giving 0.5 g., m.p. 248–252°. This was recrystallized from acetone–pentane, m.p. alone, and mixed with the phenol from the mother liquor of the starting material, 252–253.5°. The absorption spectrum showed λ_{max} 381, 300, 290, 265 mμ (log ε 3.74, 2.76, 3.64, 4.67).

3-Carbomethoxy-6-hydroxy-5-keto-3-methyl-1,2,3,3a,4,5-hexahydroacephenanthrylene (VIb) (a).—The benzene mother liquor from the hydrolysis of the Friedel–Crafts reaction products was evaporated, and the residue was crystallized from nitromethane, rejecting material insoluble in hot nitromethane. This gave 2.7 g., m.p. 104–109.5°; recrystallized from methanol, m.p. 111–114°.

Anal. Calcd. for $C_{19}H_{18}O_4$: C, 73.53; H, 5.85. Found: C, 73.64; H, 5.69.

The ultraviolet absorption spectrum was the same as that of the preceding phenol.

(b).—To 2.1 g. of the free acid VIa, was added 50 ml. of ethylene chloride, 20 ml. of methanol and 2 ml. of concentrated sulfuric acid. This was refluxed for 5 hours, diluted with water and extracted with ethylene chloride.

The ethylene chloride solution was washed with saturated sodium bicarbonate, and dried over sodium sulfate. The solvent was evaporated and the residue was crystallized from ethyl acetate–pentane, m.p., alone and mixed with (a) above 111–114°. The ultraviolet absorption spectrum was identical with that of (a). The yield was 1.1 g. This esterification could also be performed using methanol and boron trifluoride etherate.

This substance, like the free acid, dissolved in alkali to give a greenish-yellow fluorescent solution.

3-Carbomethoxy-5-keto-6-methoxy-3-methyl-1,2,3,3a,4,5-hexahydroacephenanthrylene (VIc).—The phenolic ester VIb was esterified with diazomethane in ether–methanol to give a dark red oil. This was crystallized from isopropyl alcohol and then from methanol; m.p. 106–107°. The very faintly yellow crystals formed a solution in alcohol with violet fluorescence; λ_{max} 372, 311, 299, 257, 221 mμ (log ε 3.62, 3.76, 3.84, 3.67, 4.38).

Anal. Calcd. for $C_{20}H_{20}O_4$: C, 74.05; H, 6.22; mol. wt., 324. Found: C, 74.26; H, 6.61; mol. wt. (Rast), 317.

The 2,4-dinitrophenylhydrazone of this keto-ester was prepared by heating in acidified ethanol with Brady's reagent. It had m.p. 273° dec. It was too insoluble to recrystallize and was extracted with hot ethyl acetate and ethanol to purify it.

Anal. Calcd. for $C_{26}H_{24}N_4O_7$: C, 61.90; H, 4.80. Found: C, 61.86; H, 5.02.

Synthesis of the Preceding Acephenanthrylene (VIc) from the α-Form of 2-Methyl-2-carbomethoxy-9-methoxy-1,2,3,4-tetrahydrophenanthrene-1-acetic Acid.—To 4 g. of the half ester of Bachmann and Holmes[12] was added 125 ml. of anhydrous ether, 10 drops of pyridine and 7 ml. of purified[34] thionyl chloride. After 30 minutes at room temperature, the solvents were distilled *in vacuo* below 35°, 35 ml. of dry benzene was added and the solvents were distilled again. The residual acid chloride was dissolved in 55 ml. of benzene, the solution was cooled until the benzene began to crystallize, and 13 ml. of stannic chloride was added. After swirling for 3 minutes, the mixture was hydrolyzed with ice and hydrochloric acid. The product was taken up in ether and benzene, washed with 10% hydrochloric acid, 4% sodium carbonate solution, water, saturated sodium chloride and then dried. The solvents were removed and the residue was crystallized from methanol, yield 2.9 g. (76%), m.p. 106–107° undepressed when mixed with the preceding acephenanthrylene (VIc). The ultraviolet and infrared absorption spectra of the two substances were identical.

Anal. Calcd. for $C_{20}H_{20}O_4$: C, 74.05; H, 6.22. Found: C, 74.09; H, 6.19.

β-Form of 3-Carbomethoxy-5-keto-6-methoxy-3-methyl-1,2,3,3a,4,5-hexahydroacephenanthrylene.—Using a pro-

Cyanine Dyes. I. Absorption of Cyanines Derived from Pyranothiazole and Thiopyranothiazoles[1]

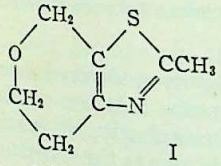
BY ROBERT H. SPRAGUE

RECEIVED JULY 27, 1956

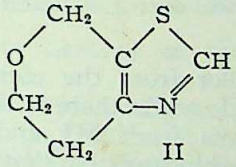
Three new thiazole bases have been prepared by condensing thioacetamide with 3-bromotetrahydro-4-pyrone, 3-bromotetrahydro-1-thio-4-pyrone and 2-bromotetrahydro-1-thio-3-pyrone. Quaternary salts of the products have given rise to new cyanine dyes, some of which are powerful photographic sensitizers. The absorptions of the new dyes are compared with those of similar dyes from benzothiazole and tetrahydrobenzothiazole.

The well known synthesis of 2-methylthiazoles by condensation of thioacetamide with α-haloketones[2] has been employed to prepare thiazole bases from 3-bromotetrahydro-4-pyrone, 3-bromotetrahydro-1-thio-4-pyrone and 2-bromotetrahydro-1-thio-3-pyrone.

Thus 3-bromotetrahydro-4-pyrone was treated with thioacetamide giving 2-methyl-6,7-dihydro-4-H-pyrano[4,3d]thiazole (I). Although (I) has not been reported in the literature, the corresponding unsubstituted thiazole II has been prepared by Sorkin and Erlenmeyer[3] by condensing thioformamide with 3,5-dibromotetrahydro-4-pyrone. The enol forms of the reactants condense with elimination of water and hydrobromic acid.



I



II

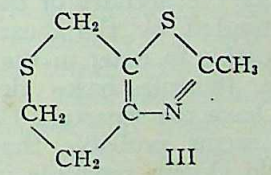
Since the product contained no bromine, Erlenmeyer postulated that the extra bromine atom in the five position of the pyrone ring was eliminated by "reductive splitting" and replaced by hydrogen.

Erlenmeyer isolated only the 3,5-dibromo ketone on treatment of tetrahydro-4-pyrone with N-bromosuccinimide (36% yield, m.p. 156–157°); however, attempts to repeat his work in this Laboratory led to a mixture of the dibromo derivative with a monobromo compound, in which the latter predominated. The mixture was purified by vacuum distillation giving a 24% yield of 3-bromotetrahydro-4-pyrone in the form of a colorless liquid (b.p. 76–80° at 2 mm.) which darkened rapidly and solidified on standing.

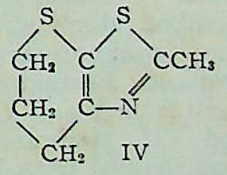
In a second experiment the crude product was recrystallized from ethanol without previous distillation resulting in a small yield of the dibromo compound melting at 159–161°.

Both products condensed readily with thioacetamide in ethanol solution. Contrary to Erlenmeyer's findings in the analogous thioformamide reaction, a bromine-substituted thiazole was obtained from the dibromopyrone. The bases gave crystalline quaternary salts with ethyl iodide and were analyzed in this form.

Bromination of tetrahydro-1-thio-4-pyrone[4] with N-bromosuccinimide gave a very unstable bromoketone, which nevertheless could be condensed with thioacetamide at low temperature. The product, 2-methyl-6,7-dihydro-4-H-thiopyrano[4,3d]thiazole (III), formed quaternary salts with alkyl halides which were very reluctant to crystallize. However, a crystalline hydrochloride was obtained on saturating a solution of the base in ether with hydrogen chloride and this derivative was used for analysis.



III



IV

A base IV, isomeric with III, was similarly prepared by condensing thioacetamide with the bromoketone derived from tetrahydro-1-thio-3-pyrone.[5] Of the two possible monobromo derivatives of the latter the product isolated is believed to be the 2-bromo compound V, rather than the 4-bromo isomer VI, for the following reasons:

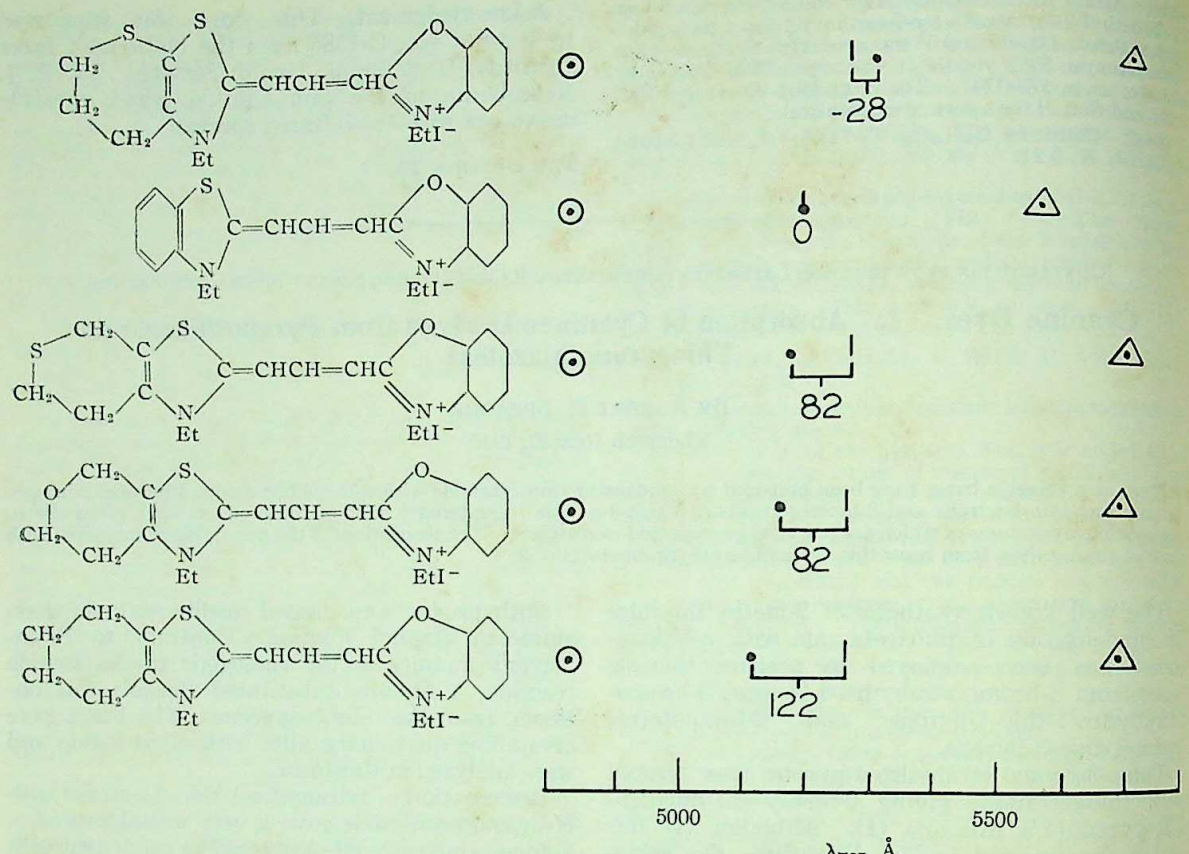

Fig. 1.—Values of $\lambda_{max.}$ of unsymmetrical carbocyanines and related symmetrical dyes: ●, unsymmetrical dye; ⊙, symmetrical oxacarbocyanine (VIII); △, second related symmetrical dye; ⊥, indicates arithmetic mean between ⊙ and △; deviation is indicated by ⊤ and its magnitude is shown in Å.

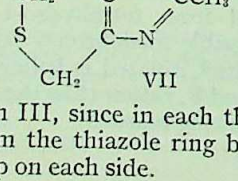
It has been noted by several workers that the sulfur atom in the system $-\overset{|}{S}-\overset{|}{C}-$ (H) has a considerable proton-releasing effect on the attached carbon atom.[6-8] This would enhance the activity of the 2-carbon atom, already activated by the 3-carbonyl group, causing the bromine to enter in that position. Furthermore, the thiazole bases derived from V and VI would have the structure IV and VII, respectively. It seems probable that dyes derived from VII would closely resemble in



VII

color those from III, since in each the sulfur atom is insulated from the thiazole ring by at least one methylene group on each side.

However, in structure IV the sulfur atom is situated adjacent to that in the thiazole ring and therefore might be expected to participate in the resonating system responsible for the color of dyes containing this nucleus. As detailed below, it was found that dyes derived from IV differ markedly in color from the corresponding dyes derived from III, while there is little difference between similar dyes from III and I. Consequently, it seems highly probable that the new base has the structure IV and therefore its precursor has the structure V. There was no indication that IV was a mixture of two isomers, since the distilled product crystallized readily and quaternary salts prepared from it were sharp melting solids.

Several representative dyes of the various cyanine types were prepared from quaternary salts of the new bases.

Discussion of Absorptions of Dyes

Striking differences are noted when the absorptions of the dyes from the new bases are compared with the corresponding data from tetrahydrobenzothiazole and benzothiazole, using the convenient technique developed by Brooker, *et al.*, in their studies of color and constitution.[9]

Brooker has shown that the color of unsymmetrical cyanine dyes of various types appears to be de-

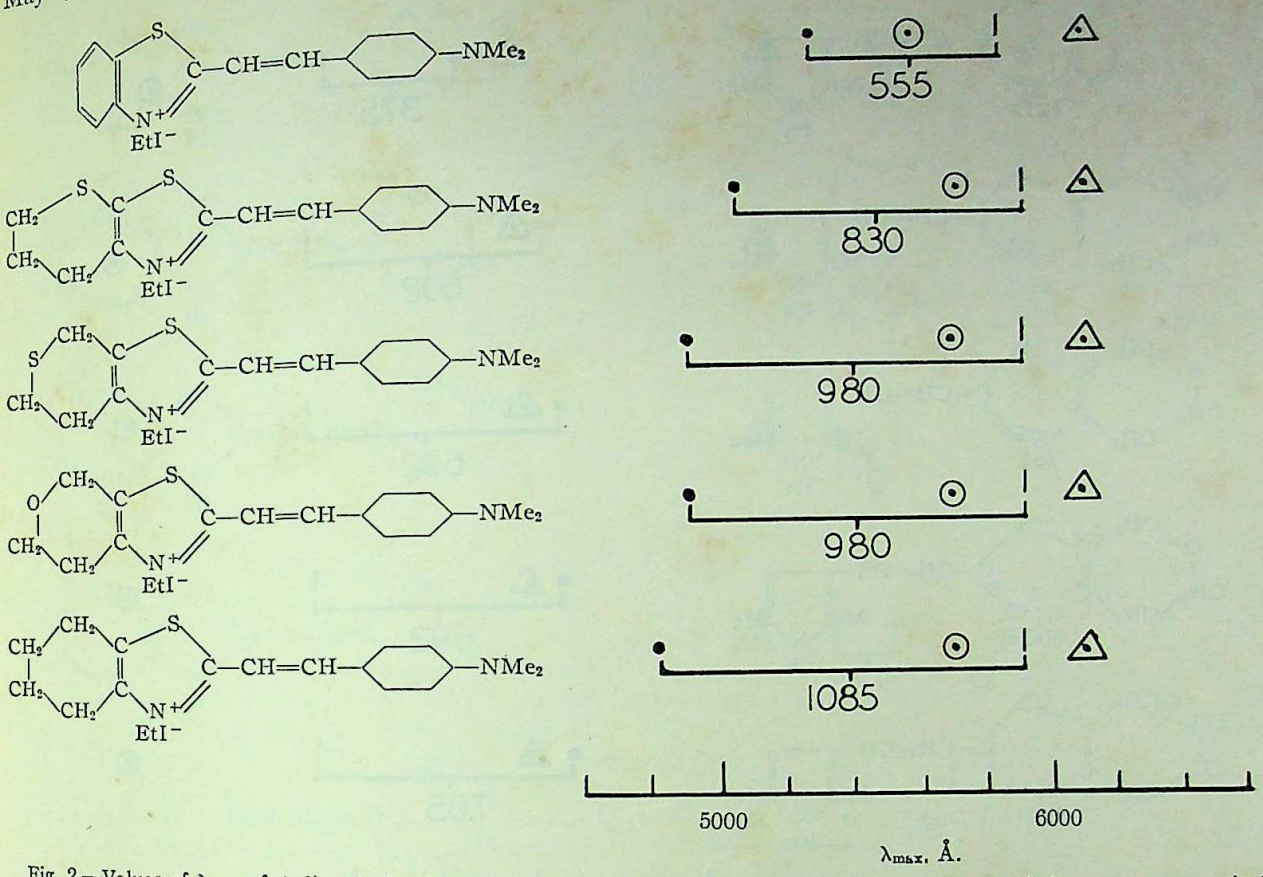

Fig. 2.—Values of λ_{max} of *p*-dimethylaminostyryl dyes and related symmetrical dyes: ●, styryl dye; ⊙, symmetrical carbocyanine; △, Michler hydrol blue; ⊥, arithmetic mean between ⊙ and △; deviation is indicated by ⊤ and its magnitude is shown in Å. For a detailed study of similar dyes see Brooker, *et al.*[9g]

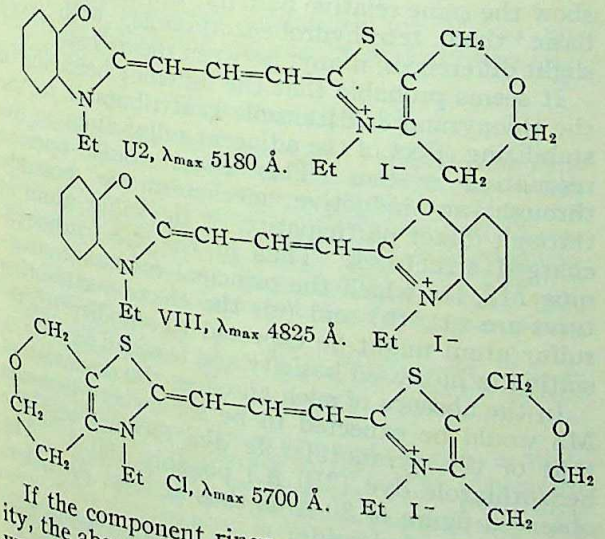
pendent largely on the relative basicity of the heterocyclic rings involved.

For example, the unsymmetrical oxapyranothiazolocarbocyanine (U2) may be considered the structural cross of the symmetrical oxacarbocyanine (VIII) and the symmetrical pyranothiazolocarbocyanine (Cl).



If the component rings are of comparable basicity, the absorption maximum of U2 should be midway between the maxima of the parent dyes, *i.e.*, at 5262 Å. Since the absorption maximum of U2 was found to be 5180 Å., the difference of 82 Å. (called by Brooker the "deviation") indicates that one of the rings is more basic than the other. The corresponding dye from tetrahydrobenzothiazole (U1) gives a similar difference of 122 Å., while the dye from benzothiazole was found by Brooker and co-workers to have zero deviation.[9h] These data together with those for the two isomeric thiopyranothiazole dyes are plotted in Fig. 1.

It already has been pointed out by Brooker[9g,i] that tetrahydrobenzothiazole is considerably more basic than benzothiazole, and since the pyranothiazole and thiopyranothiazoles are structurally very similar to the former, it might be expected that they would closely resemble it in basicity. From Fig. 1 it is seen that the deviations of U2 and U3 are indeed very close to U1 and lie between those of U1 and the corresponding benzothiazole dye. However, dye U4, which is isomeric with U3, has a negative deviation and thus the thiopyrano[3,2d]thiazole nucleus appears to be considerably less basic than tetrahydrobenzothiazole and very similar to benzothiazole, small negative deviations usually being regarded as equivalent to zero.[9j]

On the other hand, data shown in Fig. 2 for the *p*-dimethylaminostyryl series and in Fig. 3 for the pyrrolocarbocyanine series indicate a different order of basicity. In Fig. 2 all three of the new dyes S1, S2 and S3 show deviations lying between those of the tetrahydrobenzothiazole and benzothiazole dyes, S3 again being the least basic of the three but still considerably more basic than benzothiazole. The same order is observed in Fig. 3, the resem-

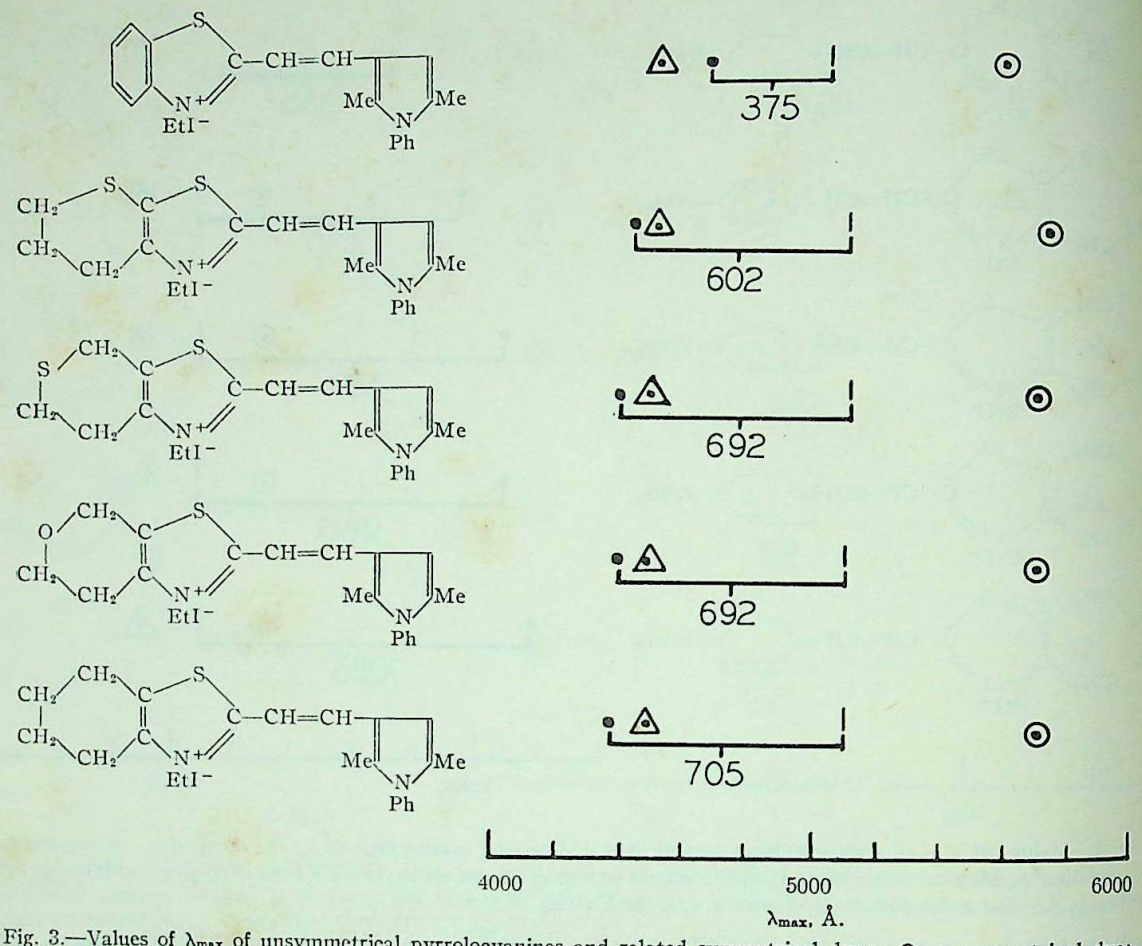

Fig. 3.—Values of λ_{max} of unsymmetrical pyrrolocyanines and related symmetrical dyes: ●, unsymmetrical dye; △, symmetrical cyanine with two pyrrole nuclei; ⊙, second symmetrical cyanine; ⊥, arithmetic mean between ⊙ and △; deviation is indicated by ⊤ and its magnitude is shown in Å. For a detailed study of pyrrolocyanines see Brooker and Sprague.[11]

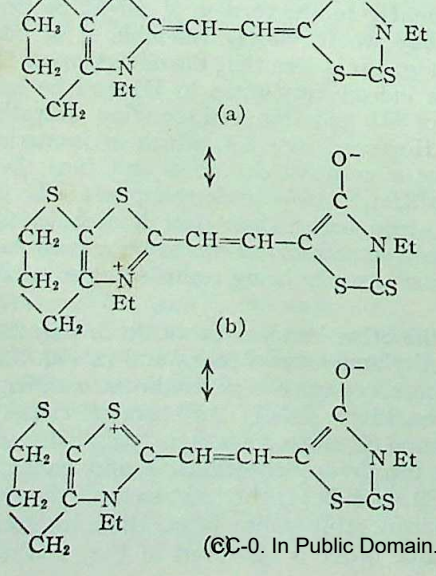
blance to tetrahydrobenzothiazole being even more marked than in the styryl series.

It is, therefore, all the more interesting to find that in the merocarbocyanine series, as shown in Fig. 4, the order of basicity is reversed, the thiopyrano[3,2d] nucleus now appearing to be more basic than tetrahydrobenzothiazole. It is noteworthy that in all four series pyrano[4,3d]thiazole and thiopyrano[4,3d]thiazole consistently show the same relative basicity, *i.e.*, somewhat less basic than tetrahydrobenzothiazole, with very slight differences, if any, between themselves.



It seems probable that the different behavior of the thiopyrano[3,2d]thiazole is attributable to the stabilizing effect of the adjacent sulfur atom on the resonating system. This effect could operate through an inductive mechanism or possibly through direct participation of the sulfur atom in charged structures. Thus in the merocarbocyanine M3, for which the principal resonance structures are (a), (b) and (c), the electron-attracting sulfur atom might be expected to stabilize (c) resulting in increased basicity and lessened deviation.

In the absence of such an effect the deviation of M3 would be expected to be somewhere between that of the pyranothiazole dye (70 Å.) and the benzothiazole dye (210 Å.) possibly 100 Å. The observed figure of 30 Å. is thus at least 70 Å. less than the expected value.

Too much emphasis on the results shown in Fig. 4 is perhaps not justified since, as Brooker has already stated,[9j] this series does not lend itself readily to differentiation between highly basic nuclei. Nevertheless a difference of 70 Å. between the ob-

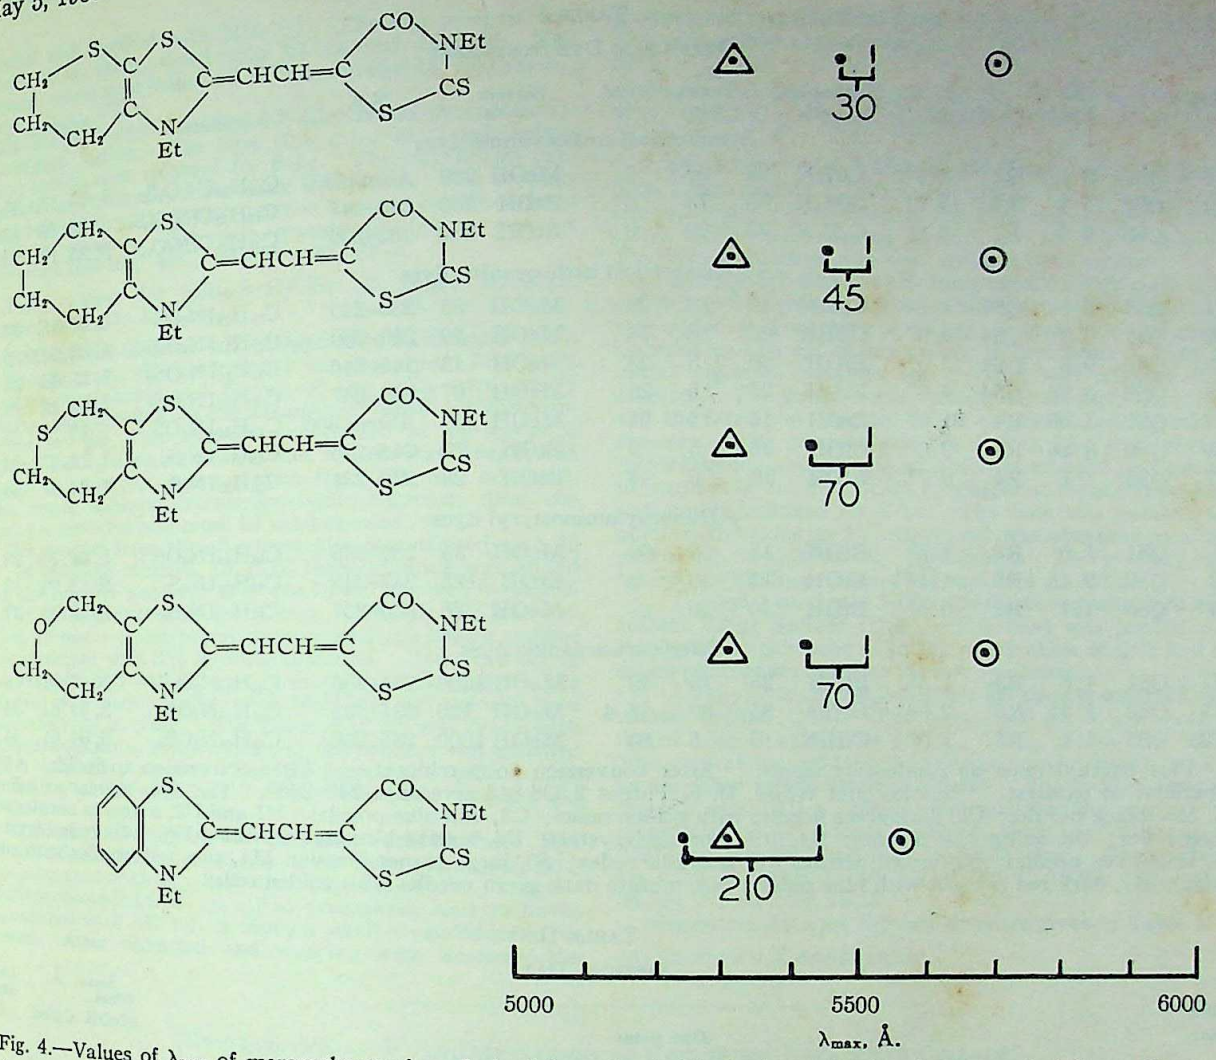

Fig. 4.—Values of λ_{max} of merocarbocyanines derived from 3-ethylrhodanine and related symmetrical dyes: ●, merocarbocyanine; ⊙, symmetrical carbocyanine; △, symmetrical dye with two rhodanine nuclei (oxonol); ⊥, arithmetic mean between ⊙ and △; deviation is indicated by ⊣ and its magnitude is shown in Å. For a detailed study of the merocarbocyanines see Brooker, *et al.*[9i]

served and predicted deviations for M3 is undoubtedly significant and can be explained as suggested above.

Experimental[10]

Quaternary salts used are: QS1, 1-ethyl-2-methyl-6,7-dihydro-4-H-pyrano(4,3d)thiazolium iodide; QS2, 1-ethyl-2-methyl-6,7-dihydro-4-H-thiopyrano(4,3d)thiazolium ethyl sulfate; QS3, 1-ethyl-2-methyl-6,7-dihydro-5-H-thiopyrano(3,2d)thiazolium ethyl sulfate; QS4, 2-(2-acetanilidovinyl)-3-ethylbenzoxazolium iodide; QS5, 1-ethyl-2-methyl-6,7-dihydro-5-H-thiopyrano(3,2d)thiazolium iodide; QS6, 1-ethyl-2-methyl-4,5,6,7-tetrahydrobenzothiazolium *p*-toluenesulfonate.[11]

Other reactants are: R-1, ethyl orthoformate; R-2, *p*-dimethylaminobenzaldehyde; R-3, 5-acetanilidomethylene-3-ethylrhodanine[9j]; R-4, 2,5-dimethyl-1-phenyl-3-pyrrolecarboxaldehyde.[9f]

Details of the preparation of new dyes are given in Table I. These include symmetrical carbocyanines (designated by C), unsymmetrical carbocyanines (U), *p*-dimethylaminostyryl dyes (S) and merocarbocyanines (M). The names of the dyes are given in Table II. In the syntheses the reactants were heated in the solvent indicated for the specified time. The yield of purified dye is given after two crystallizations from the solvent shown in the table.

(10) Melting points are uncorrected. Microanalyses are by Schwarzkopf Microanalytical Laboratory, New York.

(11) L. G. S. Brooker and F. L. White, U. S. Patent 2,336,843.

Details of the preparation of the new bases and their quaternary salts follow.

3-Bromotetrahydro-4-pyrone.—Tetrahydro-4-pyrone[3] (30 g., 1 mol), N-bromosuccinimide (54 g., 1 mol) and 200 ml. of dry CCl_4 were refluxed with stirring under strong ultraviolet light for 20 minutes. A violent reaction occurred after an induction period of 15 minutes. The mixture was chilled, filtered, the solvent evaporated on the steam-bath and the residue distilled under reduced pressure. The fraction boiling at 60–80° at 2 mm. (21 g.) was redistilled. The product was thus obtained as a colorless liquid boiling at 76–80° at 2 mm., yield 13 g., 24%. On standing, the material rapidly darkened to a pinkish-brown and it was therefore used at once in the preparation of the thiazole base. In a later experiment it was found that distillation of the somewhat unstable bromo compound was unnecessary for use in the thiazole condensation. Using the crude bromo derivative an over-all yield of 20% of thiazole was obtained in a large run from 253 g. of tetrahydropyrone.

2-Methyl-6,7-dihydro-4H-pyrano(4,3d)thiazole (I).—3-Bromotetrahydro-4-pyrone (13.0 g., 1 mol), thioacetamide (5.5 g., 1 mol) and absolute ethanol (25 ml.) were heated to boiling under reflux. After the initial vigorous reaction subsided, the mixture was refluxed for 1 hr. The mixture was evaporated nearly to dryness, and the residue was extracted repeatedly with warm dilute HBr. The chilled extract was basified with dilute NH_4OH solution and the oily product was taken up in ether. The ether solution was dried with K_2CO_3, evaporated and the residue was distilled under reduced pressure. The product was

obtained as a nearly colorless strong smelling oil which boiled at 110 to 115° at 15 mm., yield 4.5 g., 40%.

1-Ethyl-2-methyl-6,7-dihydro-4H-pyrano(4,3d)thiazolium Iodide (QS1).—The base (2.1 g., 1 mol) was refluxed with ethyl iodide (5 g., 1 mol + 150% excess) for 24 hr. The crystalline product was crushed under acetone, chilled and filtered. The nearly colorless crystals melted with decomposition at 142–143°, yield 3.5 g., 83%.

Anal. Calcd. for $C_9H_{14}INOS$: I, 40.80; N, 4.50; S, 10.30. Found: I, 40.84; N, 4.21; S, 10.18.

7-Bromo-2-methyl-6,7-dihydro-4H-pyrano(4,3d)thiazole.—3,5-Dibromotetrahydro-4-pyrone[3] (3.1 g., 1 mol), thioacetamide (1.5 g., 1 mol + excess) and absolute ethanol (25 ml.) were refluxed for 2 hr. The alcohol was evaporated and the residue was extracted with dilute HCl. The acid solution was washed with ether to remove tarry material,

Digitized by Arya Samaj Foundation Chennai and eGangotri

filtered and basified with NH_4OH. The oily product was taken up in ether, dried with K_2CO_3 and distilled. The product was a pale yellow oil boiling at 140–145° at 15 mm., yield 0.3 g., 9%.

7-Bromo-1-ethyl-2-methyl-6,7-dihydro-4H-pyrano(4,3d)-thiazolium Iodide.—The base (0.3 g., 1 mol) and excess ethyl iodide were refluxed for 6 hr. The oily brown precipitate crystallized on standing overnight. The crystals were collected, washed with acetone and recrystallized from absolute ethanol. The pale orange crystalline product melted at 164–168° dec., yield 50 mg., 10%.

Anal. Calcd. for $C_9H_{13}BrINOS$: N, 3.59; S, 8.22. Found: N, 3.69; S, 8.40.

2-Methyl-6,7-dihydro-4-H-thiopyrano(4,3d)thiazole (III).—Twenty grams of tetrahydro-1-thio-4-pyrone,[4] 30.5 g. of N-bromosuccinimide and 50 ml. of dry CCl_4 were gently warmed under reflux on the steam-bath until a violent reaction set in. The mixture was chilled in an ice-bath, filtered from succinimide and the filtrate was evaporated under water-pump vacuum until the CCl_4 was removed. The crude 3-bromo-tetrahydro-1-thio-4-pyrone thus obtained is unstable and must be used at once.

The product from the above reaction was diluted with 25 ml. of absolute ethanol, 12 g. of thioacetamide was added and the mixture was kept at 0° for 24 hr. followed by standing at room temperature for 3 days. The alcohol was distilled off under water-pump vacuum and the brown residue was extracted with 3% hydrochloric acid. After extracting the acid solution with ether to remove tarry impurities, the solution was made alkaline with $NaHCO_3$ and the oily base was taken up in ether. The ether solution was dried with anhydrous K_2CO_3, evaporated and the product was distilled under reduced pressure. The product was a pale yellow oil boiling at 125–135° at 8 mm. The yield was 5.0 g., 17%.

2-Methyl-6,7-dihydro-4H-thiopyrano(4,3d)thiazole Hydrochloride.—The base (16 g.) in absolute ether (500 ml.) was saturated with dry hydrogen chloride at 0°. The solvent was decanted from the sticky precipitate, and the latter was stirred with 150 ml. of acetone until crystallization occurred. After filtration and washing with acetone, the product was recrystallized from 100 ml. of absolute ethanol. The pale yellow crystals had m.p. 180–181°, yield 12.0 g., 62%.

Anal. Calcd. for $C_7H_{10}ClNS_2$: C, 40.43; H, 4.85; N, 6.74; S, 30.87. Found: C, 40.65; H, 4.88; N, 6.70; S, 31.00.

1-Ethyl-2-methyl-6,7-dihydro-4H-thiopyrano(4,3d)thiazolium Ethyl Sulfate (QS2).—For use in the dye syntheses, equimolecular proportions of the base and freshly distilled ethyl sulfate were heated at 110 to 115° for 5 minutes. The viscous product was used without purification.

2-Methyl-6,7-dihydro-5H-thiopyrano(3,2d)thiazole (IV).—Twenty-five grams (1 mol) of tetrahydro-1-thio-3-pyrone[5] was added to a mixture of 38.2 g. (1 mol) of N-bromosuccinimide and 50 ml. of dry carbon tetrachloride. After the initial vigorous reaction, the mixture was refluxed for 5 minutes. The mixture was chilled, the succinimide filtered and the filtrate evaporated as far as possible under reduced pressure. The product was mixed with 15.0 g. (1 mol) of thioacetamide and 100 ml. of absolute ethanol and allowed to stand at 0° for 3 hr., then overnight at room temperature and finally refluxed for 2 hr. The base was isolated and purified the same as IV above and was obtained as a pale yellow oil, b.p. 90 to 92° at 0.5 mm. The product crystallized on chilling. The yield was 13.4 g., 36%.

1-Ethyl-2-methyl-6,7-dihydro-5H-thiopyrano(3,2d)thiazolium Ethyl Sulfate (QS3).—The base was heated with ethyl sulfate the same as in the preparation of QS2 and the crude product was used in the dye syntheses.

1-Ethyl-2-methyl-6,7-dihydro-5H-thiopyrano(3,2d)thiazolium Iodide (QS5).—The base (10.0 g., 1 mol) was refluxed with ethyl iodide (20 g., 100% excess) for 16 hr. The crystalline product was crushed under ether, washed on the filter with acetone and dried. The yield of light tan crystals was 13.0 g., 68%. For analysis the product was recrystallized twice from absolute ethanol (10 ml. per g.). The pure material had m.p. 150–153° dec. *Anal.* Calcd. for $C_9H_{14}INS_2$: I, 38.80; N, 4.28; S, 19.60. Found: I, 38.51; N, 4.11; S, 19.52.

Absorption data for the new dyes are given in Table II.

Some Methyl Derivatives of *p*-Quaterphenyl[1]

BY HENRY GILMAN AND EUGENE A. WEIPERT

RECEIVED SEPTEMBER 17, 1956

Condensation of *p*-terphenyl-4-yllithium and 4,4′-biphenylenedilithium with 2-, 3- and 4-methylcyclohexanone, followed by dehydration, has been used to synthesize monomethyltetrahydro-*p*-quaterphenyls and dimethyloctahydro-*p*-quaterphenyls, respectively. The corresponding *p*-quaterphenyl derivatives are formed by dehydrogenation with chloranil. The effect of structure on melting points and on solubilities is discussed.

Chain-type polyaryls have been shown to be superior solutes in liquid solution scintillators.[2–4] The use of hydrocarbons as solutes reaches a limit with *p*-terphenyl because those of higher molecular weight are limited by their sparing solubility in the commonly employed aromatic solvents. The introduction of methyl groups on the terminal rings of *p*-quaterphenyl seemed a direct method of surmounting this limitation in view of an expected decrease in melting point and increase in solubility corresponding to the reduction of symmetry. Also, of significance is the conclusion of Hayes, Ott and Rogers[3] that methyl groups do not generally cause an appreciable change in the scintillation ability of the solute.

Table I shows that this expectation was justified. It is interesting to note the marked correspondence of melting point and solubility in toluene through this series. Among the completely aromatic compounds the one outstanding increase in melting point occurs with the 4,4′′′-dimethyl compound (125° higher than the 3,3′′′-isomer), and this is accompanied by a drop to nearly complete insolubility. The 4-methyl derivative is rather unusual in that it melts higher than the more symmetrical parent hydrocarbon (320°) while it is slightly more soluble. The series of compounds containing cyclohexene rings exhibits the same trends but in more pronounced fashion. While the melting points are somewhat unreliable because of decomposition of those melting above 200°, it is evident that the close grouping of melting points in the three monomethylated compounds is a reflection of a similar situation in the completely aro-

matic series. The melting points of the monomethyl-*p*-quaterphenyls proceed from 172 to 330° and the solubilities drop from 26 g./l. to only 1 g./l. In the partially saturated series the span of melting points is only between 184 and 208° while the solubilities drop from 48 to 4 g./l. With methyl groups on both terminal rings the scope of these variations is greatly magnified: the 4,4‴-derivatives being very high melting and comparatively insoluble, while the 2,2‴-dimethyl compounds have surprisingly low melting points and high solubilities in view of their molecular weight and symmetry.

TABLE I

MELTING POINTS AND SOLUBILITIES OF SOME METHYLATED *p*-QUATERPHENYLS

Substituent	*p*-Quaterphenyl derivative M.p., °C.	*p*-Quaterphenyl derivative Solubility in toluene, g./l.	Tetrahydro (or octahydro) derivative M.p., °C.	Tetrahydro (or octahydro) derivative Solubility in toluene, g./l.
2-Methyl	172–173	26.0	184–185	48.0
3-Methyl	244–245	3.0	200 dec.	10.7

Unsubstituted	320[a]	0.8		

[a] F. Ullmann and G. M. Meyer, *Ann.*, **332**, 52 (1904).

The monomethyl derivatives were prepared by condensation of *p*-terphenyl-4-yllithium with the appropriately substituted methylcyclohexanone, followed by dehydration of the intermediate carbinol and dehydrogenation of the olefin according to scheme I. In analogous fashion the symmetrically dimethylated quaterphenyls were prepared from 4,4′-dilithiobiphenyl according to scheme II.

Of the numerous methods available for dehydration of the intermediate cyclohexanol derivatives, vigorous stirring with Lucas reagent as prescribed by Crawford and Nelson[5] was clearly superior. Most of the more common acid catalysts require conditions that afford poor contact between these intractable carbinols and the reagent. In using the Lucas reagent it is not even necessary to isolate the crude carbinol, since it is dehydrated in the benzene solution resulting directly from the organometallic-ketone reaction.

Dehydrogenation to the aromatic system with sulfur and selenium gave poor yields and led to difficulties in purification. The method of Arnold and Collins[6] employing chloranil as the oxidant in refluxing xylene proved to be much cleaner and provided satisfactory yields. Isolation and purification of the product from this oxidation was more conveniently carried through as suggested by Crawford and Nelson[5] since the products could not be distilled under reasonable conditions.

The compounds described at this time were prepared incidental to a study concerned with organic liquid solution scintillators. Evaluation of the compounds for this purpose is being made by Drs. Wright H. Langham, F. Newton Hayes and Donald G. Ott of the Los Alamos Laboratories who will report the results later.

Experimental[7]

4-(Methyl-1-cyclohexen-1-yl)-*p*-terphenyl.—To a stirred solution of 0.040 mole of *p*-terphenyl-4-yllithium[8] in 130 ml. of ether was added 4.71 g. (0.042 mole) of 2-methylcyclohexanone in 60 ml. of benzene. The suspension was stirred at gentle reflux for 30 minutes, then cooled and hydrolyzed with 50 ml. of 10% hydrochloric acid. An additional 150 ml. of benzene was added, and the layers were separated. The organic layer was distilled until the temperature reached 60° and the remaining benzene suspension stirred at gentle reflux for 2 hr. with 60 ml. of Lucas reagent. The layers were separated and the organic layer washed with water, sodium bicarbonate and water again. Evaporation of the benzene solution left a gummy residue which was crystallized from 150 ml. of 1:1 benzene–ethanol to give 8.70 g. (68%) of white powder, melting over the range 168–174°. After seven recrystallizations from benzene–ethanol there remained 5.50 g. (43%) of white plates, melting at 184–185°. The product turned pale yellow upon exposure to direct sunlight.

Anal. Calcd. for $C_{25}H_{24}$: C, 92.59; H, 7.41. Found: C, 92.50; H, 7.67.

2-Methyl-*p*-quaterphenyl.—A mixture of 3.24 g. (0.010 mole) of 4-(methyl-1-cyclohexen-1-yl)-*p*-terphenyl and 4.96 g. (0.020 mole) of chloranil was heated in 50 ml. of refluxing xylene for 12 hr. The mixture was cooled and diluted with 150 ml. of petroleum ether (b.p. 60–70°). The precipitated brown solid was filtered and extracted with 50 ml. of hot ethyl acetate. This extract was diluted with

50 ml. of benzene and combined with the xylene–ligroin filtrate. The combined organic solution was extracted with three 60-ml. portions of 5% potassium hydroxide, then evaporated to dryness. The residue was crystallized twice from a 1:3 benzene–ethanol mixture to give 1.24 g. (38.7%) of pale yellow material melting at 170–172°. Sublimation of this material at 160° (0.01 mm.) and recrystallization of the sublimate from the same solvent mixture afforded white needles melting at 172–173°.

Anal. Calcd. for $C_{25}H_{20}$: C, 93.75; H, 6.25. Found: C, 93.57; H, 6.39.

4-(Methyl-1-cyclohexen-1-yl)-*p*-terphenyl.—Using the same quantities and conditions as described for the 2-methyl isomer, there was obtained 6.25 g. (49%) of shiny plates from benzene which melted at 200° with decomposition.

Anal. Calcd. for $C_{25}H_{24}$: C, 92.59; H, 7.41. Found: C, 92.31; H, 7.72.

3-Methyl-*p*-quaterphenyl.—Chloranil oxidation as above and recrystallization from benzene afforded a 62% yield of nearly white plates melting at 244–245.5°. The analytical sample was obtained by sublimation at 210° (0.01 mm.) and melted at 245–246°.

Anal. Calcd. for $C_{25}H_{20}$: C, 93.75; H, 6.25. Found: C, 93.43; H, 6.51.

4-(4-Methyl-1-cyclohexen-1-yl)-*p*-terphenyl.—Once again the same quantities and conditions were employed; however, the crude product after treatment with Lucas reagent melted over the range 205–235° and resisted purification by recrystallization. The crude material was sublimed at 200° (0.01 mm.) to provide 3.15 g. (32%) of white material with a melting range of 204–208°. Recrystallization from benzene raised this to 208° with decomposition.

Anal. Calcd. for $C_{25}H_{24}$: C, 92.59; H, 7.41. Found: C, 92.69; H, 7.42.

4-Methyl-*p*-quaterphenyl.—4-(4-Methyl-1-cyclohexen-1-yl)-*p*-terphenyl (1.62 g., 0.005 mole) was dehydrogenated with 2.48 g. (0.010 mole) of chloranil in 25 ml. of xylene by refluxing for 8 hr. Upon dilution of the xylene solution with petroleum ether as before, both the product and the dihydrochloranil precipitated. This mixture was extracted continuously with hot ethanol to remove dihydrochloranil and then with toluene which dissolved the desired product. When cooled, the toluene extract deposited 1.05 g. (65.6%) of nearly white plates having a melting range of 322–329°. Sublimation at 210° (0.01 mm.), followed by recrystallization from toluene, afforded 0.64 g. (38%) of clear plates melting at 328–330°.

Anal. Calcd. for $C_{25}H_{20}$: C, 93.75; H, 6.25. Found: C, 94.04; H, 5.98.

4,4′-Bis-(methyl-1-cyclohexen-1-yl)-biphenyl.—To a solution of 0.025 mole of 4,4′-biphenylenedilithium[9] in 100 ml. of 1:1 benzene–ether was added, over a period of 30 minutes, a solution of 5.72 g. (0.051 mole) of 2-methylcyclohexanone in 50 ml. of benzene. The resulting gray-green suspension was stirred at gentle reflux for 3 hr., then hydrolyzed with 50 ml. of 10% hydrochloric acid. The layers were separated and the organic layer washed with water and filtered from a trace of solid material. This solution was distilled until the temperature had reached 60° and the remaining benzene solution stirred at gentle reflux with 60 ml. of Lucas reagent for 2 hr. The oily solid obtained from the organic layer was crystallized from 100 ml. of ethanol to give 1.51 g. (18%) of shiny plates having a melting range of 98–103°. Two recrystallizations from ethanol raised the melting point to 107–108°. The analytical sample melted at 108.5–109°.

Anal. Calcd. for $C_{26}H_{30}$: C, 91.23; H, 8.77. Found: C, 91.07; H, 8.86.

2,2‴-Dimethyl-*p*-quaterphenyl.—The octahydro derivative (1.37 g., 0.004 mole) was treated with 3.94 g. (0.016 mole) of chloranil in 25 ml. of refluxing xylene for 12 hr. to give 0.59 g. (44%) of crude product melting over the range 125–134°. Sublimation at 120° (0.01 mm.) gave white needles having a melting range of 142–146°. Four recrystallizations from ethanol produced a pure sample melting at 150–151°.

Anal. Calcd. for $C_{26}H_{22}$: C, 93.41; H, 6.59. Found: C, 93.45; H, 6.58.

4,4′-Bis-(methyl-1-cyclohexen-1-yl)-biphenyl.—Employing quantities and conditions identical to those used for the 2-methyl isomer there was obtained 3.32 g. (39%) of pale yellow material melting at 144–146°. After four recrystallizations from 1:1 ethanol–benzene the shiny, white plates melted at 149–150°.

Anal. Calcd. for $C_{26}H_{30}$: C, 91.23; H, 8.77. Found: C, 91.31; H, 8.77.

3,3‴-Dimethyl-*p*-quaterphenyl.—Chloranil oxidation of 1.67 g. (0.005 mole) of 4,4′-bis-(methyl-1-cyclohexen-1-yl)-biphenyl produced 0.41 g. (24%) of nearly white material having a melting range of 210–215°. Sublimation at 210° (0.01 mm.) left 0.30 g. (19%) of clear plates melting at 214–215°.

Anal. Calcd. for $C_{26}H_{22}$: C, 93.41; H, 6.59. Found: C, 93.24; H, 6.64.

4,4′-Bis-(4-methyl-1-cyclohexen-1-yl)-biphenyl.—Again using the same quantities and conditions as in the preparation of the 2-methylcyclohexenyl derivative, there was recovered 2.70 g. (31%) of shiny white plates which gradually melted to a yellow-orange liquid over the range of 215–223°. Two recrystallizations from benzene left 2.20 g. (26%) which decomposed at 225°.

Anal. Calcd. for $C_{26}H_{30}$: C, 91.23; H, 8.77. Found: C, 90.77; H, 8.91.

4,4‴-Dimethyl-*p*-quaterphenyl.—Oxidation of 1.67 g. (0.005 mole) of the bis-cyclohexene compound prepared above with chloranil gave 0.81 g. (58%) of gray powder which charred slowly above 320°. After sublimation at 210° (0.01 mm.) and recrystallization from toluene there was recovered 0.26 g. (18%) of white powder melting at 338–340°. Pummerer and Seligsberger[10] reported 334° for this compound.

Studies in the Naphthalene Series. III. Synthesis of Apogossypol Hexamethyl Ether[1]

BY J. D. EDWARDS, JR., AND J. L. CASHAW

RECEIVED NOVEMBER 16, 1956

Apogossypol hexamethyl ether, the primary degradation product of gossypol, the pigment and toxic principle in cottonseed, formulated by Adams as 2,2′-bi-5-isopropyl-1,6,7-trimethoxy-3-methylnaphthyl has been synthesized by the oxidative coupling of 5-isopropyl-1,6,7-trimethoxy-3-methyl-1-naphthol and methylation of the resulting binaphthol.

Gossypol, the yellow pigment of cottonseed, has been the subject of extensive work[2] and was for-

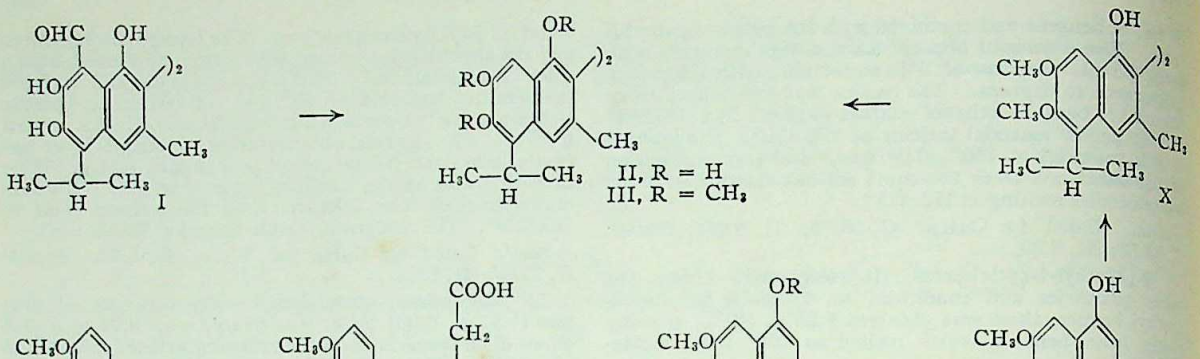
Digitized by Arya Samaj Foundation Chennai and eGangotri



mulated by Adams[3] as 2,2′-bi-1,6,7-trihydroxy-3-methyl-5-isopropyl-8-formylnaphthyl (I), as a result of his degradation studies. The postulated structure of desapogossypolone tetramethyl ether[3] was later shown to be correct by synthesis.[4] Heating of gossypol in concentrated sodium hydroxide results in the formation of apogossypol[5–7] (II), which is very unstable even in the solid state. Methylation gives apogossypol hexamethyl ether (III) which was, to a large extent, used for the degradation studies by Adams.[3]

The synthesis reported in this communication establishes conclusively the correctness of Adams' formulation[3] as to the relationship of the internuclear linkage and the groups at the 1-, 3- and 5-positions in apogossypol and desapogossypol hexamethyl ethers. This relationship has been questioned recently.[8]

The synthesis of 5-isopropyl-6,7-dimethoxy-3-methyl-1-naphthol (IX), the key intermediate in the synthesis here reported, utilized 2-isopropyl-3,4-dimethoxybenzaldehyde (IV)[9] as the starting material. The condensation of IV with diethyl succinate gave the half-ester V. Cyclodehydration of V with sodium acetate and acetic anhydride[10] gave the acetate VI which on saponification yielded 1-hydroxy-5-isopropyl-6,7-dimethoxy-3-naphthoic acid (VII). Reduction of VII with lithium aluminum hydride gave 3-hydroxymethyl-5-isopropyl-6,7-dimethoxy-1-naphthol (VIII). Hydrogenolysis of VIII with palladium-on-charcoal gave the naphthol IX.

In the preliminary studies[1] the oxidative coupling of IX to 2,2′-bi-1-(5-isopropyl-6,7-dimethoxy-3-methyl)-naphthol (X)[11] was achieved in a low yield by use of ferric chloride[12] with purified dioxane as the solvent. Later it was found that the coupling of IX to X occurred in quantitative yield by merely heating IX above its melting point. The over-all yield from IV to X was 26%. Methylation of X using aqueous dioxane as the solvent gave 2,2′-bi-5-isopropyl-1,6,7-trimethoxy-3-methylnaphthyl (III) identical in all respects with apogossypol hexamethyl ether (III) prepared from gossypol.

Acknowledgment.—The encouragement and interest of Professor R. B. Turner is gratefully acknowledged.

Experimental[13]

1-Hydroxy-5-isopropyl-6,7-dimethoxy-3-naphthoic Acid. (a) **Stobbe Condensation.**—To a mixture of 3.8 g. of sodium hydride in 30 ml. of anhydrous benzene there was added with stirring a solution of 27 g. of diethyl succinate and 11 g. of 2-isopropyl-3,4-dimethoxybenzaldehyde[9] in 50 ml. of benzene. This mixture was heated at 50° for 1 hr. after 0.75 ml. of alcohol was added. After cooling, water was added and the mixture extracted with ether. The aqueous phase was acidified and extracted with ether. The two ethereal extracts were combined and extracted with 250 ml. of 5% sodium carbonate solution. The aqueous extract was cooled and acidified with dilute hydrochloric acid. The oily precipitate was taken up in ether and dried over anhydrous sodium sulfate. Evaporation of the ether gave 14.2 g. (80%) of the oily half-ester V.

(b) **Ring Closure and Saponification.**—To 14.2 g. of the crude half ester, there was added 63.5 ml. of acetic acid, 63.5 ml. of acetic anhydride and 3 g. of fused sodium acetate. After refluxing for 4 hr., the light yellow solution was evaporated under a current of air and the semi-crystalline residue treated with 100 ml. of 5% sodium carbonate. The product was extracted with ether, and after drying over sodium sulfate, the ether was removed over a steam-bath. The crude oily product VI was then treated with 350 ml. of methanol and 350 ml. of 10% sodium hydroxide and refluxed for 3 hr. The alcohol was evaporated over a steam-bath and the aqueous extract acidified to give 10.6 g. (86%) of

(11) Since methylation of the binaphthol obtained gave a product identical with apogossypol hexamethyl ether, there can be no question that the coupling occurred at the 2-position in IX. This follows since desapogossypolone tetramethyl ether, which is obtained from apogossypol hexamethyl ether, has been shown[3] by synthesis to possess the 2,2′-linkage. A study of Fisher–Taylor–Hirschfelder models also shows that the 4-position in IX is so masked by the methyl and isopropyl groups that no coupling to give the 4,4′-bi-1-naphthol can occur.

(12) J. D. Edwards, Jr., and J. L. Cashaw, THIS JOURNAL, **76**, 6141 (1954).

(13) All analyses were done by the Huffman Microanalytical Laboratories, Wheatridge, Colorado. Melting points are uncorrected and were made on a Fisher–Johns apparatus. The infrared determinations were carried out on a Perkin–Elmer model 21 spectrophotometer, 0.1 mm. cells, solvent chloroform, concentration approximately 7%.

VII. Crystallization from benzene gave material of m.p. 226–227°. The infrared spectrum[13] exhibited carbonyl absorption at 1680 and hydroxyl absorption at 3380 cm.$^{-1}$.

Anal. Calcd. for $C_{16}H_{18}O_5$: C, 66.18; H, 6.26. Found: C, 66.32; H, 6.23.

3-Hydroxymethyl-5-isopropyl-6,7-dimethoxy-1-naphthol (VIII).—To 4 g. of lithium aluminum hydride in 200 ml. of absolute ether there was added dropwise a solution of 4.5 g. of VII in 100 ml. of ether. The mixture was refluxed for 90 minutes and allowed to stand overnight. After cooling, the mixture was decomposed by the dropwise addition of water and then acidified with dilute hydrochloric acid. After separation, the ethereal extract was washed twice with water and dried over anhydrous sodium sulfate. The ether was removed over a steam-bath and the residue crystallized from benzene to give 3.9 g. (93%) of VIII, m.p. 207–209°. The infrared spectrum[13] showed hydroxyl group absorption at 3420 and 3300 cm.$^{-1}$.

Anal. Calcd. for $C_{16}H_{20}O_4$: C, 69.53; H, 7.31. Found: C, 69.71; H, 7.20.

5-Isopropyl-6,7-dimethoxy-3-methyl-1-naphthol (IX).—To 0.15 g. of palladium-on-charcoal (10%) in 35 ml. of methanol there was added 0.5 g. of VIII in 65 ml. of methanol. One drop of concd. hydrochloric acid in 1 ml. of water was added to this mixture. It was then hydrogenated for 20 minutes in a Parr low pressure hydrogenator. Anhydrous sodium sulfate was added and the mixture suction filtered. After removal of the methanol over a steam-bath, the product was recrystallized from chloroform–petroleum ether (30–60°) to give 0.192 g. (41%) of IX, m.p. 129–130°. The infrared spectrum[13] showed the presence of an hydroxyl group (sharp band at 3570 and a broad band at 3310 cm.$^{-1}$).

Anal. Calcd. for $C_{16}H_{20}O_3$: C, 73.82; H, 7.74. Found: C, 73.76; H, 7.78.

2,2′-Bi-1-(5-isopropyl-6,7-dimethoxy-3-methyl)-naphthol (X).—A test-tube containing 0.2 g. of IX was placed in an oil-bath heated to 150°; the temperature was allowed to rise to 215° and held there for 20 minutes or until the material had melted and solidified. The product was recrystallized from benzene–methanol to give a quantitative yield of X, m.p. 271–274°.

Anal. Calcd. for $C_{32}H_{38}O_6$: C, 74.10; H, 7.38; mol. wt., 518. Found: C, 74.21; H, 7.39; mol. wt. (Rast), 447.

2,2′-Bi-5-isopropyl-1,6,7-trimethoxy-3-methylnaphthyl (III).—To a solution of 0.24 g. of X in 25 ml. of purified dioxane[14] there was added 5 ml. of an aqueous solution of 0.49 g. of potassium hydroxide. To this mixture there was added 1.1 g. of dimethyl sulfate which was then heated under reflux until reaction was complete as indicated by litmus paper. The additions of potassium hydroxide and dimethyl sulfate were repeated two times. After cooling, water was added and the reaction mixture extracted with dichloromethane. The dichloromethane phase was extracted several times with water. After drying over anhydrous sodium sulfate, the dichloromethane was removed over a steam-bath and the residue taken up in 25 ml. of diethyl ether and filtered. Upon standing 0.1 g. (42%) of 2,2′-bi-5-isopropyl-1,6,7-trimethoxy-3-methylnaphthyl (III) crystallized. It was recrystallized several times from benzene–methanol, m.p. 277–279°; mixture m.p. with apogossypol hexamethyl ether prepared from gossypol, 277–278°. The infrared[13] spectra of the natural and synthetic product were indistinguishable.

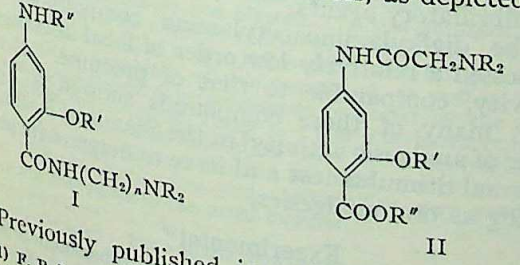
Derivatives of 4-Amino-2-hydroxybenzoic Acid. IV. Amides

BY R. O. CLINTON, S. C. LASKOWSKI, U. J. SALVADOR, HELEN G. BATES AND PATRICIA M. CARROLL

RECEIVED OCTOBER 15, 1956

Several types of amides derived from the 4-amino-2-hydroxybenzoic acid nucleus have been prepared. The first type consisted of N-(dialkylaminoalkyl)-4-amino-2-hydroxybenzamides and the related 2-alkoxy and 4-alkylamino compounds. Several of these compounds possessed outstanding activity as antifibrillatory agents. The second series was of the general type represented by an alkyl 4-(dialkylaminoacetylamino)-2-alkoxybenzoate and its related derivatives. The latter compounds were, in general, only fair local anesthetics but in certain cases possessed substantial analgesic properties. Finally, a series of variants on the 4-amino-2-alkoxybenzamide nucleus were prepared; certain of these compounds were potent oral analgesics.

The observation[1] that a very high degree of local anesthetic activity was associated with certain basic ester and thiol ester derivatives of 4-amino-2-hydroxy- and 2-alkoxybenzoic acids[2] prompted an extension of the synthetic work to two types of basic amides related to these series, as depicted in I and II.



I II

Previously published investigations[3–5] of N-ω-dialkylaminoalkylbenzamides have shown that the simple amides were considerably less active as local anesthetics than their ester counterparts and that even in the cases of 3-alkoxy-[4] or 4-alkoxy-[5] substitution the local anesthetic activity does not surpass that of the esters. However, since in the present series a very high degree of local anesthetic activity was associated with the basic ester counterparts[1] of I, it was felt that a reduction in the degree of local anesthetic activity would not be a serious defect. Further, the increased stability of the amide linkage toward hydrolysis might well be reflected in more desirable physiological properties.

The synthesis of the amides of type II was based upon the premise that the low toxicity associated

with Nirvanine[6] [methyl 5-(diethylaminoacetylamino)-2-hydroxybenzoate] might well be retained in the corresponding 4-dialkylaminoacetylamino series, while simultaneously achieving a very desirable reduction in irritation. Since the completion of this investigation, two examples of compounds related to II have been published.[7] Both compounds were hydroxy acids (II, R′ = R″ = H), prepared for testing as antitubercular agents.

In the two formulas shown, I and II, the various indicated substituent R, R′ and R″ groups were varied sufficiently to ensure the attainment, if possible, of a wide range of local anesthetic activity. In addition to the alkyl esters of II, several of the related benzamides and benzoic acids were prepared for comparison.

The benzamides of type I were prepared either by the aminolysis of a 4-nitrosalicylic ester or by the reaction between an alkoxynitrobenzoyl chloride and an amine. Subsequent reduction by conventional means led to the 4-aminobenzamides and thence by reductive alkylation to the 4-alkylaminobenzamides. These compounds are listed in Tables I, II and III and are described in the Experimental section.

The amides of type II were in general prepared by the reaction of an alkyl 2-alkoxy-4-aminobenzoate with chloroacetyl chloride, followed by amination by the appropriate secondary amine. Similar methods were used for the amide types (II, $CONH_2$ in place of COOR″). This series is summarized in Tables IV and V.

The initial observation[8] that 4-amino-2-alkoxybenzamides possessed oral analgesic activity of the order of aminopyrine in the standard Radiant Thermal Stimulus test, prompted the synthesis of a large number of variants on the former nucleus. These compounds were synthesized by straightforward methods with little difficulty; they are summarized in Table VI and in the Experimental section.

Pharmacological testing[9] of the N-dialkylaminoalkyl benzamide types, I, has indicated a high degree of local anesthetic activity for those compounds where R′ is greater than ethyl. In general this activity is less than that found for the corresponding esters, while toxicity and irritancy are similar to those found for the esters. Several of the higher members of the series, in particular N-(2-diethylaminoethyl)-4-amino-2-hexoxybenzamide (Win 8568), have shown outstanding properties as antifibrillatory agents.

The dialkylaminoacetylamino compounds, II, possessed a relatively low order of local anesthetic activity, comparable to that of procaine. However, many of these compounds showed a high order of analgesic activity[8] in the Standard Radiant Thermal Stimulus test and have undergone further testing as oral analgesics.

Experimental[10]

N-(Diethylaminoethyl)-2-hydroxy-4-nitrobenzamide Hydrochloride.—A mixture of 16.7 g. (0.079 mole) of ethyl 4-

nitrosalicylate, 23.2 g. (0.20 mole) of 2-diethylaminoethylamine and 250 ml. of dry toluene was refluxed for 8 hr. On cooling, the orange-colored solution separated into two layers. The toluene was removed *in vacuo* and the residual solid (essentially a phenolate-type salt of the base with excess 2-diethylaminoethylamine)[11] was dissolved in an excess of hot alcoholic hydrogen chloride solution. The solution was cooled, diluted with anhydrous ether and the precipitated hydrochloride was filtered. It was obtained analytically pure after a single recrystallization from absolute alcohol. The yield of bright yellow solid was 18.9 g. (75%). The physical properties of this compound, as well as those of analogous 2-hydroxy compounds prepared by the same procedure, are listed in Table I. The free bases (usually oils) were prepared by liberation from the pure hydrochlorides with potassium carbonate solution, under nitrogen. The picrates, flavianates and methiodides were prepared from the free bases in the usual manner.

N-(Diethylaminoalkyl)-2-alkoxy-4-nitrobenzamides.—Aminolysis of an alkyl 2-alkoxy-4-nitrobenzoate[2b] by means of a dialkylaminoalkylamine as above gave fair to poor yields; the yields decreased as the size of the 2-alkoxy group increased. A better procedure involved the reaction between a 2-alkoxy-4-nitrobenzoyl chloride and the amine in benzene or ether solution.

To a stirred solution of 40.0 g. (0.186 mole) of 2-methoxy-4-nitrobenzoyl chloride[2b] in 250 ml. of dry benzene, there was slowly added a solution of 21.6 g. (0.186 mole) of 2-diethylaminoethylamine in 50 ml. of dry benzene. The addition required about 0.5 hr.; the internal temperature was held at about 20° by means of a cooling bath. The resulting gummy mixture was heated to boiling, diluted with 700 ml. of dry *n*-hexane and cooled. The tan-colored solid was filtered and washed with 1:1 benzene–hexane mixture. After three recrystallizations from an absolute alcohol–*n*-hexane mixture, with decolorization by means of Darco G-60 during the first recrystallization, the product was obtained pure in 77% yield.

With the higher 2-alkoxy-4-nitrobenzoic acids it was necessary to prepare the benzoyl chloride *in situ* in the presence of pyridine, to prevent cleavage of the alkoxyl group.[2b] Under these conditions, wherein a slight initial excess of the acid over thionyl chloride was present, the excess acid was removed by extraction with an ethereal solution of the product before conversion to the hydrochloride.

and are corrected. The analyses were done by Mr. M. E. Auerbach, Mr. K. D. Fleischer and their staffs. In the text and Tables the following abbreviations are used: N^a for nitro-nitrogen by titanous chloride titration; neutral equivalent by titration with sodium methoxide in anhydrous methanol; basic N for nitrogen by titration with perchloric acid in acetic acid.

An alternative procedure involved the addition of the benzoyl chloride in alcohol-free chloroform solution to a mixture of the amine, water and sodium bicarbonate.[12] The crude yields obtained by this method were usually somewhat lower than those resulting by the direct reaction mentioned above, but the products in some cases proved to be purified more easily. For example, this method gave excellent results when applied to the preparation of N-(3-diethylamino-2-hydroxy-1-propyl)-2-methoxy-4-nitrobenzamide, whereas the direct reaction in benzene gave an almost inseparable mixture of benzoate and benzamide.

In addition to those compounds listed in Table I, there was prepared: **N-(3-(2-methyl-1-piperidyl)-(propyl)-2-methoxy-4-nitrobenzamide hydrochloride**, from the benzoyl chloride and 3-(2-methyl-1-piperidyl)-propylamine[13] in benzene solution; 82% yield. The compound formed pale yellow prisms from absolute alcohol–*n*-hexane; m.p. 167.5–169.3°.

Anal. Calcd. for $C_{17}H_{26}ClN_3O_4$: N^a, 3.76; Cl, 9.53. Found: N^a, 3.71; Cl, 9.18.

4-Nitro-2-octyloxybenzoic Acid.—The alkylation of ethyl 2-hydroxy-4-nitrobenzoic acid by means of *n*-octyl benzenesulfonate (from *n*-octyl alcohol, benzenesulfonyl chloride and pyridine) was carried out by the method previously described.[2b] Hydrolysis of the crude oily ethyl ester gave a 97% over-all yield of the acid, m.p. 92–93°. The compound crystallized from *n*-hexane in cream-colored feathery needles, m.p. 93.1–94.2°.

Anal. Calcd. for $C_{15}H_{21}NO_5$: C, 61.00; H, 7.16; N, 4.74. Found: C, 60.94; H, 7.20; N, 4.91.

Conversion to the acid chloride by means of thionyl chloride–pyridine and thence to the ethyl ester, gave the latter as a mobile oil; reduction by means of iron–hydrochloric acid gave a 77% yield of **ethyl 4-amino-2-octyloxybenzoate**, white prisms from *n*-hexane; m.p. 61.8–63.4°.

Anal. Calcd. for $C_{17}H_{27}NO_3$: C, 69.59; H, 9.27; N, 4.77. Found: C, 69.58; H, 9.02; N, 4.82.

N-(Diethylaminoalkyl)-4-amino-2-hydroxybenzamides.—The 2-hydroxy-4-nitrobenzamide hydrochlorides were reduced catalytically by hydrogen in alcoholic solution at 50 lb. pressure and 25°, using 7% palladium chloride on Darco G-60 as catalyst. Precautions were taken in the isolation procedure to minimize air oxidation of the sensitive products.

N-(Dialkylaminoalkyl)-2-alkoxy-4-aminobenzamides.—Reduction of the 2-alkoxy-4-nitrobenzamide hydrochlorides (or the free bases) was carried out by the usual iron–hydrochloric acid procedure.[2b] The isolated bases were converted into the acid salts, picrates, etc., in the usual manner. In the case of N-(3-diethylamino-2-hydroxy-1-propyl)-4-amino-2-methoxybenzamide, the compound was obtained impure (possibly due to some amide–ester interconversion); it was characterized as the picrate, m.p. 88.0–97.0° dec.

Anal. Calcd. for $C_{21}H_{28}N_6O_{10}$: N, 16.00. Found: N, 15.91.

N-(3-(2-Methyl-1-piperidyl)-propyl)-4-amino-2-methoxybenzamide dihydrochloride monohydrate crystallized from absolute alcohol–ether in white needles, m.p. 143.8–146.0°.

Anal. Calcd. for $C_{17}H_{29}Cl_2N_3O_2 \cdot H_2O$: N, 10.60; Cl, 17.89; H_2O, 4.54. Found: N, 10.85; Cl, 17.61; H_2O, 4.57.

The **flavianate** formed yellow cottony needles from dilute alcohol, m.p. 193.8–195.5°. *Anal.* Calcd. for $C_{27}H_{33}N_5O_{10}S$: S, 5.17. Found: S, 5.32.

The 2-alkoxy-4-aminobenzamide methiodides shown in Table II were prepared by the catalytic reduction (platinum oxide) of the nitrobenzamide precursors.

N-(Dialkylaminoalkyl)-4-alkylamino-2-methoxybenzamides.—Reductive alkylation of the 4-amino-2-methoxybenzamides by means of an aldehyde, zinc dust and acetic acid was carried out as usual.[2b] The products in all cases were viscous, high boiling oils; purification was carried out as previously outlined.[2a,b] **N-(3-(2-Methyl-1-piperidyl)-propyl)-4-butylamino-2-methoxybenzamide** was a glassy, straw-colored resin.

Anal. Calcd. for $C_{21}H_{35}N_3O_2$: C, 69.76; H, 9.75; N, 11.62. Found: C, 69.93; H, 9.58; N, 11.31.

The diflavianate crystallized from alcohol in bright yellow prisms, m.p. 160.9–163.9°. *Anal.* Calcd. for $C_{41}H_{47}N_7O_{18}S_2$: N, 9.90. Found: N, 9.84.

Ethyl 4-(Chloroacetylamino)-2-ethoxybenzoate.—To a solution of 20.9 g. (0.10 mole) of ethyl 4-amino-2-ethoxybenzoate in 250 ml. of warm, dry benzene there was added 12.4 g. (0.11 mole) of chloroacetyl chloride in one portion. The resulting heterogeneous mixture, which contained a gelatinous precipitate, was refluxed for 3.5 hr. Solution of the precipitate was completed in 15 minutes; the evolution of hydrogen chloride practically ceased after 2 hr. The mixture was then concentrated to a small volume *in vacuo* and diluted with about five volumes of *n*-hexane. After two recrystallizations from benzene–*n*-hexane, there was obtained 24.8 g. (87%) of pure product which crystallized in brilliant white prisms, m.p. 112.8–113.8°.

Anal. Calcd. for $C_{13}H_{16}ClNO_4$: C, 54.64; H, 5.65; N, 4.90. Found: C, 54.47; H, 5.38; N, 4.91.

With compounds which contained 2-alkoxy groups larger than ethoxy, recourse was had to the acetic acid–sodium acetate methods of Löfgren,[14] in order to prevent alkoxy cleavage.

Ethyl 4-(chloroacetylamino)-2-butoxybenzoate, 81% yield, white prisms from Skellysolve C; m.p. 81.4–83.4°. *Anal.* Calcd. for $C_{15}H_{20}ClNO_4$: Cl, 11.30. Found: Cl, 11.61.

Ethyl 4-(chloroacetylamino)-2-benzoyloxybenzoate, nearly quantitative yield, white prisms from benzene–*n*-hexane, m.p. 120 4–121.6°. *Anal.* Calcd. for $C_{18}H_{18}ClNO_4$: Cl, 10.19; N, 4.03. Found: Cl, 10.42; N, 3.99.

4-(Chloroacetylamino)-2-ethoxybenzamide, obtained in 75% yield from 4-amino-2-ethoxybenzamide (see below) by the acetic acid method, formed white needles from absolute alcohol; m.p. 194.0–198.0° dec. *Anal.* Calcd. for $C_{11}H_{13}ClN_2O_3$: N, 10.91. Found: N, 10.92.

4-(Chloroacetylamino)-2-benzyloxybenzamide, obtained from the amide (see below) by the acetic acid method in 98% yield, rosettes of white needles, from absolute alcohol–ethyl acetate; m.p. 208.0–209.3°. *Anal.* Calcd. for $C_{16}H_{15}ClN_2O_3$: N, 8.79. Found: N, 8.73.

Alkyl 4-(Dialkylaminoacetylamino)-2-alkoxybenzoates.—A mixture of the alkyl 4-(chloroacetylamino)-2-alkoxybenzoate, an amine and the appropriate alcohol was refluxed for 4 to 6 hr. After removal of the alcohol and excess amine *in vacuo*, the product was converted to the base in the usual manner. The yields of the crude bases were 75–85%. The picrates, hydrochlorides, etc., were prepared in the usual manner; *cf.* Table IV.

4-(Dialkylaminoacetylamino)-2-alkoxybenzamides.—The benzamide derivatives were prepared either from the 4-(chloroacetylamino)-benzamide by the above method, or *via* the free acid.

A mixture of 24.5 g. (0.076 mole) of ethyl 4-(diethylaminoacetylamino)-2-ethoxybenzoate, 6.4 g. (0.11 mole) of potassium hydroxide, 200 ml. of alcohol and 100 ml. of water was refluxed for 1 hr. The alcohol was removed *in vacuo* and the aqueous solution was made acidic to congo red paper with hydrochloric acid and saturated with salt. The resulting precipitate was filtered, dried thoroughly and recrystallized from absolute alcohol and from an absolute alcohol–isopropyl alcohol mixture, yielding pure **4-(diethylaminoacetylamino)-2-ethoxybenzoic acid hydrochloride**, m.p. 203.6–204.1° dec.

Anal. Calcd. for $C_{15}H_{23}ClN_2O_4$: Cl, 10.72. Found: Cl, 10.64.

To a stirred suspension of 19.1 g. (0.058 mole) of 4-(diethylaminoacetylamino)-2-ethoxybenzoic acid hydrochloride in 5.2 g. (0.066 mole) of pure pyridine and 200 ml. of dry benzene was added 7.5 g. (0.063 mole) of pure thionyl chloride. The resulting mixture was refluxed and stirred for 15 minutes; solution was not effected. The resulting slurry was poured into a mixture of 200 ml. of concentrated ammonium hydroxide and 500 ml. of water with vigorous stirring. After 15 minutes the benzene layer was separated, washed once with water, dried over Drierite and decolorized with Darco G-60. Evaporation of the benzene gave 13.4 g. of **4-(diethylaminoacetylamino)-2-ethoxybenzamide**, m.p. 135–137°. Two recrystallizations from dilute alcohol gave pure material; *cf.* Table V.

Similarly prepared were: **4-(Diethylaminoacetylamino)-2-butoxybenzoic acid hydrochloride**, m.p. 205.4–206° dec. *Anal.* Calcd. for $C_{17}H_{27}ClN_2O_4$: N, 7.81. Found: N, 7.65.

4-(Diethylaminoacetylamino)-2-benzyloxybenzoic acid hydrochloride, m.p. 180.7–182.0°. *Anal.* Calcd. for $C_{20}H_{25}ClN_2O_4$: N, 7.13; Cl, 9.02. Found: N, 7.34; Cl, 8.90.

2-Methoxy-4-nitrobenzamide.—To 1 liter of cooled, stirred, concentrated ammonium hydroxide (28%) there was added, portionwise, 70 g. of pure 2-methoxy-4-nitrobenzoyl chloride.[2b] When the addition was completed, the resulting suspension was stirred for 15 minutes, filtered and the insoluble product was washed thoroughly with water and dried at 70°. The finely powdered, crude material was stirred at 50° for 15 minutes with 500 ml. of 5% aqueous sodium hydroxide solution and the insoluble material was filtered, washed thoroughly with water and recrystallized twice from glacial acetic acid; *cf.* Table VI.

2-Ethoxy-4-nitrobenzamide.—A mixture of 32 g. (0.166 mole) of 2-ethoxy-4-nitrobenzonitrile[11] and 100 ml. of concentrated sulfuric acid was stirred and heated until the temperature of the mixture was 97°. The heat source was removed; the internal temperature spontaneously rose to 109°. When the internal temperature had dropped to 95°, the mixture was held at 96–97° for a further 1-hr. period. After quenching in 500 ml. of water, the insoluble product was filtered off, washed thoroughly with water and dried at 80°. Three recrystallizations from absolute alcohol furnished 13 g. (37%) of the pure 2-ethoxy-4-nitrobenzamide.

2-Butoxy-4-nitrobenzamide.—General method for alkoxy groups larger than ethoxy: The preparation of 2-butoxy-4-nitrobenzoyl chloride was carried out in benzene solution in the presence of pyridine.[2b] The resulting benzene suspension was added slowly to an excess of concentrated ammonium hydroxide solution, with vigorous stirring. The emulsion was filtered and the insoluble material was washed well with water. The benzene layer was separated from the filtrate and washed with water; evaporation gave a small additional amount of product. The combined fractions, after three recrystallizations from ethyl acetate, gave a 67% yield of pure 2-butoxy-4-nitrobenzamide.

4-Amino-2-alkoxybenzamides.—The reduction of the 2-alkoxy-4-nitrobenzamides was carried out either by means of iron–hydrochloric acid in dilute alcohol[2a] or by catalytic reduction with platinum oxide in alcoholic solution. The yields were good in all cases (80–95%).

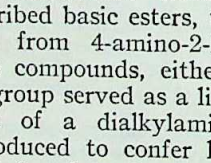
Derivatives of 4-Amino-2-hydroxybenzoic Acid. V. Basic Ethers

BY R. O. CLINTON, S. C. LASKOWSKI, U. J. SALVADOR AND PATRICIA M. CARROLL

RECEIVED OCTOBER 15, 1956

A series of alkyl 4-amino-2-(dialkylaminoalkoxy)-benzoates was prepared for testing as potential local anesthetics. The compounds proved to be good local anesthetics; of more interest was the observation that quaternary salts of these compounds exhibited a high degree of activity as ganglionic blocking agents.

Previous communications[1] from these laboratories have described basic esters, thiol esters and amides derived from 4-amino-2-hydroxybenzoic acids. In these compounds, either the carboxyl or the 4-amino group served as a linkage point for the attachment of a dialkylaminoalkyl chain, which was introduced to confer local anesthetic activity. A third point of attachment for the basic moiety, *viz.*, the 2-hydroxy group, is considered in the present communication. These compounds have the general structure shown by I.



I

Although a compound of type I has not appeared in the literature, a number of related des-amino and des-carboxy analogs have been reported. Chapman, *et al.*,[2] prepared bis-diethylaminoethoxy compounds derived from stilbestrol and hexylresorcinol. Peak and co-workers[3] synthesized several series of basic ethers derived from various chlorinated phenols, catechol, hydroquinone, etc. Furthermore Einhorn and Rothlauf[4] have prepared several alkyl 2- and 4-(2-diethylaminoethoxy)-benzoates and phenolic monobasic ethers, and Rohmann and Friedrich[5] reported the preparation of 4-(2-diethylaminoethoxy)-aniline and a number of its derivatives. In most of these cases pharmacological data have not been reported for the compounds.

Reference should also be made to the dialkylaminoalkoxyaryl compounds and related benzodioxane derivatives, which have been extensively studied by Bovet and co-workers[6] and found to have a wide variety of pharmacodynamic activities.

The alkyl 4-amino-2-(dialkylaminoalkoxy)-benzoates prepared during this investigation were tested for local anesthetic activity[7] by standard methods. In general the compounds were highly active in the intracutaneous wheal and sciatic nerve block tests but less active as corneal local anesthetics. Increasing the side chain length (*e.g.*, from 2-(2-diethylaminoethoxy)- to 2-(3-diethylaminopropoxy)-) or altering the terminal basic moiety (*e.g.*, from dimethylamino to 2-methyl-1-piperidyl) produced a substantial increase in activity. Similarly, changing the ester group from methyl to butyl increased the subcutaneous local anesthetic activity moderately and the topical (corneal) activity markedly. The

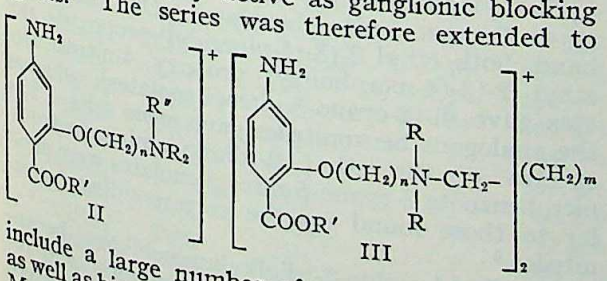
[a] N[a], see ref. 10. [b] The base melted at 42.0–48.9°. Calcd.: N, 8.28. Found: N, 8.35. [c] 4-Morpholinyl. [d] 1-Piperidyl. [e] 2-Methyl-1-piperidyl. [f] 2,6-Dimethyl-1-piperidyl.

compounds were, in general, somewhat more toxic and slightly more irritating than their basic ester counterparts[1a,b] and therefore had lower therapeutic indices. Several of the 4-amino compounds possessed a fair degree of oral analgesic activity (*cf.* reference 1d).

The alkyl 4-alkylamino-2-(dialkylaminoalkoxy)-benzoates (I, R″ = butyl, 5-hydroxyamyl, etc.), like their basic ester counterparts,[1a,b], were *less* active than their 4-amino precursors, both subcutaneously and topically (contrast: procaine *vs.* tetracaine). Moreover, the 4-alkylamino derivatives were considerably more irritating than their 4-amino precursors; for this reason only a few examples of the series were prepared. Removal of the ester group with the formation of I (R = H) destroyed all activity.

During the course of the present investigation several quaternary salts derived from I were also prepared (*cf.* II). These quaternary salts, as well as their corresponding 4-nitro precursors, were found to be highly active as ganglionic blocking agents.[8] The series was therefore extended to include a large number of representatives of II, as well as bisquaternary salts of type III (m = 0–4). Most of these compounds were very active, the greatest activity being found with compounds wherein R′ was propyl or butyl, and R and R″ were small (methyl, ethyl, etc.). Activity decreased markedly with the series shown in III as the value of m increased.



The alkyl 2-(dialkylaminoalkoxy)-4-nitrobenzoates were prepared in several ways. The direct reaction between an alkyl 2-hydroxy-4-nitrobenzoate and a dialkylaminoethyl chloride (a modified Horenstein–Pählicke reaction) gave the desired products, although in poor yields. The yields were considerably lower than those obtained previously from 2-hydroxy-4-nitrobenzonitrile[9] by the use of this reaction, indicating the pronounced steric effect of the carbalkoxy grouping.[1a] Moreover, the reaction failed completely with 3-dialkylaminopropyl chlorides, even in the presence of added iodide ion. Considerably better yields were obtained by condensation of sodio-phenolate with a dialkylaminoalkyl chloride in an anhydrous alcoholic solution or in toluene; use of the latter solvent was mandatory with highly reactive halides such as 2-dimethylaminoethyl chloride and in general was the most useful reaction medium.

The route from ethyl 2-(2-chloroethoxy)-4-nitrobenzoate *via* condensation with a secondary amine was also investigated; here again poor overall yields were obtained. The alkyl 2-(dialkylaminoalkoxy)-4-nitrobenzoates as well as their characterizing derivatives, are summarized in Table I.

The alkyl 2-(dialkylaminoalkoxy)-4-nitrobenzoate quaternary salts, listed in Table II, were prepared by the direct condensation of the free base with an alkyl halide or an α,ω-dibromoalkane. Steric effects were quite pronounced. The size of the ester group had no apparent effect since there appeared to be no difference in the rates of reaction of the methyl, ethyl, propyl or butyl esters with, *e.g.*, methyl iodide. The size of the entering R″

group and of the R_2 group(s) (*cf.* II), however, had a marked effect. When NR_2 was 2-methyl-1-piperidyl, for example, the rate of reaction with methyl iodide was only about one-tenth as fast as the reaction with the analogous nitro base wherein NR_2 was diethylamino. Reactions of the α,ω-dibromoalkanes with compounds which contained 2-dimethylaminoethoxy groups took place at a moderate rate in boiling acetonitrile; reaction with compounds which contain 2-diethylaminoethoxy groups was very slow even in boiling nitromethane.

In addition to the picrates of the alkyl 2-(dialkylaminoalkoxy)-4-nitrobenzoates listed in Table I, several 2-cyano-5-nitrophenolates were also synthesized for comparison with the analogous 2-(dialkylaminoalkoxy)-4-nitrobenzonitrile 2-cyano-5-nitrophenolates.[9] Although an extensive series of these salts was not prepared in the present work, it is of interest that the molecular compounds formed are apparently greatly influenced by steric effects, as was previously noted.[9] Ethyl 2-(2-diethylaminoethoxy)-4-nitrobenzoate, similar to 2-(2-diethylaminoethoxy)-4-nitrobenzonitrile, yielded a di-(2-cyano-5-nitrophenolate). On the other hand, both ethyl 2-(3-(1-piperidyl)-propoxy)- and ethyl 2-(3-(4-morpholinyl)-propoxy)-4-nitrobenzoates gave di-(2-cyano-5-nitrophenolates), whereas the analogous benzonitriles gave *mono* salts. The spectra of the ethyl 2-(dialkylaminoalkoxy)-4-nitrobenzoate 2-cyano-5-nitrophenolates were similar to those found for the corresponding benzonitriles.[9]

The alkyl 4-amino-2-(dialkylaminoalkoxy)-benzoates were prepared by iron–hydrochloric acid reduction of the nitro compounds. The bases were obtained crystalline in most cases; they were characterized as their phosphoric and picric acid salts. These compounds are summarized in Table III.

The alkyl 4-amino-2-(dialkylaminoalkoxy)-

benzoate quaternary salts were prepared by the catalytic reduction of the nitro-quaternary salts in the appropriate alcohol as solvent. In a number of cases the 4-amino-quaternary salts could not be obtained crystalline; those which were characterized are listed in Table IV.

Experimental[10]

Alkyl 2-(Dialkylaminoalkoxy)-4-nitrobenzoates.—Several synthetic methods, described below, were used for the preparation of the alkyl 2-(dialkylaminoalkoxy)-4-nitrobenzoates. The compounds prepared are listed in Table I.

Method A.—To a warm solution of 39.4 g. (0.20 mole) of methyl 2-hydroxy-4-nitrobenzoate in 1400 ml. of dry toluene there was added a solution prepared from 4.6 g. (0.20 mole) of sodium and 500 ml. of absolute methanol. The methanol was distilled from the stirred suspension until a constant distillation temperature of 110° was reached. To the red suspension was added 29.8 g. (0.22 mole) of 2-diethylaminoethyl chloride in 500 ml. of dry toluene, and the mixture was stirred and refluxed for 20 hr.; during this period the color faded to pale yellow. The mixture was cooled, filtered, and the insoluble material was washed thoroughly with dry benzene. Distillation of the solvents *in vacuo* left an oily residue of methyl 2-(2-diethylaminoethoxy)-4-nitrobenzoate. Conversion to the hydrochloride was effected by treatment of an ethyl acetate solution of the crude base with an excess of ethereal hydrogen chloride; after one recrystallization from absolute methanol–ethyl acetate, there was obtained an 85% yield of pure material.

This method could be used for the preparation of the majority of the esters in Table I by substituting the appropriate sodium alkoxide–alcohol mixture (depending upon the ester employed) for the sodium methoxide–methanol. The yields were high and as much as two moles of a 2-hydroxy ester could be alkylated by this method on a laboratory scale.

Method B.—A mixture of 24.7 g. (0.11 mole) of propyl 2-hydroxy-4-nitrobenzoate, 16.3 g. (0.12 mole) of 2-diethylaminoethyl chloride and 250 ml. of *n*-propyl alcohol was refluxed and stirred for 8 hr. After the usual procedure there was obtained 1.0 g. of pure propyl 2-(2-diethylaminoethoxy)-4-nitrobenzoate hydrochloride, m.p. and mixed m.p. 153–155°. The yield was not increased by prolonged refluxing.

Method C.—Ethyl 2-hydroxy-4-nitrobenzoate was alkylated by 2-chloroethyl *p*-toluenesulfonate in the usual manner.[1b] **Ethyl 2-(2-chloroethoxy)-4-nitrobenzoate** crystallized from *n*-hexane in pale yellow platelets, m.p. 56.6–57.2°.

Anal. Calcd. for $C_{11}H_{12}ClNO_5$: Cl, 12.96. Found: Cl, 12.62.

When refluxed with an ethanolic solution of a secondary amine in the presence of sodium iodide, there were obtained 50–65% yields of the corresponding ethyl 2-(2-dialkylaminoethoxy)-4-nitrobenzoates.

Method D.—The reaction between an alkyl 2-hydroxy-4-nitrobenzoate, sodium alkoxide and a dialkylaminoalkyl chloride in an alcohol under anhydrous conditions was carried out by substantially the same procedure used with 2-hydroxy-4-nitrobenzonitrile.[9] The only modification necessary was the use of the appropriate alcohol as solvent for the reaction. The effect of the alcohol was indicated by the following yield data, utilizing 2-diethylaminoethyl chloride in each case: methyl ester in methanol: (5%); ethyl ester in ethanol: (71%), propyl ester in *n*-propyl alcohol: (88%); butyl ester in *n*-butyl alcohol: (86%); methyl ester in ethanol: (70%) of *ethyl* ester basic ether (by transesterification).

Alkyl 2-(Dialkylaminoalkoxy)-4-nitrobenzoate Quaternary Salts.—The quaternary salts were prepared in every case from the pure base (liberated from the pure hydrochloride). The following methods were used.

Method A (Methiodides, Methobromides).—To a solution of the base in ethyl acetate, under anhydrous conditions, was added three moles of methyl iodide or bromide. The initially deep orange-colored solution rapidly or slowly changed in color to pale yellow as crystals deposited. After 3–20 hr. at room temperature, the mixture was filtered and the precipitate was washed thoroughly with ethyl acetate. Recrystallization from absolute alcohol or an isopropyl alcohol–ethyl acetate mixture gave a pure quaternary salt.

Ethyl iodide reacted quantitatively with ethyl 2-(2-dimethylaminoethoxy)-4-nitrobenzoate under these conditions, but no product was obtained with the 2-(2-diethylaminoethoxy) homolog at room temperature.

Method B (Alkyl Bromides).—A solution of the base in acetonitrile was mixed with three moles of the alkyl bromide and the mixture was refluxed for 36–72 hr. In the preparation of the bis-quaternaries derived from ethyl 2-(2-dimethylaminoethoxy)-4-nitrobenzoate, similar conditions were used except that a 2.4-to-1 mole ratio of base to the α,ω-dibromoalkane was used. The latter conditions also applied to the preparation of the bis-quaternaries derived from ethyl 2-(2-diethylaminoethoxy)-4-nitrobenzoate which were prepared using nitromethane as solvent; the mixtures were refluxed for 48–72 hr.

Alkyl 2-(Dialkylaminoalkoxy)-4-nitrobenzoate 2-Cyano-5-nitrophenolates.—The 2-cyano-5-nitrophenolate derivatives were prepared[9] from 0.01 mole of the alkyl 2-(dialkylaminoalkoxy)-4-nitrobenzoate and 0.02 mole of 2-hydroxy-4-nitrobenzonitrile, in ethyl acetate solution. The yields were essentially quantitative.

Ethyl 2-(2-diethylaminoethoxy)-4-nitrobenzoate di-(2-cyano-5-nitrophenolate), canary yellow prisms, m.p. 76.0–78.0°. *Anal.* Calcd. for $C_{29}H_{30}N_6O_{11}$: N^a, 6.58; N_{AP}, 2.19. Found: N^a, 6.59; N_{AP}, 2.19.

Ethyl 2-(3-(1-piperidyl)-propoxy)-4-nitrobenzoate di-(2-cyano-5-nitrophenolate), short, blunt orange needles, m.p. 125.2–126.0; λ_{max}^{alc} 234 (inflection), 265, 338, 406 mμ (ε 36,800, 27,770, 8,510, 2,100, respectively).

Anal. Calcd. for $C_{31}H_{32}N_6O_{11}$: N^a, 6.32; N_{AP}, 2.11. Found: N^a, 6.20; N_{AP}, 2.12.

Ethyl 2-(3-(4-morpholinyl)-propoxy)-4-nitrobenzoate di-(2-cyano-5-nitrophenolate), hair-like yellow-orange needles, m.p. 137.2–138.3°; λ_{max}^{alc} 234 (inflection), 265,340 mμ (ε 28,200, 25,000, 9,510, respectively). *Anal.* Calcd. for $C_{30}H_{30}N_6O_{12}$: N^a, 6.30; N_{AP}, 2.10. Found: N^a, 6.49; N_{AP}, 2.16.

2-(2-Diethylaminoethoxy)-4-nitrobenzoic Acid.—A mixture of 15.0 g. (0.043 mole) of ethyl 2-(2-diethylaminoethoxy)-4-nitrobenzoate hydrochloride, 18.3 g. (0.17 mole) of sodium carbonate and 200 ml. of 50% alcohol was stirred and refluxed for 4 hr. The alcohol was removed *in vacuo* and, after filtration, the aqueous residue was acidified to congo red paper with concentrated hydrochloric acid and saturated with ammonium sulfate. The precipitate was filtered and dried *in vacuo* at 70°; yield 13.8 g. (98%), m.p. 211–213°. Recrystallization from methanol gave the pure compound with but little loss, m.p. 212.5–213.9°.

Anal. Calcd. for $C_{13}H_{19}ClN_2O_5$: C, 48.98; H, 6.01; Cl, 11.12; N^a, 4.39. Found: C, 49.28; H, 6.13; Cl, 10.92; N^a, 4.21.

A mixture of 31.9 g. (0.1 mole) of the above hydrochloride, 8.4 g. (0.1 mole) of sodium bicarbonate and 500 ml. of absolute alcohol was stirred and refluxed for 3 hr., cooled, filtered and the filtrate was evaporated to dryness *in vacuo*. Recrystallization from isopropyl alcohol gave 25.0 g. of 2-(2-diethylaminoethoxy)-4-nitrobenzoic acid, m.p. 164.6–166.6°.

Anal. Calcd. for $C_{13}H_{18}N_2O_5$: N_{AP}, 4.97. Found: N_{AP}, 4.93.

The picrate crystallized from alcohol in cottony yellow needles, m.p. 179.2–180.4°. *Anal.* Calcd. for $C_{19}H_{21}N_5O_{12}$: N, 13.70. Found: N, 13.48.

2-(2-Dimethylaminoethoxy)-4-nitrobenzoic acid, prepared by the above method, formed cream colored plates from absolute alcohol, m.p. 193.1–194.1°. *Anal.* Calcd. for $C_{11}H_{14}N_2O_5$: N^a, 5.51. Found: N^a, 5.51.

The hydrochloride crystallized from absolute alcohol in pale yellow needles; m.p. 208.0–209.6°. *Anal.* Calcd. for $C_{11}H_{15}ClN_2O_5$: N_{AP}, 4.82; Cl, 12.20. Found: N^a, 4.70; Cl, 12.06.

(10) All melting points are corrected; they were determined in a modified Hershberg apparatus using total immersion N.B.S. calibrated thermometers. The analyses were done by Mr. M. E. Auerbach, Mr. K. D. Fleischer, and their staffs; absorption spectra by Dr. F. C. Nachod and staff. N^a is used to indicate nitro nitrogen, by titration with titanous chloride; N_{AP} indicates basic nitrogen by titration with perchloric acid; N. E. indicates neutral equivalent by titration with sodium methoxide.

The picrate was prepared by treating an aqueous solution of the hydrochloride with an excess of a saturated aqueous picric acid solution; clusters of yellow needles, m.p. 181.8–182.6°. *Anal.* Calcd. for $C_{17}H_{17}N_5O_{12}$: N^a, 11.60. Found: N^a, 11.51.

2-(3-(1-Piperidyl)-propoxy)-4-nitrobenzoic acid hydrochloride, pale yellow cottony needles from absolute alcohol, m.p. 216.8–217.5°. *Anal.* Calcd. for $C_{15}H_{21}ClN_2O_5$: N, 8.16; Cl, 10.28. Found: N, 8.17; Cl, 10.09.

The picrate, canary yellow needles from absolute alcohol, m.p. 143.0–145.0°. *Anal.* Calcd. for $C_{21}H_{23}N_5O_{12}$: N^a, 10.43. Found: N^a, 10.10.

Alkyl 4-Amino-2-(dialkylaminoalkoxy)-benzoates.—The alkyl 2-(dialkylaminoalkoxy)-4-nitrobenzoate bases or hydrochlorides were reduced by the iron–hydrochloride acid method,[1a] in the appropriate dilute alcohol as solvent, or by catalytic reduction of the hydrochloride (platinum oxide, 25°, alcohol solvent). The crystalline 4-amino bases were recrystallized from benzene or an ethyl acetate–*n*-hexane mixture. The bases did not readily yield crystalline mono- or dihydrochlorides, but the phosphates were easily prepared.[1a,9] The picrates were prepared in the usual manner, using an excess of picric acid. These compounds are listed in Table III.

Alkyl 4-Amino-2-(dialkylaminoalkoxy)-benzoate Quaternary Salts.—The reduction of the alkyl 2-(dialkylaminoalkoxy)-4-nitrobenzoate quaternary salts and bis-quaternary salts was carried out catalytically, using platinum oxide as catalyst, the appropriate alcohol or dilute alcohol as solvent, a temperature of 25° and a pressure of 40 lb. The products were isolated in the usual manner, utilizing a vacuum distillation with ethyl acetate for dehydration prior to crystallization from isopropyl alcohol–ethyl acetate or absolute alcohol. A number of the 4-amino quaternary salts could not be obtained crystalline; in certain cases these were tested as the crude oils. The crystalline 4-amino quaternary salts are listed in Table IV.

4-Amino-2-(dialkylaminoalkoxy)-benzoic Acids.—The 2-(dialkylaminoalkoxy)-4-nitrobenzoic acids or their hydrochlorides were reduced catalytically by the above method.

4-Amino-2-(2-dimethylaminoethoxy)-benzoic acid hydrochloride, white needles from absolute alcohol, m.p. 145.5–147.2° dec. *Anal.* Calcd. for $C_{11}H_{17}ClN_2O_3$: N, 10.75; Cl, 13.60. Found: N, 10.74; Cl, 13.93.

Preparation of N,N′-Disubstituted *p*-Quinonediimine-N,N′-dioxides

BY C. J. PEDERSEN

RECEIVED DECEMBER 3, 1956

Several members of a new class of compounds (I, where R and R′ are alkyl or aryl groups which may or may not be identical) have been prepared by treating either VI or VII with an excess of perbenzoic acid. They are highly colored compounds whose solutions in organic solvents are very sensitive to light. Many of them are good inhibitors of free radical polymerization as well as efficient inhibitors of autoxidation.

During a study of the action of perbenzoic acid on N,N′-disubstituted derivatives of *p*-phenylenediamine, products were obtained which were found to belong to a new class of compounds having structure I.[1] The closest references in the literature are to N-phenyl-*p*-quinoneimine-N-oxide (II),[2] 5,6-bis-(phenylimino)-2-cyclohexene-1,4-dione-N,N′-dioxide (III)[3] and phenazine-N,N′-dioxide (IV).[4]

The two methods of preparing these compounds are shown in Fig. 2. Method I consists in treating one mole of N,N′-disubstituted *p*-quinonediimine (VI) with slightly more than two moles of perbenzoic acid, and method II of treating one mole of N,N′-disubstituted *p*-phenylenediamine (VII) with a little more than three moles of perbenzoic acid.

N-Substituted *p*-nitroanilines (VIII) are obtained as by-products in method II when R or R′, or both, are unsubstituted alkyl groups. The group which comes off the nitrogen atom is always the unsubstituted alkyl group. When both R and R′ are substituted *t*-alkyl or aromatic groups, no derivative of *p*-nitroaniline is formed to any extent.

The establishment of the structure of these compounds is based mainly on work with N,N′-diphenyl-*p*-quinonediimine-N,N′-dioxide. The molecular weight and the elementary analyses of this compound are consistent with the composition of I (R and R′ = phenyl), and its structure is indicated by its hydrogenation to N,N′-diphenyl-*p*-phenylenediamine (VII R and R′ = phenyl).

It is an orange, crystalline compound whose solutions are very sensitive to light.[5] Its visible spectrum, shown in Fig. 3 has a peak at 417 mμ, ε 47,000. Structure X (R and R′ = phenyl) is

Phenyl[b]	2,4-Dinitrophenyl	II	Benzene	59	14.7	14.7	215

[a] These points were determined on a bronze block and are uncorrected. In general the compounds decomposed on melting and the melting point is not considered a good index of identity for these compounds. [b] A 40% solution of peracetic acid in glacial acetic acid was used instead of perbenzoic acid.

excluded because the spectrum of the "di-isonitrone"[6] should resemble that of *p*-quinone (peaks in ethanol: 244 mμ, ε 19,000; *ca.* 300 mμ, ε 400; 436 mμ, ε 19) and not have such a strong absorption band in the visible region. Its infrared spectrum, shown in Fig. 5, has bands at 8.03 and 13.06 μ which are characteristic for the N,N′-dioxides. The band at 6.3 μ which is characteristic for the *p*-quinonediimines (VI), is either absent or very weak in the spectra of N,N′-dioxides (I).

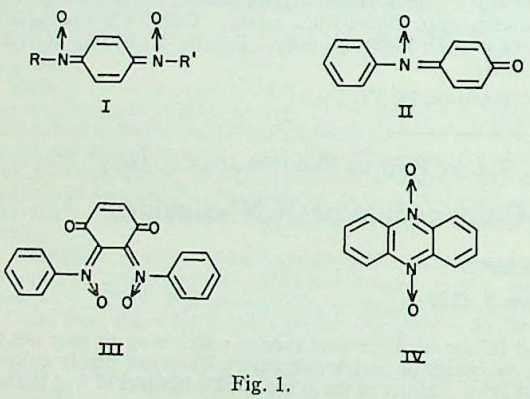

Fig. 1.

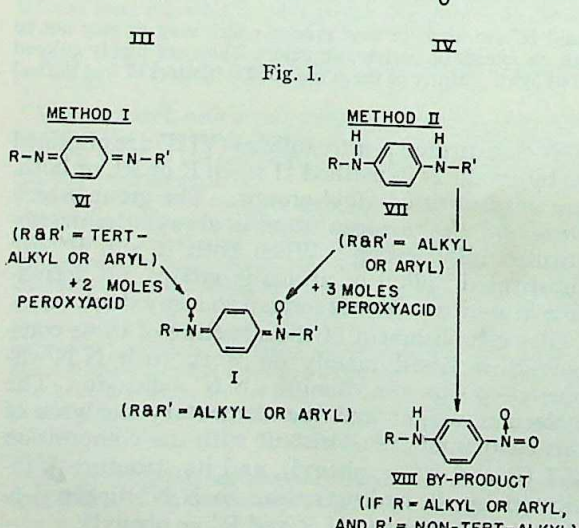

Fig. 2.

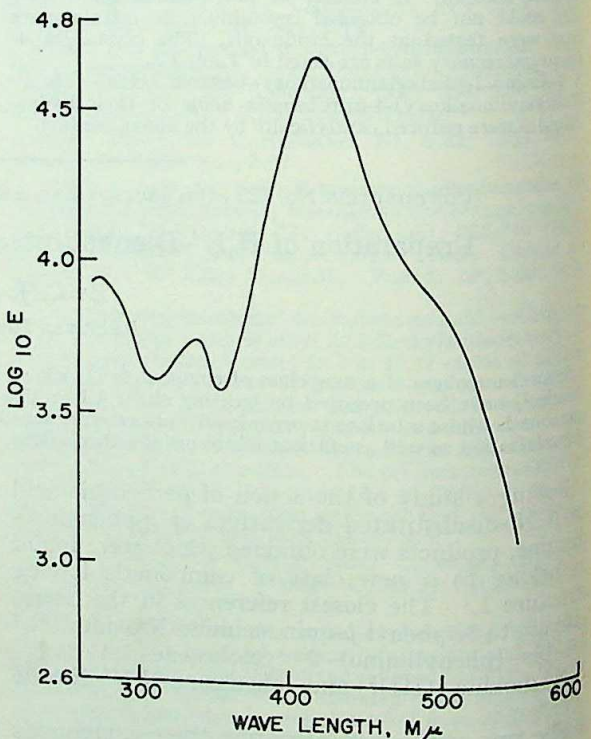

Fig. 3.—Spectrum of N,N′-diphenyl-*p*-quinonediimine-N,N′-dioxide.

Since I (R and R′ = phenyl) is an excellent inhibitor of free radical polymerization and autoxidation,[1] structure XII (R and R′ = phenyl), N,N′-(*p*-phenylene)-bis-(phenylnitroxide), was also considered, but paramagnetic resonance measurements failed to detect the presence of any unpaired electron either in the crystals or in solution. It is concluded, therefore, that I (R and R′ = phenyl) is the correct structure of N,N′-diphenyl-

p-quinonediimine-N,N′-dioxide. The compound is a dinitrone and may also be considered the N,N′-diphenyl ether of *p*-quinonedioxime.

The structure of the other compounds of this class is considered also proved because they are prepared in the same way, possess similar properties and their elementary analyses are in accord. They are strongly colored compounds, usually yellow or orange, with molecular extinction coefficients in the visible region, ranging from 17,000 to 85,000. Although their solubility is influenced by the substituents on the nitrogen atoms, they are, in general, moderately soluble at room temperature in organic solvents such as benzene, chloroform, acetone and dimethylformamide, and insoluble in water. Their solutions are rapidly decomposed on exposure to sunlight.[5] Data on these compounds are summarized in Tables I, II and III.

It should be mentioned that no attempt was made to secure maximum yields in these preparations, and it is likely that improved yields could be obtained readily by further work.

Observe that all these spectra contain bands near 8 and 13 μ which are considered to be characteristic for compounds belonging to this class.

It was mentioned previously that derivatives of *p*-nitroaniline are obtained as by-products in certain cases. Those which were identified are listed in Table IV.

N,N′-Dioxides, especially those having aryl substituents on the nitrogen atoms, are inhibitors of

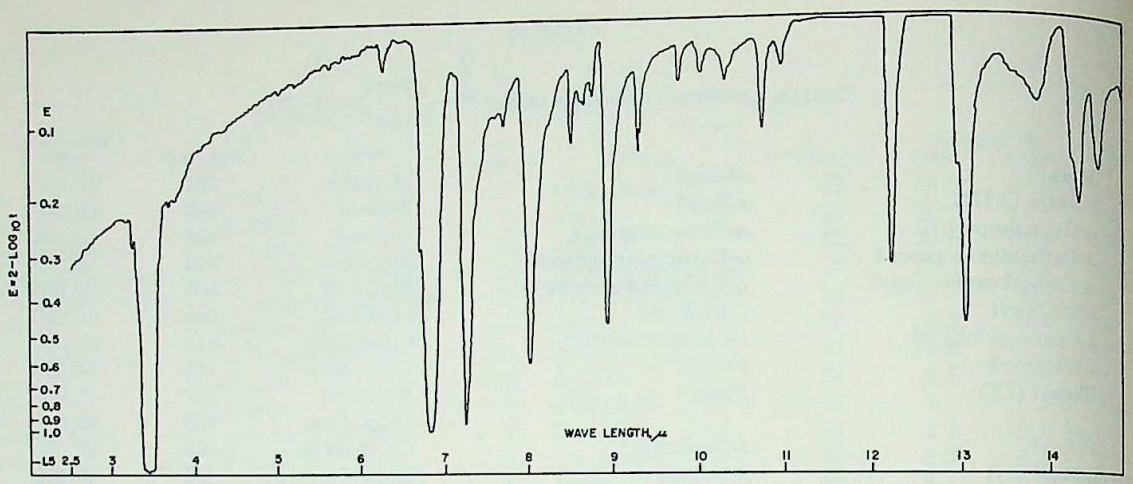

Fig. 5.—Infrared spectrum of N,N′-diphenyl-*p*-quinonediimine-N,N′-dioxide.

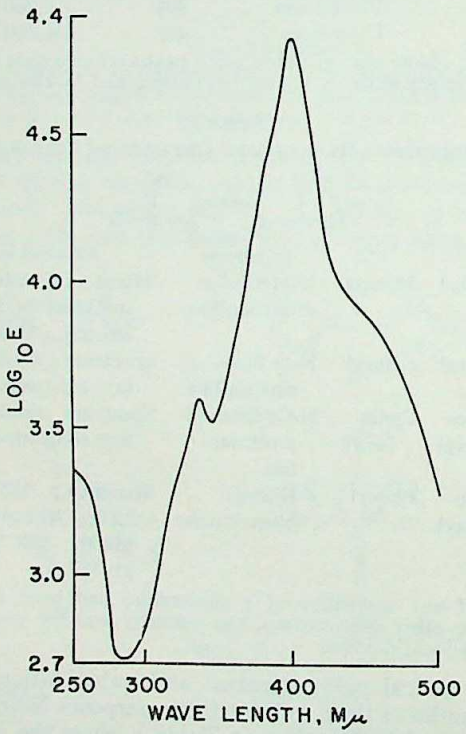

Fig. 6.—Spectrum of N,N′-di-(*sec*-butyl)-*p*-quinonediimine-N,N′-dioxide.

Note that the aryl substituted N,N′-dioxides, as a group, are more effective than the others, but there also appears to be some relationship between efficiency and the ease of removal of the oxygen atom from the nitrogen. It was found that N,N′-diphenyl-*p*-quinonediimine is obtained when N,N′-diphenyl - *p* - quinonediimine - N,N′ - dioxide and N,N′-azo-bis-(α-isobutyronitrile) are refluxed in benzene under nitrogen. This brings up the possibility that N,N′-dioxides may function as inhibitors by reacting, not with peroxy chain-carriers but with carbon free radicals.[7]

Acknowledgment.—The author wishes to thank T. D. Boice and John Willister for preparing many of the compounds; H. S. Jarrett and R. C. Ferguson for the paramagnetic resonance measurements; H. A. Kubitz for interpreting the infrared spectra; and H. E. Schroeder for his advice.

Experimental

Perbenzoic acid was prepared in chloroform or benzene by Braun's method[8] and used directly. All other materials were either laboratory samples or commercially available products.

ing *p*-quinonediimine is stable. The preparation of a number of *p*-quinonediimines with aliphatic groups on the nitrogen atoms has been described previously.[9] The *p*-quinonediimines with aromatic groups on the nitrogen atoms can be prepared in nearly quantitative yields by treating a mole of the corresponding *p*-phenylenediamine with a mole of benzoyl peroxide in benzene or chloroform. These solutions can be used for the preparation of the N,N′-dioxides without further ado.

Since the N,N′-dioxides, especially in solution, are extremely sensitive to light, their preparation must be protected from light. This property tends to make it difficult to obtain reproducible analytical and spectral data on these compounds.

N,N′-Diphenyl-*p*-quinonediimine-N,N′-dioxide (Method I).—N,N′-Diphenyl-*p*-quinonediimine (12.9 g., 0.05 mole) in 425 ml. of chloroform was mixed with 250 ml. of benzene containing 15.2 g. of perbenzoic acid (0.11 mole), and allowed to stand for 30 minutes at room temperature. The solution was washed with 500 ml. of water containing 4.8 g. of sodium hydroxide (0.12 mole), twice with water and then dried with anhydrous sodium sulfate. The solution was concentrated to 350 ml. under reduced pressure and added to 600 ml. of petroleum ether (30–60°). The orange crystals which separated overnight were filtered, washed with petroleum ether and dried at room temperature to give 12 g. of product (yield 83%).

Anal. Calcd. for $C_{18}H_{14}N_2O_2$: C, 74.5; H, 4.8; N, 9.7; mol. wt., 290. Found: C, 74.8; H, 5.1; N, 9.5; mol. wt., 288 (elevation of the boiling point of benzene).

An 84% yield of the product was obtained by using a 40% solution of peracetic acid in glacial acetic acid instead of perbenzoic acid in the above method.

N,N′-Diphenyl-*p*-phenylenediamine was obtained by hydrogenating the N,N′-dioxide in methanol with a platinum catalyst. It was identified by mixed melting point (147°), and spectrum (absorption peak in ethanol, 304 mμ, ε 27,000).

N,N′-Diphenyl-*p*-phenylenediamine is also obtained by treating the N,N′-dioxide with ascorbic acid in methanol at room temperature. The N,N′-dioxide is reduced much more slowly than the corresponding quinonediimine by ascorbic acid.

N,N′-Diphenyl-*p*-quinonediimine was obtained (yield over 82%) by refluxing one mole of the N,N′-dioxide with two moles of N,N′-azo-bis-(α-isobutyronitrile) in benzene under nitrogen for three hours. No diimine was formed in the absence of the azo-catalyst. The diimine was identified by mixed melting point (185–186°), and spectrum (absorption peaks in ethanol, 304 mμ, ε 27,000; 442 mμ, ε 7,000).

The visible spectrum of the N,N′-dioxide is shown in Fig. 3. Its spectrum in concentrated sulfuric acid, when fresh, is yellow and has an absorption peak at 468 mμ, ε 1,700, but the solution becomes bright blue within 24 hours at room temperature and has a peak at 670 mμ, ε 44,000. The blue solid product which was recovered from the blue sulfuric acid solution has not yet been identified.

Instead of getting a mole of mono-N-oxide by treating one mole of N,N′-diphenyl-*p*-quinonediimine with one mole of perbenzoic acid, half a mole of the N,N′-dioxide was obtained.

The thermal stability of the N,N′-dioxide was investigated by dissolving 3×10^{-5} mole in one liter of a mixture of trichlorobenzenes, and spectrophotometrically determining the amount of the compound left after exposure to different times and temperatures. The results are shown in Table VI.

N,N′-Dioxides in which both substituents on the nitrogen atoms are aromatic are most conveniently synthesized by first making the *p*-quinonediimine with benzoyl peroxide and using this solution in method I. Method I and method II have been varied by changing the solvent as indicated in Table I. The choice of solvent is dictated by the solubility of the starting compound and the resistance of the solvent to the action of perbenzoic acid.

TABLE VI

THERMAL STABILITY OF N,N′-DIPHENYL-*p*-QUINONEDIIMINE-N,N′-DIOXIDE IN TRICHLOROBENZENE[a]

Temp., °C.	Minutes at temp.	Decomposed,[b] %
50	10	Nil
94	20	2
152	20	6
176	20	42
202	20	Over 82
202	140	100

[a] Concentration, 3×10^{-5} mole per liter. [b] Determined spectrophotometrically.

N,N′-Bis-(1-cyanocyclohexyl)-*p*-quinonediimine-N,N′-dioxide (Method II).—1,1′-(*p*-Phenylenediimino)-carbonitrile, 3.2 g. (0.01 mole), dissolved in 200 ml. of acetone was added to 118 ml. of benzene containing 4.35 g. of perbenzoic acid (0.0315 mole). The mixture was shaken and allowed to stand overnight at room temperature. On chilling the solution in ice-water, a precipitate formed which was filtered, washed with acetone and dried at room temperature to give 2.8 g. of orange crystals (yield 79%). The properties of this compound are given in the tables.

N,N′-Dicyclohexyl-*p*-quinonediimine-N,N′-dioxide (Method II).—N,N′-Dicyclohexyl-*p*-phenylenediamine (12.2 g., 0.045 mole), dissolved in 100 ml. of benzene was added dropwise with agitation to 468 ml. of benzene containing 19.8 g. of perbenzoic acid (0.143 mole), and kept at 5° with external cooling. The mixture was stirred for 1 hour more and washed three times with 10% aqueous sodium bicarbonate to remove the benzoic acid. The solution was dried with anhydrous sodium sulfate, concentrated under reduced pressure and cooled to yield 10.5 g. of yellow crystals (yield 77%). Other properties of this compound are given in the tables.

Anal. Calcd. for $C_{18}H_{26}N_2O_2$: C, 71.6; H, 8.61; N, 9.3. Found: C, 71.8; H, 8.62; N, 9.4.

N,N′-Diphenyldiphenoquinonediimine-N,N′-dioxide (XIV) (Method II).—N,N′-Diphenylbenzidine (0.5 g., 0.00149 mole) dissolved in 7.5 ml. of dimethylformamide was added with stirring at room temperature to 16.4 ml. of benzene containing 0.678 g. of perbenzoic acid (0.0049 mole). After 22 hours the reaction product which had precipitated was filtered, washed with benzene and petroleum ether, and dried to give 0.45 g. of purplish brown crystals (yield 83%) which melted with decomposition at 280°; maximum absorption in chloroform, 485 mμ, ε 33,000.

Anal. Calcd. for $C_{24}H_{18}N_2O_2$: N, 7.65. Found: N, 7.5.

N-Phenyl-N′-(2,4-dinitrophenyl)-*p*-quinonediimine-N,N′-dioxide (Method II).—N-Phenyl-N′-(2,4-dinitrophenyl)-*p*-phenylenediamine (7 g., 0.02 mole) partially dissolved in 200 ml. of benzene was mixed with 34 g. of 40% solution of peracetic acid in glacial acetic acid (0.179 mole of peracid) and allowed to stand in the dark at room temperature for 12 days. The deposits were filtered, washed with benzene and dried to yield 4.5 g. of maroon crystals (yield 59%). The properties of this compound are given in the tables.

Neither *p*-quinone dibenzenesulfonimide[10] nor N,N′-bis-(2,4-dinitrophenyl)-*p*-phenylenediamine could be converted to the corresponding N,N′-dioxides with perbenzoic acid.

A Study of the Decomposition of *p*-Nitrophenethyltrimethylammonium Iodide by Means of the Hydrogen Isotope Effect[1]

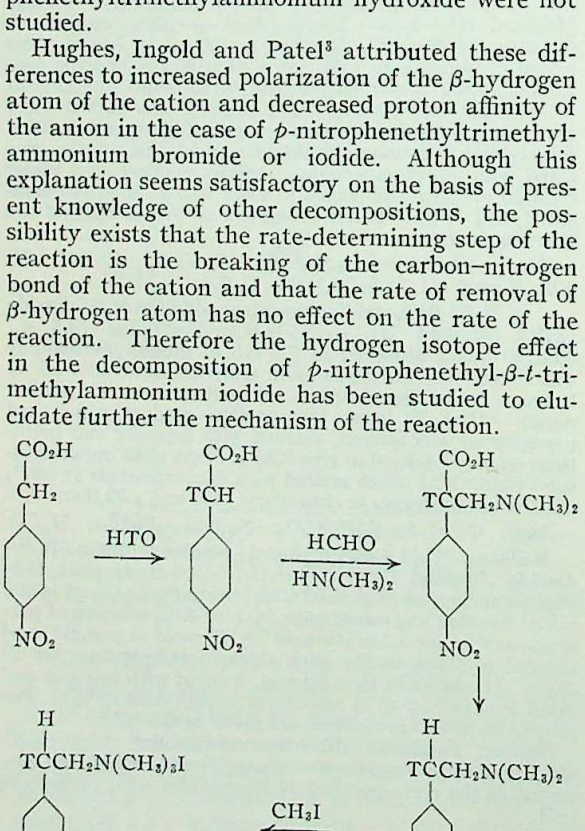
BY ERNEST M. HODNETT AND JOHN J. FLYNN, JR.

RECEIVED NOVEMBER 5, 1956

The hydrogen isotope effect in the decomposition of *p*-nitrophenethyl-β-*t*-trimethylammonium iodide in water at 100° has been measured. A hydrogen atom on the carbon adjacent to the ring is removed from a labeled molecule 7.4 times as rapidly as a tritium atom in the same position. A hydrogen atom in this same position in an inactive molecule is removed 15% faster than a hydrogen atom in the corresponding position of the labeled molecule. The existence of these differences in rate of reaction establishes the mechanism of the decomposition as being that of an attack on the hydrogen atom in the β-position to the ammonium group.

Hughes and Ingold[2] reported that the decomposition of phenethyltrimethylammonium hydroxide in water at 100° is first order in hydroxide ion as well as in the cation. *p*-Nitrophenethyltrimethylammonium iodide and the corresponding bromide each decompose in water at 100° with unimolecular kinetics. These latter decompositions are retarded by acids, unaffected by neutral salts and accelerated by bases although the rate constants were not reported. The kinetics of decomposition of *p*-nitrophenethyltrimethylammonium hydroxide were not studied.

Hughes, Ingold and Patel[3] attributed these differences to increased polarization of the β-hydrogen atom of the cation and decreased proton affinity of the anion in the case of *p*-nitrophenethyltrimethylammonium bromide or iodide. Although this explanation seems satisfactory on the basis of present knowledge of other decompositions, the possibility exists that the rate-determining step of the reaction is the breaking of the carbon–nitrogen bond of the cation and that the rate of removal of β-hydrogen atom has no effect on the rate of the reaction. Therefore the hydrogen isotope effect in the decomposition of *p*-nitrophenethyl-β-*t*-trimethylammonium iodide has been studied to elucidate further the mechanism of the reaction.



p-Nitrophenethyl-β-*t*-trimethylammonium iodide was prepared by the reactions.

Aqueous solutions of the *p*-nitrophenethyl-β-*t*-trimethylammonium iodide were sealed in tubes and held at 100° for various times. The remaining ammonium salt was precipitated as the sparingly soluble picrate and the latter dried and assayed for tritium. For low extents of reaction the product of the reaction was isolated by formation of the dibromide of the *p*-nitrostyrene which was purified and assayed. From these data it was possible to calculate the various isotope effects in the reaction.

Experimental

Preparation of *p*-Nitrophenethyltrimethylammonium Iodide.—Ten grams of phenethylamine was added during 1.5 hr. to 50 ml. of fuming nitric acid at −10°. Nitration occurred immediately; the mixture was allowed to warm slowly to 0° at which point ice and sodium hydroxide were added. The mixture of amines was extracted with ether and isolated as their hydrochlorides. A single crystallization from alcohol gave 6 g. of almost colorless plates of *p*-nitrophenethylamine hydrochloride,[4] m.p. 209–210°.

To the *p*-nitrophenethylamine obtained from 2 g. of the corresponding hydrochloride by neutralization with a base, extraction with ether and evaporation of the ether was added 5 g. of sodium carbonate, 5 ml. of absolute ethyl alcohol and with care 7 ml. of methyl iodide. After the initial vigorous reaction had subsided, it was completed by refluxing the mixture on a water-bath. The carbonate was removed by filtration, washed with ether and neutralized with 47% hydriodic acid. The quaternary ammonium iodide was collected by filtration, washed with acetone and ethyl ether and crystallized from 95% ethyl alcohol. Two grams of feathery lemon-yellow leaflets melting at 206° was obtained. The melting point reported[2] for *p*-nitrophenethyltrimethylammonium iodide is 199°.

Preparation of *p*-Nitrophenethyl-β-*t*-trimethylammonium Iodide.—*p*-Nitrophenylacetic acid (1.8 g., 0.01 mole) was placed in a tube with 1 ml. of tritiated water (7.13 mc./g.). The tube was sealed and placed in a bath at 100° for four days. The tritiated water was recovered by distillation on the vacuum line, and the acid was recrystallized once from water, dried and assayed. With an activity of 77.7 μc./mmole of acid and a recovery of 78%, the activity in the acid was 8.5% of that in the original water, but the actual loss in activity was negligible.

This *p*-nitrophenylacetic-α-*t* acid was shaken with 2 ml. of water and neutralized with a concentrated solution of dimethylamine. One milliliter of formalin was added and the solution was allowed to stand at room temperature for four days. The solid which crystallized on standing was separated by filtration. Unreacted *p*-nitrophenylacetic-α-*t* acid was recovered by acidifying the mixture with hydrochloric acid. The α-(*p*-nitrophenyl)-β-dimethylaminopropionic-α-*t* acid[5] after crystallization from water melted at 164°. The yield was 1 g. or 54% of the theory. The radioactivity of the acid was 54 μc./mmole, representing retention of 69.5% of the initial specific activity. Since on a statistical basis

one-half of the tritium atoms would be lost in the reaction, this recovery represents a favorable isotope effect.

The amino acid was mixed with 50 mg. of copper carbonate and 1 ml. of pyridine. The mixture was refluxed until evolution of gas had stopped. Water was added to the mixture until a reddish-brown oil separated. The oil layer was washed with water and extracted with ether. Evaporation of the ether gave *p*-nitrophenethyl-β-*t*-dimethylamine.

This amine was treated with 3 ml. of methyl iodide in a water-bath for 1 hr. *p*-Nitrophenethyl-β-*t*-trimethylammonium iodide, which crystallized out on cooling, was filtered off, recrystallized from 95% ethyl alcohol and dried. The yield from 1 g. of the aminopropionic acid was 0.3 g. (21% of theory). The activity was 50 μc./mmole and the melting point was 197°.[2]

Determination of the Isotope Effect.—A solution buffered at *p*H 7 was prepared[6] by diluting a mixture of 29.63 ml. of 0.1 *N* sodium hydroxide and 50 ml. of 0.1 *M* diacid potassium phosphate to 100 ml. Three grams of *p*-nitrophenethyl-β-*t*-trimethylammonium iodide was dissolved in 30 ml. of this buffer solution. Two 1-ml. portions were removed for confirmation of the initial concentration. Two 1-ml. portions and one 2-ml. portion were removed and sealed in small tubes for study of the reaction mixture at 50, 65 and 80% of complete reaction. The remaining solution (24 ml.) and the latter three portions were placed in an oil-bath at 100°. After 45 min. the 24-ml. portion was taken from the bath, and two 1-ml. portions were removed for determination of the extent of the reaction by precipitation of the picrate of the remaining reactant.

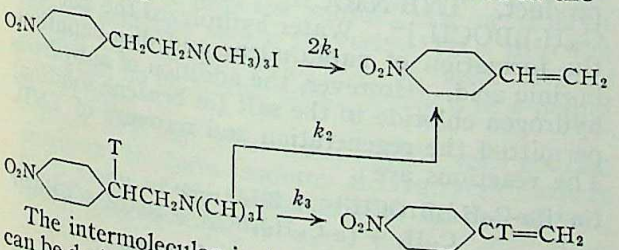
The remainder of the 24-ml. portion of the reaction solution was shaken with petroleum ether to extract *p*-nitrostyrene. The petroleum ether was then evaporated and the residue dissolved in 1 ml. of carbon tetrachloride and treated with 5 drops of bromine. The mixture was heated in a water-bath for 5 min. and the liquid evaporated off with a stream of nitrogen. The residue after recrystallization from aqueous methyl alcohol melted at 71°; m.p. reported[7] for *p*-nitrostyrene, 72–73°.

The other reaction mixtures were removed from the bath at the proper times and the extents of reaction determined by precipitation of the remaining reactant as the picrate. The picrates were assayed for tritium to obtain the molar activity of the remaining reactants.

No exchange of hydrogen atoms occurred between *p*-nitrophenethyl-β-*t*-trimethylammonium iodide and water under the same conditions at which decomposition occurred. This was demonstrated by heating *p*-nitrophenethyltrimethylammonium iodide in tritiated water until one-half of the former had decomposed. Assay of the remaining reactant showed no radioactivity.

Discussion of Results

Three reaction rate constants are involved in the process studied



The intermolecular isotope effect, $2k_1/(k_2 + k_3)$, can be derived from the equation

$$(k_2 + k_3)/2k_1 = 1 + (\log N_1/N_2)/\log (1 - f)$$

where f is the fraction reacted, and N_1/N_2 is the ratio of molar activity of the reactant at a given time to that of the initial reactant.

The secondary isotope effect, k_3/k_1, can be found from

$$k_3/2k_1 = N_3/N_1 \text{ (as } f \to 0)$$

where N_3 is the molar activity of the first product of the reaction.

The intramolecular isotope effect, k_3/k_2, can be determined from the above ratios.

The data obtained in this investigation are summarized in Table I; each figure represents from 2 to 5 assays for which the average deviation is not greater than ±0.5%.

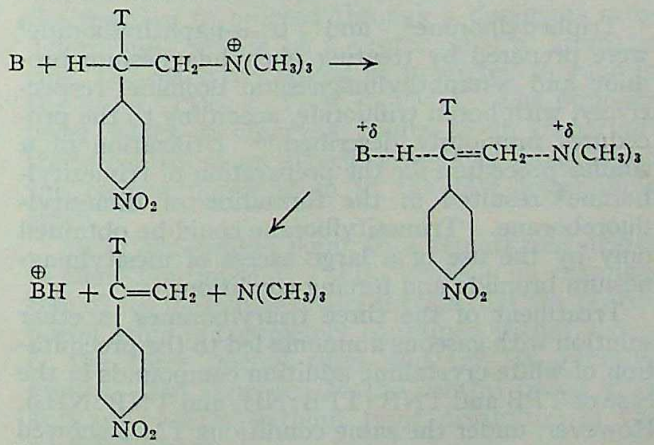
TABLE I

DECOMPOSITION OF *p*-NITROPHENETHYL-β-*t*-TRIMETHYLAMMONIUM IODIDE IN WATER AT 100°

Run	Extent of reacn., %	Activity of picrate, μc./mmole	Activity of *p*-nitrostyrene dibromide, μc./mmole	$\frac{k_3}{2k_1}$	$\frac{k_2 + k_3}{2k_1}$
I	0	11.53			
	17.3	12.33	5.43	0.455	
	43.7	14.95			0.550
	61.8	19.42			.458
II	0	12.33			
	8.6	12.70	5.18	0.414	
	82.6	29.58			0.500
III	0	12.64			
	50.0	18.07			0.484
	65.4	22.43			.459
	71.1	22.80			.510

From these results, the following values for the isotope effects have been calculated together with the average deviations, intermolecular isotope effect, $2k_1/(k_2 + k_3)$, 2.03 ± 0.11; intramolecular isotope effect, k_3/k_2, 7.4 ± 2.8; secondary isotope effect, k_3/k_1, 0.868 ± 0.04.

These ratios show beyond doubt that the decomposition of *p*-nitrophenethyl-β-*t*-trimethylammonium iodide in water at 100° occurs at a rate different from that of the normal compound. This difference proves that the bond between the hydrogen atom and the carbon atom which is adjacent to the ring is broken in the rate-determining step of the reaction. The point of attack on the molecule is therefore a hydrogen atom on the carbon atom beta to the ammonium group, as shown in the reaction scheme



Although Hughes and Ingold[2] found unimolecular kinetics for this reaction, it must be only pseudo-unimolecular.

It seems likely that the hydrogen atoms on the carbon atom adjacent to the ring are activated by the nitro group by the inductive effect as well as by conjugation. These hydrogen atoms may be ac-

tivated enough to react with molecules as weakly basic as water molecules, thereby producing a pseudo-unimolecular reaction. The exact nature of the attacking molecule, if any, is the subject of further investigation.

Studies in Stereochemistry. XXII. The Preparation and Reactions of Trimesitylborane. Evidence for the Non-localized Nature of the Odd Electron in Triarylborane Radical Ions and Related Free Radicals[1]

BY HERBERT C. BROWN AND VANCE H. DODSON

RECEIVED AUGUST 13, 1956

Trimesitylborane has been synthesized and its chemical behavior compared with that of triphenyl- and tri-α-naphthylboranes. In contrast to the latter compounds, trimesitylborane is far less reactive toward oxygen and water. Moreover, it fails to add either ammonia or sodium alkoxides. It is concluded that the steric effects of the three mesityl groups are so large as to hinder greatly the approach of a reacting molecule to the central atom. On the other hand, sodium reacts with trimesitylborane to form sodio derivatives analogous to those previously reported for triphenyl- and tri-α-naphthylborane. Since the vacant *p*-orbital of the boron atom is so completely blocked by the three mesityl groups, the ready formation of sodio derivatives in the case of trimesitylborane argues strongly for the entrance of the electron from the sodium atom into a non-localized orbital of the trimesitylborane molecule.

Differences in the chemical behavior of certain trialkylboranes can be correlated with the steric requirements of the alkyl groups in the boron derivative. Thus, trimethylamine forms a more stable addition compound with trimethylborane than does ammonia, whereas the reverse is true in the case of tri-*t*-butylborane.[2] Indeed, in this case trimethylamine exhibits no tendency to unite with the boron component.

It appeared of interest to examine the behavior of a borane derivative which might be expected to be even more hindered than tri-*t*-butylborane. Accordingly, the synthesis of trimesitylborane was undertaken and a study made of its chemical properties. For purposes of comparison, triphenyl- and tri-α-naphthylborane were included in the study. The behavior of these three compounds toward ammonia, sodium methoxide and *t*-butoxide, oxygen, water, sodium hydroxide and sodium metal was compared.

Results

Triphenylborane[3] and tri-α-naphthylborane[3] were prepared by treating phenylmagnesium bromide and α-naphthylmagnesium bromide, respectively, with boron trifluoride, according to the procedures previously described.[4,5] Utilization of a similar procedure for the preparation of trimesitylborane[3] resulted in the formation of dimesitylfluoroborane. Trimesitylborane could be obtained only by the use of a large excess of mesitylmagnesium bromide and forcing conditions.

Treatment of the three triarylboranes in ether solution with gaseous ammonia led to the precipitation of white crystalline addition compounds in the case of TPB and TNB ($TPB:NH_3$ and $TNB:NH_3$). However, under the same conditions TMB showed no tendency to react with ammonia. The data are summarized in Table I.

TABLE I

REACTIONS OF TPB, TNB AND TMB WITH AMMONIA

Triarylboron R_3B	Wt. of R_3B, g.	Wt. of combined ammonia, g.	Wt. of ammonia calcd. for $R_3B:NH_3$, g.
TPB	0.4380	0.0293	0.0308
	0.6753	.0471	.0473
TNB	1.2131	.0518	.0527
	0.5162	.0218	.0224
TMB	.1902	.0004	.0088
	.4458	.0007	.0206

Benzene solutions of TPB and TNB could be titrated stoichiometrically by standard solutions of sodium methoxide in methanol, using phenolphthalein as indicator. In the case of TNB it was demonstrated that the neutralization reaction involved the reaction of a sodium methoxide molecule with the TNB molecule by isolating the product, $TNB{\cdot}NaOCH_3$, presumably $Na^+[(\alpha\text{-}C_{10}H_7)_3BOCH_3]^-$. Water hydrolyzed the salt with the formation of naphthalene and di-α-naphthylborinic acid. However, the addition of anhydrous hydrogen chloride to the salt (in benzene solution) permitted the regeneration and recovery of TNB. The reactions are

$$Na^+[(\alpha\text{-}C_{10}H_7)_3B{:}OCH_3]^- + 2H_2O \longrightarrow C_{10}H_8 + (\alpha\text{-}C_{10}H_7)_2BOH + NaOH + CH_3OH$$

$$Na^+[(\alpha\text{-}C_{10}H_7)_3B{:}OCH_3]^- + HCl \xrightarrow{\text{benzene}} (\alpha\text{-}C_{10}H_7)_3B + NaCl + CH_3OH$$

In titrations of TPB and TNB with sodium *t*-butoxide in *t*-butyl alcohol the indicator changed color when less than 50% of the stoichiometric quantity of base had been added. However, benzene solutions of TMB failed to react with either base. The results of several typical titrations are summarized in Table II.

The reactivities of the triarylboranes toward oxygen were examined in α-bromonaphthalene solution. Both TPB and TNB were found to

react with dry oxygen gas in a molar ratio of 1 O_2 to 2 R_3B. The reaction is presumed to be

$$R_3B + {}^1/_2O_2 \longrightarrow R_2BOR$$

In the case of TPB the absorption of oxygen was complete in approximately 1 hr. at 25°, whereas TNB required 50 days for completion. TMB solutions showed no absorption of oxygen in periods as long as 15 months. The results of typical experiments are summarized in Table III.

TABLE III

REACTION OF TPB AND TNB (IN α-BROMONAPHTHALENE) WITH OXYGEN

TPB[a,c] Time, hr.	TPB[a,c] Oxygen reacted ml. (S.T.P.)	TNB[d,f] Time, days	TNB[d,f] Oxygen reacted, ml. (S.T.P.)
0	0	0	0
0.25	9.9	3	7.9
0.50	11.5	17	11.9
0.75	11.6	42	12.8
1.25	12.4	54	13.2
2.25	12.4	66	13.1[e]
24.0	12.4[b]		

[a] 0.933 mmole. [b] 0.496 mmole. [c] 1.0 O_2/1.9 TPB. [d] 1.116 mmole. [e] 0.526 mmole. [f] 1.0 O_2/2.1 TNB.

TPB hydrolyzed moderately rapidly in cold water, forming a mixture of phenylboric oxide, C_6H_5BO, and phenylboronic acid, $C_6H_5B(OH)_2$. Neither TNB nor TMB showed any significant change after prolonged contact with cold water. However, refluxing water converted TNB partially into naphthalene and α-naphthylboronic acid, $C_{10}H_7B(OH)_2$. Dilute sodium hydroxide rapidly converted TPB into the sodium salt of phenylboronic acid and slowly converted TNB into the sodium salt of α-naphthylboronic acid. Dilute alkali had no noticeable effect on TMB in a period of four days.

Both TPB and TNB react readily with sodium amalgam to form sodium derivatives[6,7] which have many of the characteristics of the triarylmethyl free radicals.[8]

$$(C_6H_5)_3B + Na \longrightarrow [(C_6H_5)_3B\cdot]^-Na^+$$

Treatment of TMB with sodium amalgam in dry ethyl ether led to the take-up of sodium and the formation of a colored addition compound. The amount of sodium reacted could be varied from TMB·Na to TMB·2Na, depending upon the concentration of sodium in the amalgam and the reaction time.[9]

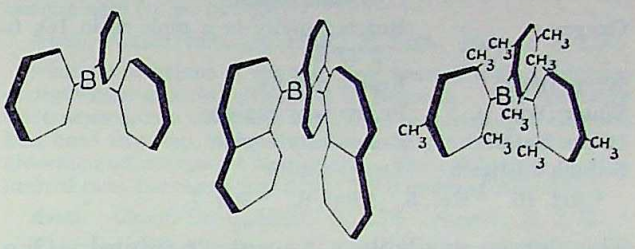
Discussion

Examination of molecular models of the three triarylboranes indicates that the shielding of the boron atom by the three surrounding aryl groups increases in the order TPB < TNB < TMB. Simplified line drawings of the three compounds are shown in Fig. 1.



Triphenylboron Tri-α-naphthylboron Trimesitylboron

Fig. 1.—Diagrams illustrating steric situation of the central boron atom in TPB, TNB and TMB.

Support for this conclusion is provided by the available data summarized in Table IV.

Ammonia reacts with both TPB and TNB, but not with TMB, whereas the more hindered base, trimethylamine, reacts only with TPB. Even sodium methoxide, a very strong base with low steric requirements, fails to react with TMB.

The reaction of oxygen with organoboranes is believed to proceed by a direct attack on the central boron atom by the oxygen molecule.[10] The remarkable difference in the reactivities of TPB, TNB and TMB with oxygen is in accord with this interpretation.

The hydrolysis is catalyzed by acid. In the similar acid-catalyzed solvolysis of aryltrimethylsilanes,[11] it has been shown the reaction proceeds through an attack of a proton on the aromatic ring and a solvent molecule on the silicon atom. If the steric requirements of the groups on the silicon atom are maintained constant, the reaction rate increases with electron-donating substituents in a manner typical of that to be expected for an electrophilic substitution. In the present case, were the reaction to proceed through a dominant rate-determining attack of a proton on the aromatic ring, the reactivity would be predicted to vary in the order, TPB < TNB < TMB. The opposite order which is observed points to an important steric control of an attack of a water molecule on the central boron atom in the rate-determining stage.

All of the results point to a remarkable degree of steric hindrance in TMB. Indeed, an examination of the molecular model reveals that the central boron atom is completely contained within a cage of the three phenyl rings and the six *o*-methyl groups. No approach to the central boron atom appears possible without prior disruption of this protecting cage.

On this basis the ready reaction of sodium amalgam with TMB is particularly interesting.

The three alkyl or aryl groups in a borane derivative, R_3B, are believed to utilize sp^2-hybrid orbitals.

[a] Ref. 16. [b] Ref. 5. [c] Ref. 6. [d] Ref. 7.

This leaves available a vacant 2*p*-orbital. One possible interpretation of the reaction with triarylboranes involves the transfer of the electron from sodium to this vacant 2*p*-orbital.

Recently, the magnetic susceptibility of TMB·Na was examined.[9] The results indicate that in dilute solution in tetrahydrofuran the molecule is monomeric and possesses one unpaired electron.

However, there are difficulties in assigning this odd electron to the 2*p*-orbital. The boron atom is so completely surrounded by the three mesityl groups that this does not appear to be a reasonable electronic structure for $[TMB\cdot]^-$ unless the improbable assumption is made that the odd electron has no steric requirements. Partial or complete modification of the structure to sp^3-hybrid orbitals offers no solution to the difficulty. The only reasonable solution to the dilemma involves the assumption that the electron transferred from the sodium atom to the TMB must enter an orbital associated with the entire molecule rather than an orbital associated primarily with the boron atom.[12]

The behavior of TPB, TNB and TMB toward sodium amalgam is qualitatively quite similar. On this basis there appears to be no reason to assign a special structure or interpretation to the TMB derivative. It is concluded, therefore, that the odd electron in the monosodio derivatives of the triarylboranes is probably associated with an orbital common to the entire molecule.

It is tempting to extrapolate this conclusion to the triarylmethyls. This has, of course, been the favored interpretation of the electronic structure of these free radicals.[13] However, recent results of Weissman and Snowden appear to point to another conclusion.[14] As a result of data obtained in a magnetic resonance study of triphenylmethyl, these authors have concluded that the odd electron in this free radical appears to be relatively closely associated with the nucleus of the methyl carbon atom. If this conclusion is supported by further work, it will suggest a major difference in the electronic structures of the triarylborane radical ions and the triarylmethyl free radicals and will require a major revision of present theories regarding the electronic structures of these free radicals. The present results argue strongly for a non-localized configuration for the odd electron in the trimesitylborane radical ion and, presumably, in the related triarylmethyl free radicals.

(12) In the reaction of sodium with polycyclic hydrocarbons in certain ether solvents, the electron is also assumed to enter a vacant orbital within the aromatic system, forming a free radical ion similar to that here postulated for TMB·Na; D. Lipkin, D. E. Paul, J. Townsend and S. I. Weissman, *Science*, **117**, 534 (1953).

Experimental Part

Preparation of Triarylborane Compounds. (A) Triphenylborane.—The procedure used to prepare TPB was essentially that described by Krause.[4] TPB was obtained in yields of approximately 60% as a white crystalline solid, m.p. 138° under nitrogen. The product was stored in sealed tubes and handled in a nitrogen atmosphere in subsequent experiments. The compound was analyzed for boron by the method described by Fowler and Kraus.[15] This same procedure was used in all of the boron analyses reported in this paper.

Anal. Calcd. for $C_{18}H_{15}B$: B, 4.47. Found: B, 4.51.

(B) Tri-α-naphthylboron.—TNB was prepared according to the procedure outlined by Brown and Sujishi.[5] Crude α-bromonaphthalene (Columbia Organic Chemicals Co.) was distilled and the fraction, b.p. 146–148° at 20 mm., was used. The TNB was crystallized from benzene and dried in a stream of nitrogen gas. The benzene of crystallization was removed by slowly warming the solid in a round bottom flask to 160° at 0.5 mm. to a constant weight. The product melted at 205–206°.

Anal. Calcd. for $C_{30}H_{21}B$: B, 2.76. Found: B, 2.74.

(C) Trimesitylboron.—Because of the difficulties experienced in forcing the reaction to proceed to the synthesis of trimesitylboron, the experimental procedure will be described in some detail. A standard 500-ml. three-necked flask (round bottom), equipped with a dropping funnel, ball joint stirrer, and water cooled condenser, was used. In a typical preparation, an anhydrous ethyl ether solution of bromomesitylene (0.240 mole, 47.8 g.), was added dropwise from the funnel to the flask containing magnesium turnings (0.29 g. at., 7.0 g.) and 100 ml. of anhydrous ether. The solution was refluxed during the addition period, which required approximately one hour, and for 4 to 5 hr. after the addition was complete. The solution was then allowed to stand at room temperature overnight. A slow but steady stream of nitrogen was passed through the system during the reflux period and a constant positive pressure of nitrogen gas was maintained in the system during the standing period. Dry toluene (150 ml.) was added to the flask and the mixture was heated to reflux temperature for 30 minutes to dissolve the precipitated Grignard reagent. Freshly distilled boron trifluoride etherate (0.036 mole, 5.1 g.), dissolved in 50 ml. of ether, was transferred to the dropping funnel and added to the stirred and refluxed solution of the Grignard over a period of 30 minutes. The condenser was replaced by a "goose-neck" adapter and the ether was distilled from the reaction flask. The condenser was replaced in the system and 50 ml. of toluene was added to the flask, and the solution was stirred and refluxed for 4 hr. On cooling to

Digitized by Arya Samaj Foundation Chennai and eGangotri

room temperature, the solution separated into an upper clear brick red layer and a lower yellow brown viscous layer. The entire reaction mixture was transferred to a 1-liter separatory funnel containing 300 ml. of cold water and crushed ice. After the initial hydrolysis reaction had subsided, 55 ml. of concentrated hydrochloric acid was added to dissolve the insoluble magnesium compounds and unreacted magnesium. Ice was added from time to time to keep the reaction mixture cool. After thoroughly shaking the mixture over a period of 20 minutes, the slightly turbid aqueous layer was withdrawn and the organic layer was washed with three 200-ml. portions of cold water. The yellow organic layer was then placed over calcium chloride to dry. Approximately one-half of the solvent was removed by distillation. The concentrated solution was treated with 150 ml. of 95% ethanol. A white to pale yellow solid immediately precipitated from solution. The solid was filtered and recrystallized from 300 ml. of 95% ethanol. The snow-white product weighed 4.5 g. and melted at 190.5–191.5°. Approximately two more grams of recrystallized product was obtained by evaporating the ethanol solution to one-half its original volume and allowing the solution to stand for 4 hours at room temperature.

Anal. Calcd. for $C_{27}H_{33}B$: B, 2.94; H, 9.03; C, 88.03. Found: B, 2.90; H, 9.10; C, 88.09.

Solubility of TMB.—An excess of solid TMB was added to 40 ml. of the solvent in a vessel, and the vessel was stoppered and placed in a constant temperature bath for 48 hr. During this period the mixture was shaken intermittently to facilitate saturation. Five ml. portions of the clear supernatant solution were withdrawn with a pipet and the solvent was removed by warming the solutions on a hot-plate at 60 to 70°. The results indicated a solubility per 100 ml. of solution at 25° of 6.96 g. in carbon tetrachloride, 1.25 g. in acetone, 0.08 g. in 95% ethanol, 4.98 g. in ethyl ether and 16.5 g. in benzene.

Preparation of Dimesitylboron Fluoride.—Mesitylmagnesium bromide was prepared according to the procedure outlined for TMB. Boron trifluoride etherate (0.073 mole) was added to the Grignard reagent (0.228 mole) over a period of 1.5 hr., and the reaction mixture was refluxed for 2 more hr. After standing at room temperature for 24 hr., the solution separated into two layers. The upper yellow orange ether layer was transferred, under nitrogen pressure, to a 125-ml. claisen flask and the ether was removed by distillation at atmospheric pressure. The residue was distilled at reduced pressure. A colorless liquid which distilled over the range 127–129° at 0.5 mm. pressure solidified in the receiver on cooling. The product melted at 75.5–76.0° in a sealed tube.

Anal. Calcd. for $C_{18}H_{22}BF$: B, 4.04; F, 7.09. Found: B, 3.97; F, 6.99.

When dimesitylboron fluoride was treated with water, dimesitylborinic acid was formed. After recrystallization from petroleum ether, the white crystalline solid melted at 140–141°.

Anal. Calcd. for $C_{18}H_{22}BOH$: C, 81.21; H, 8.73; B, 4.05. Found: C, 80.95; H, 8.99; B, 3.95.

Preparation of Ammonia Addition Compounds.—Anhydrous ether solutions of TPB and TNB were saturated with dry ammonia gas, and the solvent was removed at reduced pressure. The triarylboron compounds showed a gain in weight that checked well with that calculated for TPB:NH_3 and TNB:NH_3. Their melting points were in good agreement with those values given in the literature.[5,16] The very slight gain in weight shown by TMB when treated in a similar way was attributed to occluded solvent and not to reacted ammonia.

Titration with Sodium Alkoxides.—Anhydrous benzene solutions of TPB and TNB were titrated with freshly prepared and standardized sodium methoxide and sodium *t*-butoxide, using phenolphthalein as an indicator. Benzene solutions of TMB turned pink after the addition of the first drop of the alkoxide solution.

Benzene solutions of TNB which had been titrated with sodium methoxide to the phenolphthalein end-point were placed in a vacuum line, and the solvents were removed at reduced pressure. The white solid residue did not melt on heating but turned brown at 155–160° and black at 200°.

Anal. Calcd. for $Na^+[C_{30}H_{21}B{:}OCH_3]^-$: B, 2.42. Found: B, 2.40.

Benzene solutions of the salt were shaken with 50 ml. of distilled water and titrated with standard hydrochloric acid to a phenolphthalein end-point. The amount of titratable material, which was assumed to be sodium hydroxide, was found to be present in a mole ratio of 1:1 with respect to the original TNB. Other products formed by the hydrolysis of the salt were identified as naphthalene and di-α-naphthylborinic acid (m.p. 148–150°).

Anal. Calcd. for $C_{20}H_{14}BOH$: B, 3.85. Found: B, 3.83.

Benzene solutions of the salt were treated with a solution of hydrogen chloride dissolved in benzene. The solutions were heated on a hot-plate until all excess hydrogen chloride had been expelled, then filtered free of precipitated sodium chloride and evacuated to dryness. The solid white residue melted over the range 204–206° (TNB melts at 205–206°).

Anal. Calcd. for $C_{30}H_{21}B$: B, 2.76. Found: B, 2.73.

Reaction with Oxygen.—Weighed samples of TPB were transferred, in a nitrogen atmosphere, to the reaction bulb and dissolved in 20.0 ml. of α-bromonaphthalene. The bulb was attached to the reaction system (ball-joint), and the system was evacuated to a pressure of 0.5 mm. Pure dry oxygen gas was allowed to flow into the system and enough mercury was run into a side-arm U-tube to seal the system. The arm of the U-tube adjacent to the reaction flask was previously calibrated to represent the volume of the reaction flask and glass tubing to the mark on the side arm. A mercury-leveling device was attached to the open side of the U-tube and the pressure of the oxygen in the sealed system was adjusted to that of the atmosphere. The volume, pressure and temperature of the oxygen in the system were recorded at the beginning of the experiment and at various time intervals thereafter. Corrections for the volume of solvent in the reaction bulb were made for each reading. The reacting solution was continually agitated with a magnetic stirrer during the course of the reaction. Solutions of TNB and TMB in the same solvent were treated in a like manner.

A number of organic compounds were investigated and α-bromonaphthalene was found to fit best the needs for a solvent, having a very low vapor pressure and showing little or no signs of reacting with oxygen. A 20.0-ml. volume of the solvent was found to absorb 1.3 ml. of oxygen at S.T.P. This volume was subtracted from the final measured volume of reacted oxygen before calculating the number of moles of oxygen that had reacted.

Reaction with Water.—Mixtures of solid TPB and distilled water were shaken intermittently for a period of 8 hr. at room temperature. A pale brown residue was formed and this was filtered, dried in air and recrystallized from petroleum ether. The recrystallized material melted at 201.5–202.5° and was identified as phenylboric oxide. Evaporation of the aqueous solution produced a small amount of white solid, melting at 215°. The latter product was found to be phenylboronic acid. Refluxing a TPB and water mixture for 20 minutes produced the same materials.

Anal. Calcd. for C_6H_5BO: B, 10.41. Found: B, 10.32. Calcd. for $C_6H_5B(OH)_2$: B, 8.89. Found: B, 8.83.

TNB did not react with distilled water after treatment at room temperature for 8 hr. The melting point of the insoluble residue differed from that of the starting material by less than 1°. After refluxing in water for 1 hr., the insoluble residue was identified as a mixture of naphthalene and unreacted TNB. The aqueous solution yielded a white solid (m.p. 195°) on evaporation to dryness which was identified as α-naphthylboronic acid. A refluxing period of 2.5 hr. was required for complete conversion to these products.

Anal. Calcd. for $C_{10}H_7B(OH)_2$: B, 6.29. Found: B, 6.22.

Samples of TMB failed to react with water at room temperature after 8 hr. and after refluxing for 8 hr. The melting points of the starting material and the final product varied by less than 1°.

Reaction with Aqueous Sodium Hydroxide.—TPB was shaken with 0.05 *N* aqueous sodium hydroxide for a period of 4 hr. at room temperature. At the end of this time the samples had reacted completely and the products had gone into solution. The solution was neutralized with dilute hydrochloric acid and extracted with ether. The ether ex-

(16) E. Krause, *Ber.*, **57**, 813 (1924).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

tract was washed with water and evaporated to dryness. The residue was recrystallized from petroleum ether and identified as phenylboronic acid (m.p. 215°).

TNB was treated in the same way but the mixture was allowed to stand at room temperature for four days. The insoluble residue present was filtered and identified as a mixture of naphthalene and unreacted TNB. The filtrate was neutralized and extracted with ether. A small amount of α-naphthylboronic acid was obtained from the ether extract (m.p. 195°). TMB failed to react with 0.05 *N* sodium hydroxide after a period of 4 days at room temperature.

Reaction with Sodium Metal.—The procedures used were similar to those previously utilized for TPB[6] and TNB.[7] Since a detailed study recently has been described for the reaction of sodium with TMB,[9] we shall give only a brief summary of our observations.

A weighed sample of TMB was added to freshly prepared sodium amalgam in a dry glass bulb, and the bulb was swept out with dry nitrogen gas. Anhydrous ether was added and the bulb was sealed and set aside at room temperature. The bulb was shaken several times during the reaction period. The solution became pink, then purple and finally a yellow solid crystallized from the solution. At the end of the reaction period, the seal was broken and the ether solution was transferred to a flask containing distilled water. The bulb was rinsed several times with ether to remove all of the yellow solid adhering to the walls of the bulb. The rinses were added to the water and the ether was removed from the mixture by warming on a hot-plate. As the ether evaporated from the mixture, a white solid precipitated in the flask. The aqueous residue, containing the white precipitate, was titrated with standard hydrochloric acid to a phenolphthalein end-point. The insoluble residue was identified as TMB. The base was assumed to be sodium hydroxide. For samples that had been allowed to stand for 24 hr. the mole ratio of sodium to TMB varied from 1.09:1 to 1.53:1. A mixture of TMB and sodium amalgam which had been set aside for two months gave a 1.9 (Na) to 1 (TMB) mole ratio. No significant difference was noted between the ease of reaction of sodium with TMB as compared to TPB[6] or TNB.[7]

(±)-18-Fluoro-10-methyloctadecanoic Acid (Fluorotuberculostearic Acid)[1]

BY F. L. M. PATTISON AND R. G. WOOLFORD

RECEIVED NOVEMBER 5, 1956

Racemic fluorotuberculostearic acid (Vb) was prepared readily from 8-fluoroöctanoic acid by anodic coupling reactions. The sodium salt showed antitubercular activity *in vitro* but not *in vivo*.

From the knowledge gained from the study of fluoroacetates[2] and of other series of toxic compounds,[3] it has become increasingly apparent that certain biological systems are unable to differentiate between organic compounds containing the methyl group (CH_3^-) and the fluoromethyl group (FCH_2^-), respectively. Compounds containing the latter group, once assimilated, may then disturb or block the enzyme systems normally responsible for the metabolism of the non-fluorinated materials.

Occurring in the lipid sheath of the tubercle bacillus are a variety of fatty acids, including the levorotatory isomer of 10-methyloctadecanoic acid (tuberculostearic acid).[4] By applying the above observations regarding the fluoromethyl group to this acid, it was argued that 18-fluoro-10-methyloctadecanoic acid (fluorotuberculostearic acid) might readily be assimilated by the tubercle bacillus and that the toxic action of the fluorine atom might then result in its death. It was for this reason then that fluorotuberculostearic acid was prepared. If the racemic acid had shown high antitubercular activity, its resolution would have been undertaken; since its activity *in vivo* was low, this proved to be unnecessary. All compounds described in this article are therefore in the racemic form.

Fluorotuberculostearic acid was prepared by two routes, as is shown below. The work of Linstead, Lunt and Weedon[5] was of great value in selecting the experimental conditions. Some observations regarding symmetrical and unsymmetrical anodic coupling reactions of ω-fluorocarboxylic acids have been presented earlier.[6]

8-Fluoroöctanoic acid[6,7] (I) and methyl hydrogen β-methylglutarate[5] (II) (100% excess) on electrolysis formed a mixture of methyl 11-fluoro-3-methylundecanoate (IIIa), 1,14-difluorotetradecane and dimethyl β,β′-dimethylsuberate. The crude mixture, after hydrolysis with 10% sodium hydroxide, was separated into neutral and acidic fractions; the former gave 1,14-difluorotetradecane (20%), while the latter gave 11-fluoro-3-methylundecanoic acid (IIIb) (45%) and β,β′-dimethylsuberic acid (37%).

The anodic coupling of IIIb and methyl hydrogen azelate followed by hydrolysis of the resultant mixture gave the two symmetrical products, 1,20-difluoro-9,12-dimethyleicosane (23%) and hexadecanedioic acid (36%); a crude fraction of fluorotuberculostearic acid (Vb) also was obtained; this was found to be contaminated with azelaic acid, which had codistilled during attempted purification. Attempts to remove this impurity by preferential solubility in hot water and by treatment with alcoholic lead acetate[5] were unsuccess-

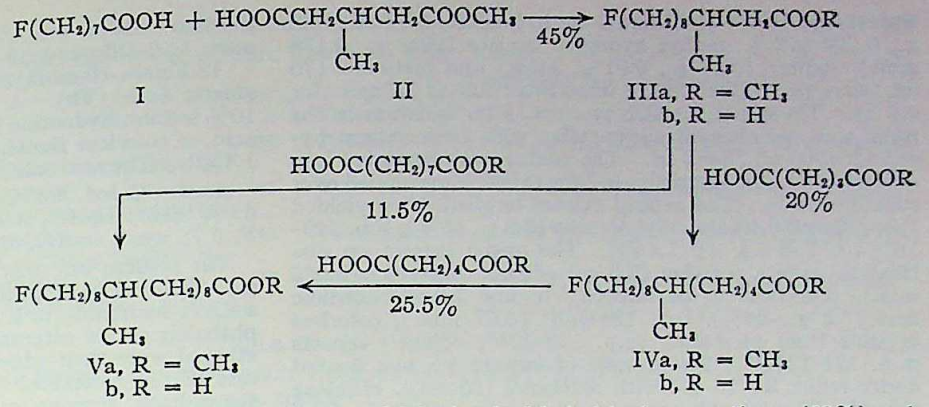
Digitized by Arya Samaj Foundation Chennai and eGangotri



ful. The crude acid was therefore re-esterified and fractionated to give methyl fluorotuberculostearate (Va) (11.5%). A portion of the pure ester was hydrolyzed with 10% sodium hydroxide and fractionated to give the pure fluorotuberculostearic acid (Vb). The acid was converted to the sodium salt for biological testing (see below).

Because of the above purification difficulties, methyl fluorotuberculostearate was prepared from 11-fluoro-3-methylundecanoic acid (IIIb) by a route involving two coupling reactions. The first of these, using methyl hydrogen glutarate, yielded on distillation methyl 14-fluoro-6-methyltetradecanoate (IVa) (20%), dimethyl suberate (57%) and 1,20-difluoro-9,12-dimethyleicosane (21%). The ester IVa was hydrolyzed to the acid IVb (93%), which in turn was coupled with methyl hydrogen adipate to give methyl fluorotuberculostearate (Va) (25.5%); dimethyl sebacate also was isolated (30%). This longer method, while proceeding in lower over-all yield, avoided some of the separation and purification difficulties encountered in the shorter method.

Sodium fluorotuberculostearate was screened[8] against virulent *Mycobacterium tuberculosis* var. *hominis* (strain H37Rv) both *in vitro* and *in vivo*. In the former, it caused complete inhibition of growth at a concentration of 1.25 γ/ml. in the absence of bovine serum but was inactive at a concentration of 20 γ/ml. in a medium containing 10% bovine serum. Because of the high toxicity, the diet concentration for the *in vivo* test was reduced from 0.125% to 0.0125%; at this lower concentration, the compound did not prolong the lives of tuberculous mice and is therefore inactive in what must be considered the crucial test.

Sodium fluorotuberculostearate was found to have an L.D. 50 of 2.7 mg./kg. (intraperitoneal injection into mice). The tolerated diet level of 0.0125% used on the tuberculous mice probably corresponds to just under 25 mg./kg./day. Of the other intermediates and by-products, 11-fluoro-3-methylundecanoic acid (L.D. 50, 2.42 mg./kg.) and 1,20-difluoro-9,12-dimethyleicosane (L.D. 50, 57 mg./kg.) were subjected to the usual toxicological screening by intraperitoneal injection into mice. Some of these results will be discussed in a future communication.

Experimental[9]

Procedure.—The equipment, method and conditions were the same as previously described.[6]

Intermediates.—8-Fluoroöctanoic acid[6,7] was prepared by the oxidation of 8-fluoroöctanol.[10] Methyl hydrogen β-methylglutarate was prepared as described by Linstead, Lunt and Weedon.[5] Methyl hydrogen adipate (62%) and azelate (67%) were prepared by the modified procedure[10] of Swann, Oehler and Buswell.[11] Methyl hydrogen glutarate was prepared from glutaric acid by conversion to the anhydride, followed by treatment with methanol.

11-Fluoro-3-methylundecanoic Acid (IIIb).—A mixture of 8-fluoroöctanoic acid (20.0 g., 0.123 mole), methyl hydrogen β-methylglutarate (40.0 g., 0.25 mole), sodium (0.46 g., 0.02 g. atom) and methanol (70 ml.) was electrolyzed at 1.9 amp. for 6 hr. by the procedure described for unsymmetrical couplings.[6] The crude neutral product, having been isolated in the usual way,[6] was hydrolyzed by heating under reflux with 10% aqueous sodium hydroxide (300 ml.) for 3 hr. The product was separated into neutral and acidic fractions, and the ethereal extracts of each were dried over sodium sulfate. The neutral fraction yielded 1,14-difluorotetradecane (2.9 g., 20%), b.p. 146–147° (10 mm.), n_D^{25} 1.4224. We have previously reported[6] b.p. 148° (11 mm.) and n_D^{25} 1.4218. Fractionation of the acidic fraction through a modified Podbielniak column yielded 11-fluoro-3-methylundecanoic acid (12.0 g., 45%), b.p. 152–153° (2.7 mm.), n_D^{25} 1.4393. *Anal.* Calcd. for $C_{12}H_{23}O_2F$: C, 66.02; H, 10.61. Found: C, 66.27; H, 10.81. Further distillation of the acidic residue through a short Vigreux column yielded β,β'-dimethylsuberic acid (9.3 g., 37%), b.p. 184–186° (1.0 mm.), m.p. 87–90°. Linstead, Lunt and Weedon[12] report m.p. 90–92° for a mixture of stereoisomeric β,β'-dimethylsuberic acids.

14-Fluoro-6-methyltetradecanoic Acid (IVb).—A mixture of 11-fluoro-3-methylundecanoic acid (IIIb) (15.0 g., 0.069 mole), methyl hydrogen glutarate (20.1 g., 0.138 mole), sodium (0.23 g., 0.01 g. atom) and methanol (70 ml.) was electrolyzed at 1.7 amp. for 4.5 hr. The cell contents were diluted with water, neutralized with acetic acid and thoroughly extracted with ether. The extracts were washed with sodium carbonate and with water and were dried over sodium sulfate. After removal of the ether, the residue yielded three products on careful fractionation: (1) dimethyl suberate (7.9 g., 57%) b.p. 142–144° (15 mm.), n_D^{25} 1.4320; Vogel[13] reports b.p. 148° (20 mm.), n_D^{20} 1.43370. (2) Methyl 14-fluoro-6-methyltetradecanoate (IVa) (3.8 g., 20%), b.p. 120–121° (0.10 mm.), n_D^{25} 1.4387. *Anal.* Calcd. for $C_{16}H_{31}O_2F$: C, 70.04; H, 11.39. Found: C, 70.36; H, 11.26. (3) 1,20-Difluoro-9,12-dimethyleicosane (2.45 g., 21%), b.p. 156–157° (0.25 mm.), n_D^{25} 1.4438. *Anal.* Calcd. for $C_{22}H_{44}F_2$: C, 76.23; H, 12.79. Found: C, 76.42; H, 12.55.

The ester IVa (3.0 g., 0.011 mole) was hydrolyzed with 10% sodium hydroxide (50 ml.) by heating under reflux until homogeneous (*ca.* 45 minutes). The solution was cooled, diluted with water, acidified with dilute hydrochloric acid and extracted with ether. The extracts were washed with water and dried over sodium sulfate. After removal of the ether, the residue on fractionation through a short Vigreux column yielded 14-fluoro-6-methyltetradecanoic acid (2.5 g., 93%), b.p. 146° (0.10 mm.), n_D^{25} 1.4454.

Anal. Calcd. for $C_{15}H_{29}O_2F$: C, 69.20; H, 11.23. Found: C, 69.47; H, 11.25.

undecanoic Acid.—11-Fluoro-3-methylundecanoic acid (15.0 g., 0.069 mole), methyl hydrogen azelate (28.0 g., 0.139 mole), sodium (0.23 g., 0.01 g. atom) and methanol (70 ml.) were electrolyzed by the usual procedure at 1.7 amp. for 4.5 hr. The crude reaction product, after isolation in the usual way, was heated under reflux with 10% sodium hydroxide (200 ml.) for 3 hr. The mixture was separated into neutral and acidic fractions, and the extracts were dried over sodium sulfate. The neutral extract on distillation yielded 1,20-difluoro-9,12-dimethyleicosane (2.8 g., 23%), b.p. 149–150° (0.15 mm.), n_D^{25} 1.4438. The acidic extract on distillation gave a fraction (3.6 g.) of b.p. 148–154° (0.025 mm.), presumed to be impure Vb, and hexadecanedioic acid (7.2 g., 36%), b.p. 184–188° (0.07 mm.), colorless crystals from methanol, m.p. 123–124°; Chuit[14] reports m.p. 124–124.2°. The sample of impure Vb was heated under reflux for 16 hr. with methanol (20 ml.), ethylene chloride (25 ml.) and concentrated sulfuric acid (0.2 ml.).[15] After dilution with water, the ethylene chloride layer was separated and distilled through a short Vigreux column to yield methyl fluorotuberculostearate (2.5 g., 11.5%), b.p. 149–150° (0.10 mm.), n_D^{25} 1.4433.

Anal. Calcd. for $C_{20}H_{39}O_2F$: C, 72.68; H, 11.90. Found: C, 72.88; H, 11.90.

(b) **From 14-Fluoro-6-methyltetradecanoic Acid.**—A mixture of 14-fluoro-6-methyltetradecanoic acid (2.0 g., 0.0077 mole), methyl hydrogen adipate (2.5 g., 0.0156 mole), sodium (0.035 g., 0.0015 g. atom) and methanol (75 ml.) was electrolyzed at 1.5 amp. for 50 minutes. Isolation and distillation of the products in the usual way gave two fractions: (1) dimethyl sebacate (1.08 g., 30%), b.p. 76–78° (0.02 mm.), n_D^{25} 1.4368; Stahl and Pessen[16] report n_D^{25} 1.4368. (2) Methyl fluorotuberculostearate (0.62 g., 25.5%), b.p. 126–127° (0.02 mm.), n_D^{25} 1.4433. The distillation residue was too small to allow of the isolation of pure 1,26-difluoro-9,18-dimethylhexacosane.

18-Fluoro-10-methyloctadecanoic Acid (Fluorotuberculostearic Acid) (Vb).—A portion of Va was hydrolyzed with 10% sodium hydroxide in the usual manner to yield the free acid, a colorless liquid of b.p. 159–160° (0.05 mm.), n_D^{25} 1.4500. The acid solidified just below room temperature.

Anal. Calcd. for $C_{19}H_{37}O_2F$: C, 72.10; H, 11.79; F, 6.00; neut. equiv., 316.5. Found: C, 72.14; H, 11.68; F, 5.7; neut. equiv., 318.2.

The sodium salt was prepared as follows: the acid (1.3 g.), dissolved in ethanol (20 ml.), was titrated with 0.25 *N* sodium hydroxide to a faint pink end-point, using phenolphthalein as an external indicator. A few drops of Vb in ethanol were then added to return the solution to the acid side of the indicator. The solution was evaporated on a steam-bath, forming a colorless solid. After drying in a vacuum desiccator, the sodium salt was found to be non-hygroscopic and sufficiently soluble in water for biological testing.

Acknowledgments.—The work described herein was carried out under Contract (DRB X-24) with the Defence Research Board of Canada, to whom grateful acknowledgment is made for financial assistance and for permission to publish this work. The authors wish also to express their indebtedness to the National Research Council of Canada for the award of a bursary to R.G.W.; to Mr. J. B. Stothers for valuable help in the preliminary phases of the investigation; to Dr. I. G. Walker, Defence Research Medical Laboratories, Toronto, for carrying out the toxicity determinations; and to Parke, Davis and Co., Detroit, Mich., for screening sodium fluorotuberculostearate against *M. tuberculosis*.

Toxic Fluorine Compounds. XVI.[1] Branched ω-Fluorocarboxylic Acids

BY F. L. M. PATTISON AND R. G. WOOLFORD

RECEIVED DECEMBER 3, 1956

Six branched ω-fluorocarboxylic acids, $F(CH_2)_nCHMe(CH_2)_mCOOH$, were prepared by anodic coupling reactions. The toxicological results may be explained on the basis of two modes of breakdown: (1) when *m* is odd, the compounds form intermediate oxidation products which in turn break down to give ω-fluorocarboxylic acids containing a total of *n* carbon atoms; (2) when *m* is even, β-oxidation occurs in the usual way, resulting in toxicity figures comparable to those of the unbranched ω-fluorocarboxylic acids, $F(CH_2)_{n+m+1}COOH$. Thus, compounds in which *n* is the same have approximately the same toxicity, irrespective of *m* and hence of the total length of the chain.

The unique pharmacological properties of the ω-fluorine atom in aliphatic compounds have been outlined in earlier reports in this series. By an examination of the toxicity of members of any series $F(CH_2)_nX$, it has been possible to deduce the probable metabolic fate of the group X. As an extension of this work, we have now prepared some branched ω-fluorocarboxylic acids (Table II), in order to obtain information regarding the metabolism of the corresponding unfluorinated branched-chain acids.

The value of unsymmetrical anodic coupling reactions in the synthesis of fluorine compounds has already been indicated.[2,3] The procedure used in the present work to obtain the compounds listed in Table I was essentially the same as that described earlier. In general, ω-fluorocarboxylic acids were electrolyzed in the presence of an excess of the appropriately substituted glutaric acid half-ester

$$F(CH_2)_{n-1}COOH + HOOCCH_2CHMeCH_2COOCH_3 \longrightarrow F(CH_2)_nCHMeCH_2COOCH_3 \longrightarrow F(CH_2)_nCHMeCH_2COOH$$

Simple homologation of II by means of the Arndt–Eistert synthesis yielded 11-fluoro-4-methylundecanoic acid (V). The preparation of 18-fluoro-10-methyloctadecanoic acid (VI) has been described in an earlier report.[3]

The results presented in Table II indicate that compounds in which *n* is odd are non-toxic whereas those in which *n* is even are toxic, irrespective of *m* and hence of the total length of the carbon chain. It is convenient to discuss this observation and the

resultant biochemical conclusions under two main headings.

(1) **When m is Odd (Compounds I–IV).**—The most striking feature apparent in this class of compounds is the pronounced difference in toxicity between the branched and the corresponding unbranched ω-fluorocarboxylic acids. The mere introduction of one or more methyl groups in the β-position results in the complete reversal of the toxicological pattern. Clearly, β-oxidation of the main chain is not occurring in the usual manner. Originally, it was considered likely that methyl ketones were formed[6,7] as intermediates by loss of two carbon atoms ($F(CH_2)_nCHMeCH_2COOH \rightarrow F(CH_2)_nCOMe$). While it is possible that this is indeed the case to a certain extent, it is nevertheless unlikely that methyl ketones are the sole or even the main intermediates, since the toxicities of II and III are not sufficiently similar to those of the anticipated methyl ketones[5] (Table II) to justify drawing any such definite conclusion. Additional evidence against this simple ketone formation is supplied by the report[8] that β-methyl-*n*-valeric acid forms, not methyl ethyl ketone, but acetone. An alternative mode of breakdown is suggested by the observation of Barker,[9] as a result of work with *Clostridium kluyveri* extracts, that fatty acids can give rise to the corresponding β-unsaturated acids; if this mechanism be applied to compounds I–III, the postulated intermediate, $F(CH_2)_{n-1}CH{=}CMeCH_2COOH$, could on subsequent oxidation form the ω-fluorocarboxylic acid containing a total of n carbon atoms. In short, the nature of the intermediary metabolites is uncertain, and the most reasonable interpretation of the toxicity results is that the members under consideration form ω-fluorocarboxylic acids containing a total of n carbon atoms, presumably through the intermediate formation of oxidation products which may or may not include the above-mentioned ketones and unsaturated acids. That the toxic members ultimately form fluoroacetate is indicated[10] by the high citric acid level in the tissues of animals poisoned by III.

$$F(CH_2)_nCHMeCH_2COOH \longrightarrow [\text{intermediate}] \longrightarrow F(CH_2)_{n-1}COOH$$

(2) **When m is Even (Compounds V and VI).**—In contrast to the compounds described above, the toxicity of the two members of this class are very similar to those of the corresponding unbranched acids, within the limits of biological variation. Thus the introduction of the methyl group causes no change in the general toxicological pattern of the unbranched ω-fluorocarboxylic acids. The obvious conclusion is that these branched acids, after initial formation of the thiol-ester of coenzyme A, progressively lose two carbon atoms by β-oxidation until an acid possessing an α-methyl substituent is produced; this can then undergo further β-oxidation, since an α-methyl substituent apparently results in no interference with the normal process.[11–14] Thus the branched acids of this class show toxicity figures very similar to those of the unbranched acids, $F(CH_2)_{n+m+1}COOH$.

$$F(CH_2)_nCHMeCH_2CH_2COOH \longrightarrow F(CH_2)_nCHMeCOOH \longrightarrow F(CH_2)_{n-1}COOH$$

The fundamental distinction between the above two metabolic mechanisms is well illustrated in the case of the two isomeric acids III and V, which differ only in the position of the methyl group. The simple shift of the methyl group to the adjacent carbon atom results in one acid being over 20 times more toxic than the other.

It is also of interest to consider the progressive substitution of 8-fluoroöctanoic acid. The unsubstituted acid previously has been reported[4] to be very toxic. The substitution of one methyl group on the β-carbon atom (I) results in a remarkable drop in toxicity (nearly 200 fold), as explained by mechanism 1 above. The substitution of two methyl groups on the β-carbon atom results in another non-toxic acid (IV), the lack of toxicity of which probably is associated with complete blockage of the β-oxidation process. The latter derivative (IV) is analogous to ethyl 4-fluoro-3,3-dimethylbutanoate, $FCH_2CMe_2CH_2COOEt$, which previously has been reported[15] to be non-toxic, presumably for the same reason.

It is probably justifiable to extend the above mechanisms of intermediary metabolism to unfluorinated branched acids, $CH_3(CH_2)_nCHMe(CH_2)_mCOOH$. Thus, if m is even, the acid will be metabolized by essentially the same route as the unsubstituted acid, $CH_3(CH_2)_{n+m+1}COOH$; whereas if m is odd, the probable end-products of metabolism will be formed by β-oxidation of $CH_3(CH_2)_{n-1}COOH$.

The results and conclusions presented provide further examples of the ω-fluorine atom acting as a "tag" in the elucidation of metabolic mechanisms. The general method is of wide application, and readily could provide information regarding the metabolism of many different types of branched and unbranched aliphatic compounds.

Experimental[16]

Equipment and Intermediates.—The electrolyses were carried out in the cell and by the general procedure described previously.[2] The ω-fluorocarboxylic acids were prepared[2,4] by hydrolysis of ω-fluoronitriles[17] or by oxidation of ω-fluoroalcohols.[18] Methyl hydrogen β-methylglutarate was prepared as described by Linstead, Lunt and Weedon.[19] Methyl hydrogen β,β-dimethylglutarate (b.p. 153–154° (14 mm.), $n^{25}D$ 1.4398) was prepared from β,β-dimethylglutaric acid[20] by conversion to the anhydride followed by treatment with anhydrous methanol.[21] Diazomethane was prepared[22] from N-methyl-N-nitroso-*p*-toluenesulfonamide.

8-Fluoro-3-methyloctanoic Acid (I).—5-Fluorovaleric acid (20.0 g., 0.167 mole) and methyl hydrogen β-methylglutarate (53.4 g., 0.334 mole) were electrolyzed by the general procedure for unsymmetrical couplings.[2] Methyl hydrogen β-methylglutarate (13.5 g.) and sodium (0.57 g., 0.025 mole) were dissolved in methanol in the electrolysis cell, and a current of 1.7 amp. was applied. A methanolic solution of the remainder of the starting materials was added slowly and at such a rate as to maintain the current at 1.7 amp. Total volume of methanol used was 70 ml. When the reaction solution became slightly alkaline to litmus (*ca.* 10 hours), the electrolysis was stopped. The solution was diluted with water, acidified with glacial acetic acid, and extracted with ether. After removal of the ether, the residue was hydrolyzed by heating under reflux with 10% sodium hydroxide (300 ml.) for three hours. The resultant mixture was separated into neutral and acidic fractions using aqueous sodium carbonate, and the ether extracts of each were dried over sodium sulfate. The neutral fraction on distillation yielded 1,8-difluoroöctane (1.30 g., 10%), b.p. 70° (10 mm.), $n^{25}D$ 1.3943. We have previously reported[2] b.p. 75–75.5° (13 mm.) and $n^{25}D$ 1.3933. Distillation of the acidic fraction through a short Vigreux column gave 8-fluoro-3-methyloctanoic acid (8.9 g., 30%), b.p. 97–98° (0.15 mm.), $n^{25}D$ 1.4287.

Anal. Calcd. for $C_9H_{17}FO_2$: C, 61.35; H, 9.73. Found: C, 61.45; H, 9.53.

Further distillation of the acidic residue yielded β,β'-dimethylsuberic acid (12.2 g., 36%), b.p. 172–174° (0.4 mm.), m.p. 87–90°. Linstead, Lunt and Weedon[23] report m.p. 90–92° for a mixture of stereoisomeric β,β'-dimethylsuberic acids.

10-Fluoro-3-methyldecanoic Acid (II).—A mixture of 7-fluoroheptanoic acid (12.0 g., 0.081 mole), methyl hydrogen β-methylglutarate (26.0 g., 0.163 mole), sodium (0.28 g., 0.012 mole) and methanol (70 ml.) was electrolyzed, as above. The reaction was complete after 4.5 hours at a current of 1.7 amp. After isolation and hydrolysis in the usual way, the resultant mixture was separated into neutral and acidic fractions. The ethereal solution of each was dried over sodium sulfate. The neutral fraction on distillation yielded 1,12-difluorododecane (1.69 g., 20%), b.p. 120° (10 mm.), $n^{25}D$ 1.4177. We have previously reported[2] b.p. 120° (10 mm.) and $n^{25}D$ 1.4170. Distillation of the acidic fraction through a short Vigreux column gave 10-fluoro-3-methyldecanoic acid (7.0 g., 42%), b.p. 120–121° (0.50 mm.), $n^{25}D$ 1.4392.

Anal. Calcd. for $C_{11}H_{21}FO_2$: C, 64.67; H, 10.36. Found: C, 64.85; H, 10.29.

Further distillation of the acidic residue yielded β,β'-dimethylsuberic acid (5.8 g., 35%), with the same physical constants as described above.

11-Fluoro-3-methylundecanoic Acid (III) has been previously described.[2] Its methyl ester, prepared as an intermediate in other work, was obtained as follows. The acid III (15.0 g., 0.069 mole), methanol (25 g.), ethylene chloride (75 ml.) and concd. sulfuric acid (0.8 ml.) were heated under reflux for 16 hours. The mixture was cooled and diluted with water. The ethylene chloride layer was washed with aqueous sodium carbonate and with water. Distillation yielded the methyl ester (14.7 g., 92%), b.p. 95.5–96° (0.2 mm.), $n^{25}D$ 1.4330.

Anal. Calcd. for $C_{13}H_{25}FO_2$: C, 67.20; H, 10.85. Found: C, 67.25; H, 10.90.

8-Fluoro-3,3-dimethyloctanoic Acid (IV).—A mixture of 5-fluorovaleric acid (20.0 g., 0.167 mole), methyl hydrogen β,β-dimethylglutarate (58.0 g., 0.333 mole), sodium (0.57 g., 0.025 mole) and methanol (70 ml.) was electrolyzed, as above. The reaction was complete after 10 hours at a current of 1.7 amp. After isolation and hydrolysis, the resultant mixture was separated into neutral and acidic fractions. The ethereal solution of each was dried over sodium sulfate. The neutral fraction on distillation yielded 1,8-difluoroöctane (1.27 g., 10%), with the same physical constants as described above. Distillation of the acidic fraction through a short Vigreux column gave 8-fluoro-3,3-dimethyloctanoic acid (9.5 g., 30%), b.p. 124–125° (1.0 mm.), $n^{25}D$ 1.4340.

Anal. Calcd. for $C_{10}H_{19}FO_2$: C 63.14; H, 10.07. Found: C, 63.28; H, 9.97.

The acidic residue was recrystallized from methanol to yield $\beta,\beta,\beta',\beta'$-tetramethylsuberic acid (14.6 g., 38%), m.p. 169–170°. Birch, *et al.*,[24] report m.p. 169.5°.

10-Fluoro-3-methyldecanoyl Chloride.—10-Fluoro-3-methyldecanoic acid (6.0 g., 0.029 mole) was added dropwise to boiling thionyl chloride (4.8 g., 0.040 mole). The resultant mixture was heated for an additional two hours on a steam-bath. Fractional distillation of the product gave 10-fluoro-3-methyldecanoyl chloride (5.3 g., 81.5%), b.p. 112–114° (1.5 mm.), n^{25}D 1.4410.

Anal. Calcd. for $C_{11}H_{20}ClFO$: C, 59.32; H, 9.05; Cl, 15.93. Found: C, 59.38; H, 9.04; Cl, 15.98.

11-Fluoro-4-methylundecanoic Acid (V).—A solution of 10-fluoro-3-methyldecanoyl chloride (5.3 g., 0.024 mole) in anhydrous ether (25 ml.) was added to a stirred ethereal solution of diazomethane (5.9 g., 0.14 mole) cooled in an ice-bath. Stirring was continued for three hours in the cold and then for three hours at 20–25°. The ether was removed *in vacuo* at 20–25°. The residual diazomethyl ketone, a bright yellow liquid, was dissolved in dioxane (100 ml.) and was added dropwise with stirring to a mixture of freshly prepared silver oxide (2 g.), sodium carbonate (5 g.) and sodium thiosulfate (3 g.) in water (200 ml.) at 70°. The mixture was stirred at 70° for two hours with occasional addition of fresh silver oxide. The temperature was then raised to 90° for 10 hours. The black silver residue was removed by filtration, and the filtrate was acidified with dilute nitric acid. The resultant solution was extracted with ether and separated into neutral and acidic fractions. After drying over sodium sulfate and removal of the ether, the acidic fraction was distilled through a short Vigreux column to yield 11-fluoro-4-methylundecanoic acid (1.4 g., 27%), b.p. 150–151° (0.2 mm.), n^{25}D 1.4393.

Anal. Calcd. for $C_{12}H_{23}FO_2$: C, 66.02; H, 10.61. Found: C, 66.02; H, 10.60.

18-Fluoro-10-methyloctadecanoic acid (VI) has been previously described.[3]

Acknowledgments.—The work described herein was carried out under Contract (DRB X-24) with the Defence Research Board of Canada, to whom grateful acknowledgment is made for financial assistance and for permission to publish this work. The authors wish also to express their indebtedness to the National Research Council of Canada for the award of a bursary to R. G. W.; and to Drs. J. M. Parker and I. G. Walker, Defence Research Medical Laboratories, Toronto, for carrying out the toxicity and citric acid determinations.

Toxic Fluorine Compounds. XVII.[1] Some 1-Fluoroalkanes, ω-Fluoroalkenes and ω-Fluoroalkynes

BY F. L. M. PATTISON AND J. J. NORMAN

RECEIVED DECEMBER 26, 1956

Some 1-fluoroalkanes (*n*-alkyl fluorides), ω-fluoroalkenes and ω-fluoroalkynes were prepared for biochemical studies, and for use as intermediates in the synthesis of other compounds. The even-chain 1-fluoroalkanes are very toxic. Whereas no clear-cut conclusions could be drawn regarding the biochemical breakdown of 1-alkenes, evidence was obtained for ω-oxidation of 1-fluoroalkanes, and, less convincingly, for hydration of 1-alkynes to the corresponding methyl ketones. Ethyl ω-fluorolactate, $FCH_2CH(OH)COOEt$, the preparation of which is described, was found to be non-toxic.

The three classes of monofluorinated hydrocarbons described in this paper were prepared for toxicological studies, and hence to obtain information regarding the breakdown *in vivo* of the unfluorinated analogs. ω-Oxidation had previously been postulated[2] in the biological degradation of certain fluoroketones; it was recognized that the study of 1-fluoroalkanes would provide additional evidence for this mechanism. The results presented here are in conformity with the suggestion. In an earlier report[3] was mentioned the toxicity of 11-fluoro-1-undecene; the inference was drawn that the alkene was converted to the intermediate 11-fluoro-1,2-undecanediol,[4] which in turn was oxidized with loss of one carbon atom. The toxicities of the ω-fluoro-1-alkenes presented below do not tally with this simple mechanism. In regard to the biological fate of the 1-alkynes, hydration to the corresponding methyl ketones was considered most likely; the toxicity figures shown in Table II, supplemented by some studies of citric acid accumulation, lend support for this prediction.

Preparation

The majority of the 1-fluoroalkanes were prepared from alkyl halides or alkyl sulfonates by treatment with potassium fluoride in diethylene glycol.[5–10] Special procedures, for example the cleavage of an alkyl *p*-toluenesulfonate with silver fluoride in acetonitrile, were used in a few instances, but none proved superior to the two above-mentioned methods, both of which already have been described. All the 1-fluoroalkanes have been prepared previously in other laboratories.

The ω-fluoroalkenes listed in Table I were prepared from ω-haloalkenes or from ω-methanesulfonoxyalkenes[10] by treatment with potassium fluoride in diethylene glycol. All four members were prepared by the former method, while 5-fluoro-1-pentene was obtained also by the latter method.[10]

The ω-fluoroalkynes[3] were prepared either by treatment[11] of the appropriate ω-fluoroalkyl bromides and iodides[12] with sodium acetylide, or by fluorination of the corresponding ω-chloroalkynes[13,14] with potassium fluoride in ethylene glycol or diethylene glycol. By the former method were prepared 5-fluoro-1-pentyne, 6-fluoro-1-hexyne, 7-fluoro-1-heptyne and 8-fluoro-1-octyne, while the latter method yielded 5-fluoro-1-pentyne, 6-fluoro-1-hexyne, 9-fluoro-1-nonyne, 1,4-difluoro-2-butyne and 1-fluoro-4-chloro-2-butyne.

Properties

Chemical.—As has been noted by other workers,[7,8,15] 1-fluoroalkanes are very stable liquids. It is unfortunate that the early misconception[16] regarding the instability of monofluoro aliphatic compounds has persisted for so long. Notwithstanding the growing number of stable monofluoro aliphatic compounds reported in the literature during the last ten years, two recent reviews[17,18] still repeat Henne's observation that a single fluorine atom in an aliphatic compound causes instability. Of some three hundred primary monofluoro compounds prepared in the course of our study of toxic materials, only a handful have proved to be unstable and, in these few instances, the instability was associated almost exclusively with some other functional group in the molecule.

The ω-fluoro-1-alkenes reacted readily with performic acid[19] to yield the corresponding ω-fluoro-1,2-alkanediols; by this means were prepared 5-fluoro-1,2-pentanediol and 11-fluoro-1,2-undecanediol; the former was converted without purification into 4-fluorobutanal.[20] 3-Fluoro-1,2-propanediol was more conveniently prepared by hydrolysis of epifluorohydrin.[21,22] The latter was obtained in 50% yield by fluorination of epichlorohydrin in a stainless steel autoclave at 215–225° using anhydrous potassium fluoride. In most runs, the maximum pressure developed was 190–210 p.s.i., but in one instance, unaccountably, the pressure rose to 3000 p.s.i., with almost total loss of product; it is therefore essential that this reaction be carried out in a pressure vessel equipped with an emergency pressure relief device. Both epifluorohydrin and 3-fluoro-1,2-propanediol on oxidation with nitric acid afforded ω-fluorolactic acid; the crude acid was esterified prior to purification.

The ω-fluoro-1-alkynes formed copper, silver and mercuric salts; the last of these served as a convenient means of characterization. The ω-fluoro-1-alkynes tended to lose fluorine in the presence of reactants such as sodamide and Grignard reagents,[23] rather than undergoing the reactions characteristic of the non-fluorinated alkynes. Thus, the reaction of 6-fluoro-1-hexyne with sodamide resulted in an indeterminate mixture of products, and with ethylmagnesium bromide followed by carbon dioxide produced fluorine-free polymers. Whereas 1,4-difluoro-2-butyne was stable, 1-fluoro-4-chloro-2-butyne decomposed extensively when distilled at atmospheric pressure.

Physical.—All the 1-fluoroalkanes listed in Table II have been prepared and examined independently by Vogel and co-workers.[7,8] Since the physical constants obtained were essentially the same in both laboratories, it was mutually agreed that the details would be presented in a forthcoming publication by these workers rather than by us. Physical constants and analytical results of the ω-fluoroalkenes and ω-fluoroalkynes and of some precursors and derivatives are shown in Table I.

Toxicological.—The most striking feature of the figures listed in Table II is the very high toxicity of the 1-fluoroalkanes, and more particularly of the members containing an even number of carbon atoms. They are indeed among the most toxic of the ω-fluoro-compounds; this fact, coupled with their relatively high volatility, emphasizes the need for caution in their manipulation. The hazardous nature of the 1-fluoroalkanes, recorded here for the first time, is the more surprising when contrasted with the outstanding stability of the members, and points a warning to industrial workers who may encounter these materials as by-products in commercial processes.

The alternation in toxicity of the 1-fluoroalkanes indicates the existence of a biochemical degradative mechanism akin to that of the ω-fluorocarboxylates.[24] A reasonable interpretation of this observation consequently points to initial ω-oxidation of the 1-fluoroalkanes, resulting in the formation of ω-fluorocarboxylates containing the same number of carbon atoms ($F(CH_2)_nCH_3 \rightarrow F(CH_2)_nCOOH$); the fluoro-acids, once formed, would then be degraded by β-oxidation.[25] In support of this is the marked similarity in toxicity between the 1-fluoroalkanes, particularly those containing an even number of carbon atoms, and the corresponding ω-fluorocarboxylates.[24] Further evidence in favor of the ω-oxidation mechanism is supplied by high citric acid levels found in animals poisoned by the even chain 1-fluoroalkanes, indicat-

(23) We also have reported loss of fluorine in Grignard reactions involving ω-fluoroalkylmagnesium halides; F. L. M. Pattison and W. C. Howell, *J. Org. Chem.*, **21**, 879 (1956). In a related investigation, we have shown loss of fluorine from 1-fluorohexane by treatment with alkylmagnesium halides; W. J. Cott and F. L. M. Pattison, unpublished results.

(24) F. L. M. Pattison, S. B. D. Hunt and J. B. Stothers, *J. Org. Chem.*, **21**, 883 (1956).

(25) I. G. Walker and J. M. Parker have suggested convincingly that oxidative attack on the 1-fluoroalkanes may occur not only at the end but also in the middle of the chain; this theory, based on studies of citric acid accumulation,[26] will be discussed in a forthcoming publication by these workers.

ing[26] the ultimate formation of fluoroacetate. In short, ω-oxidation provides a satisfactory explanation of the toxicity results of the 1-fluoroalkanes[25] and of the fluoromethyl alkyl ketones described earlier.[2]

The four ω-fluoroalkenes listed in Table II are all toxic, irrespective of the length of their carbon chains. Hence no clear-cut conclusions can be drawn from these figures regarding the biochemical fate of the alkene grouping. The earlier suggestion[3] that the alkene group was oxidized to the diol and then to the aldehyde ($-CH=CH_2 \rightarrow -CH(OH)-CH_2OH \rightarrow -CHO$) clearly requires modification because of the high toxicity of 6-fluoro-1-hexene; hence a competitive metabolic route, such as ketone[2] formation ($-CH=CH_2 \rightarrow -CH(OH)CH_3 \rightarrow -COCH_3$), also may be available. That the diols, once formed, are indeed oxidized to aldehydes or acids with loss of one carbon atom is supported by the two figures presented in Table II.

Ethyl ω-fluorolactate was found to be non-toxic, as was expected from the low toxicity of the closely related fluoropyruvic acid.[27] This result thus provides evidence that 3-fluoro-1,2-propanediol (toxic) forms some metabolite other than fluorolactate (non-toxic), and at the same time implies that in general α-glycols are not oxidized to the corresponding α-hydroxyacids; this implication is therefore consistent with the oxidative cleavage of α-glycols postulated above.

The alternation in toxicity shown by the ω-fluoro-1-alkynes indicates that the alkyne grouping is attacked *in vivo*. From a comparison of the toxicity pattern of the ω-fluoro-1-alkynes with that previously described for the ω-fluoroalkyl methyl ketones[2] it is suggested that hydration of the alkyne grouping may be the initial step in its degradation

TABLE II

TOXICITY RESULTS

Compound	Formula	L.D. 50 for mice (intraperitoneal), mg./kg.
1-Fluorohexane	$CH_3(CH_2)_5F$	1.7
1-Fluoroheptane	$CH_3(CH_2)_6F$	35
1-Fluoroöctane	$CH_3(CH_2)_7F$	2.7
1-Fluorononane	$CH_3(CH_2)_8F$	21.7
1-Fluorodecane	$CH_3(CH_2)_9F$	1.7
1-Fluoroundecane	$CH_3(CH_2)_{10}F$	15.5
1-Fluorododecane	$CH_3(CH_2)_{11}F$	2.5
5-Fluoro-1-pentene	$F(CH_2)_3CH=CH_2$	5.4
6-Fluoro-1-hexene	$F(CH_2)_4CH=CH_2$	2.8
11-Fluoro-1-undecene	$F(CH_2)_9CH=CH_2$	9.3
1,4-Difluoro-2-butene	$FCH_2CH=CHCH_2F$[a]	6.1
3-Fluoro-1,2-propanediol	$FCH_2CH(OH)CH_2OH$[a]	16.8
11-Fluoro-1,2-undecanediol	$F(CH_2)_9CH(OH)CH_2OH$[b]	1.75
Ethyl ω-fluorolactate	$FCH_2CH(OH)COOEt$[c]	>100
1-Hexyne	$CH_3(CH_2)_3C\equiv CH$	>100
6-Fluoro-1-hexyne	$F(CH_2)_4C\equiv CH$	5.7
7-Fluoro-1-heptyne	$F(CH_2)_5C\equiv CH$	53
8-Fluoro-1-octyne	$F(CH_2)_6C\equiv CH$	7.5
9-Fluoro-1-nonyne	$F(CH_2)_7C\equiv CH$	79

[a] For comparison, FCH_2COOH has L.D. 50, 6.6 mg./kg.[24] [b] For comparison, $F(CH_2)_9CHO$ has L.D. 50, 1.95 mg./kg.[20] and $F(CH_2)_9COOH$ has L.D. 50, 1.5 mg./kg.[24] [c] The high L.D. 50 is consistent with the relatively non-toxic nature of $FCH_2COCOOH$.[27]

(—C≡CH → —$COCH_3$); the fact that the fluoroalkynes are all rather less toxic than the corresponding fluoroketones may indicate, however, that hydration is not the sole metabolic route. Ultimate formation of fluoroacetate from 6-fluoro-1-hexyne and from 7-fluoro-1-heptyne was shown by citric acid accumulation in the tissues of poisoned animals. That both the even *and* odd members caused citric acid accumulation is a unique point in common between the fluoroalkynes and the fluoroalkyl methyl ketones; moreover, with both classes, the accumulation was greater with the even chain members (on a molar basis). While the toxicity pattern and citric acid levels are thus in substantial agreement with the hydration of the alkyne grouping to the corresponding methyl ketone, independent work is still required to confirm or disprove this postulate.

Experimental[30]

Intermediates.—The ω-fluoroalkyl halides were prepared as described previously.[12] The ω-chloroalkyl iodides were prepared from ω,ω′-dichloroalkanes.[31] 5-Bromo-1-pentene[32] was prepared from 5-hydroxy-1-pentene using phosphorus tribromide; 6-bromo-1-hexene[33] and 11-bromo-1-undecene[34] were prepared similarly from 6-hydroxy-1-hexene[35] and 11-hydroxy-1-undecene,[36] respectively. 1,4-Dichloro-2-butene was purchased commercially.[35] 5-Chloro-1-pentyne[37] was prepared from 5-hydroxy-1-pentyne[38] by treatment with thionyl chloride; the other ω-chloro-1-alkynes were prepared from the appropriate ω-chloroalkyl iodides using sodium acetylide in the usual way.[11] 1,4-Dihydroxy-2-butyne was kindly donated by General Aniline and Film Corporation, 435 Hudson St., New York 14, N. Y. Potassium fluoride and diethylene glycol were purified as described previously.[39]

1-Fluoroalkanes. (a) From *n*-Alkyl Chlorides and Bromides.—The following example is representative of the general method. For the lower members, continuous removal[5,6] of the product gave satisfactory results.

1-Fluoroundecane.—A mixture of anhydrous potassium fluoride (15.0 g., 0.26 mole), diethylene glycol (80 g.) and 1-chloroundecane (34.0 g., 0.18 mole) was heated at 135° for 23 hours with vigorous stirring; the period of heating may be reduced, with slight diminution of yield. The mixture was cooled and diluted with an equal volume of water. The organic layer was separated, and the aqueous layer was extracted with ether. The combined organic layer and extracts were treated with bromine in ether until a faint orange color persisted, and then were washed successively with water, aqueous sodium carbonate and water again. The product, after being dried over sodium sulfate and removal of the ether, was fractionally distilled, yielding 1-fluoroundecane (15.0 g.), b.p. 102–102.5° (23 mm.), $n^{25}D$ 1.4131, and then unchanged 1-chloroundecane (9.0 g.). Gryszkiewicz-Trochimowski, *et al.*,[21] report b.p. 90° (12 mm.). The yield, calculated on reacted 1-chloroundecane, was 66%.

Anal. Calcd. for $C_{11}H_{23}F$: C, 75.80; H, 13.30. Found: C, 75.61; H, 13.03.

By essentially the same procedure were prepared: **1-fluorohexane** (52% yield, from 1-bromohexane, isolated by continuous removal at atmospheric pressure), **1-fluoroheptane** (39% yield, from 1-chloroheptane, isolated by continuous removal under reduced pressure), **1-fluoroöctane** (48% yield, from 1-bromoöctane, isolated by continuous removal under reduced pressure), **1-fluorononane** (31% yield, from 1-chlorononane, isolated by dilution with water) and **1-fluorododecane** (57% yield, from 1-bromododecane, isolated by dilution with water).

(b) From *n*-Alkyl Methanesulfonates.—This previously described procedure[10] was used for the preparation of **1-fluorohexane** (67% yield) and **1-fluorodecane** (48% yield).

ω-Fluoroalkenes and Derivatives. 5-Fluoro-1-pentene.—A mixture of anhydrous potassium fluoride (61.0 g., 1.05 moles) and diethylene glycol (200 g.) was heated to 110° in a three-necked flask equipped with a thermometer, a mercury-seal stirrer and a distillation assembly. 5-Bromo-1-pentene (104.8 g., 0.703 mole) was then added dropwise to the stirred mixture; after about half the quantity had been added, a colorless liquid began to distil at a b.p. of 55–70°. The heating was continued until distillation ceased. The product (35.9 g.) was found to be free of acid, and was therefore fractionated directly through a Todd still, giving 25.8 g. (42%) of a colorless, sweet-smelling liquid. 5-Fluoro-1-pentene may also be obtained from the corresponding methanesulfonoxyalkene.[10]

6-Fluoro-1-hexene.—A mixture of anhydrous potassium fluoride (18.0 g., 0.3 mole), diethylene glycol (70 g.) and 6-bromo-1-hexene (30.0 g., 0.18 mole) was heated at 90° for two hours with vigorous stirring. The pressure was then slowly reduced until a steady, slow rate of distillation resulted. Toward the end of the reaction, the heating was increased and the pressure further reduced until distillation ceased. The residue was heated at 120° for an additional hour at atmospheric pressure, and then was cooled, diluted with water and extracted with ether. The extracts were added to the distillate, and the combined liquids were washed successively with water, aqueous sodium carbonate and water again. The product, after drying over sodium sulfate and removal of the ether, yielded 6-fluoro-1-hexene (5.2 g.) and then unchanged 6-bromo-1-hexene (9.0 g.). The yield, calculated on reacted 6-bromo-1-hexene, was 40%.

11-Fluoro-1-undecene.—A mixture of 11-bromo-1-undecene (62.0 g., 0.28 mole), anhydrous potassium fluoride (33.6 g., 0.58 mole), diethylene glycol (60 g.) and butyl carbitol (60 g.) was heated at 180° for six hours with vigorous stirring. After cooling overnight, the mixture was diluted with water (200 ml.). The organic layer was separated, and the aqueous layer was extracted with ether. The combined organic layer and extracts were washed and dried, and yielded on fractionation 21.0 g. (46%) of 11-fluoro-1-undecene.

1,4-Difluoro-2-butene.—A mixture of anhydrous potassium fluoride (70.0 g., 1.2 moles), diethylene glycol (150 g.) and 1,4-dichloro-2-butene (46.0 g., 0.37 mole) was heated at 115° for 2.5 hours with continuous stirring. The resultant mixture was cooled, diluted, separated, extracted, dried and fractionated as above, yielding 20.2 g. (60%) of 1,4-difluoro-2-butene. A higher fraction, suspected of being 1-fluoro-4-chloro-2-butene, was found to be unstable.

Epifluorohydrin.—In an electrically heated, stainless-steel autoclave, fitted with a stirrer and an emergency pressure relief device (a rupture disk leading to a fume-hood), was placed a mixture of commercial epichlorohydrin (783 g., 8.5 moles) and anhydrous potassium fluoride (700 g., 12.1 moles). The temperature was raised to 215–225° and maintained in that range for 5.5 hours. The maximum pressure developed was 210 p.s.i. The liquid was distilled from the autoclave leaving only the solids behind. The combined distillates from two identical runs (1165 g.) were fractionated through a Todd still, giving 342 g. of epifluorohydrin and 736 g. of recovered epichlorohydrin. The yield based on reacted epichlorohydrin was 50%.

As mentioned in the Discussion, a serious pressure hazard developed during one run, under apparently identical conditions. When the temperature reached 225°, the pressure had reached 440 p.s.i. The heating was stopped immediately, but within five minutes the temperature had risen spontaneously to 252° and the pressure had passed 1000

(30) (a) The majority of the microanalyses were performed by Mr. J. F. Alicino, Metuchen, N. J., and by the Schwarzkopf Microanalytical Laboratory, Woodside 77, N. Y. (b) The melting points and boiling points are uncorrected.

Digitized by Arya Samaj Foundation Chennai and eGangotri

p.s.i. and was rising rapidly. Within another five minutes, the temperature was >255° and the pressure was 3000 p.s.i. The total distillate from 737 g. of epichlorohydrin consisted of 25 g. of a brown liquid. It is therefore essential that the reaction be carried out in a pressure vessel equipped with an emergency pressure relief device.

3-Fluoro-1,2-propanediol.—Epifluorohydrin (20.0 g., 0.213 mole), 10% sulfuric acid (2 ml.) and water (16 ml.) were heated under reflux on a steam-bath for one hour. The solution was allowed to cool, and then was neutralized with solid sodium carbonate. The water was removed under reduced pressure, and the residue was distilled twice, yielding 3-fluoro-1,2-propanediol (18.3 g., 76%).

5-Fluoro-1,2-pentanediol and **11-fluoro-1,2-undecanediol** have been described earlier.[20]

Ethyl ω-Fluorolactate.[40]—Water (58 ml.) and concentrated nitric acid (20 ml.) were placed in a 500-ml. flask fitted with a reflux condenser, a mercury-seal stirrer and a dropping funnel. Epifluorohydrin (58.0 g., 0.76 mole) was added dropwise over 15 minutes to the dilute nitric acid, heated on a steam-bath. A further 100 ml. of concentrated nitric acid was then added, and the mixture was heated for three hours and left overnight at room temperature. Water and nitric acid were distilled off under reduced pressure. The oxalic acid formed during the oxidation was removed by the addition of hot water (1 l.) and then powdered calcium carbonate until effervescence ceased (*ca.* 70 g.). The precipitate was removed by filtration under vacuum at 60°, and the filtrate was acidified with 100 ml. of concentrated hydrochloric acid. The fluorolactic acid was isolated by continuous extraction with ether. Esterification by azeotropic distillation with ethanol and benzene gave ethyl ω-fluorolactate (40.0 g., 39%) as a colorless liquid.

The **3,5-dinitrobenzoate**, recrystallized from 95% ethanol, had m.p. 91–91.5°. Dr. Rivett reported[40] the *p*-bromophenacyl ester to have m.p. 126°, the ***p*-nitrobenzoate** to have m.p. 67–67.5°, and the **benzoate** to be an oil.

ω-Fluoroalkynes.—The following examples are representative of the two general methods. (a) **From ω-Fluoroalkyl Bromides and Iodides. 6-Fluoro-1-hexyne.**—The method was adapted from a previously described procedure.[11] Ferric nitrate (0.3 g. per mole of sodium used) was placed in a 500-ml. flask fitted with a stirrer, a gas inlet tube, and a device for adding sodium.[11] The flask was half-filled with liquid ammonia, and acetylene (scrubbed with concentrated sulfuric acid and dried with calcium chloride) was passed into the system at the rate of 5–10 bubbles per second. After 15 minutes, small pieces of sodium (13.0 g., 0.56 mole) were added to the ammonia solution on a piece of wire at such a rate that metallic sodium solutions were never formed, as indicated by an absence of a blue coloration. The acetylene flow was continued for a further 15 minutes after all the sodium had been added, to decompose any disodium acetylide which might have been formed. 4-Fluorobutyl iodide (100 g., 0.50 mole) was added dropwise to the stirred sodium acetylide solution. The mixture was then stirred for a further five hours to complete the reaction. The volume of the mixture was kept more or less constant by the occasional addition of small portions of liquid ammonia. Ammonium hydroxide (50 ml.) was added to decompose any residual sodium acetylide or sodamide, and the resultant mixture was diluted with water (1 l.). The organic product was isolated by ether extraction. The extracts were washed with dilute hydrochloric acid and then with water, and were dried over calcium chloride. The ether was removed, and the residue was fractionated, yielding 6-fluoro-1-hexyne (44.5 g., 89%) as a colorless, very volatile liquid.

By the above method were prepared **5-fluoro-1-pentyne** (isolated only as the mercury derivative, from 3-fluoropropyl bromide), **7-fluoro-1-heptyne** (53% yield, from 5-fluoroamyl bromide), and **8-fluoro-1-octyne** (63% yield, from 6-fluorohexyl bromide).

(b) **From ω-Chloro-1-alkynes. 6-Fluoro-1-hexyne.**—Ethylene glycol (200 g.) and anhydrous potassium fluoride (52.0 g., 0.90 mole) were placed in a three-necked flask fitted with a mercury-seal stirrer, a dropping funnel and a distillation assembly. The mixture was heated to 120° and 6-chloro-1-hexyne (42.0 g., 0.36 mole) was added dropwise to the vigorously stirred solution. After about one-third of the chloroalkyne had been added, a liquid, boiling at *ca.* 110°, began to distil. When all the chloroalkyne had been added, the temperature of the mixture was gradually raised to maintain the still-head temperature. The distillate was washed with water and was then dried over calcium chloride. Fractional distillation yielded 6-fluoro-1-hexyne (20.8 g., 57%).

By the above method was prepared **5-fluoro-1-pentyne** (isolated only as the mercury derivative).

9-Fluoro-1-nonyne.—9-Chloro-1-nonyne (2.6 g., 0.016 mole), anhydrous potassium fluoride (1.5 g., 0.026 mole) and diethylene glycol (10 g.) were placed in a sealed tube, 10 cm. long and 16 mm. in diameter. The tube was mounted in a mechanical shaker, and was heated electrically at 120° for 24 hours with vigorous shaking. The contents of the tube, after cooling, were diluted with water. The fluoroalkyne was separated using a hypodermic syringe and was dried over calcium chloride. Fractionation gave crude 9-fluoro-1-nonyne of b.p. 70–80° (25 mm.), which, on refractionation through a microdistillation assembly, yielded the pure fluoroalkyne (0.6 g., 26%).

1,4-Difluoro-2-butyne and **1-Fluoro-4-chloro-2-butyne.**—1,4-Dihydroxy-2-butyne was converted to 1,4-dichloro-2-butyne (b.p. 59–60° (13 mm.), n^{25}D 1.5040) in 85% yield using thionyl chloride and pyridine at room temperature. A mixture of anhydrous potassium fluoride (35.0 g., 0.60 mole) and ethylene glycol (200 g.) was heated to 120°, and 1,4-dichloro-2-butyne (49.4 g., 0.41 mole) was added dropwise with vigorous stirring. A brown solid was precipitated, and a very small (*ca.* 5 ml.), two-phase distillate was collected. This was washed with water and dried over calcium chloride. Distillation yielded two fractions, b.p. 70–90° and b.p. 122–130°. The first of these, on fractionation, yielded 1,4-difluoro-2-butyne (0.75 g.), while the second gave 1-fluoro-4-chloro-2-butyne (0.5 g.).

Mercury Derivatives.—Nessler reagent was prepared by dissolving mercuric chloride (66.0 g.) and potassium iodide (163.0 g.) in water (160 ml.) and then adding 10% aqueous sodium hydroxide (125 ml.). The mercury salt was formed by mixing the fluoroalkyne in five volumes of ethanol with an equal volume of Nessler reagent. The white, crystalline precipitate which formed immediately was filtered and recrystallized several times from 95% ethanol. The physical constants and analytical results are listed in Table I. The mercury derivative of 7-fluoro-1-heptyne was found to be liquid at room temperature and to crystallize at *ca.* 15°.

Silver Derivatives.—A 10% solution of the alkyne in alcohol was added to an equal volume of 10% alcoholic silver nitrate solution containing 1% ammonium hydroxide. The insoluble silver salt formed immediately. It was dissolved by gentle heating and crystallized as fine, colorless crystals on cooling. These were filtered and washed with cold alcohol.

Copper Derivatives.—Equimolar quantities of the alkyne and 10% ammoniacal cuprous chloride were mixed and shaken. The insoluble copper salt was filtered, was washed with acetone to remove water, and finally was washed with ether to remove extraneous organic material.

Acknowledgments.—The work described herein was carried out under Contract (DRB X-24) with the Defence Research Board of Canada, to whom grateful acknowledgment is made for financial assistance and for permission to publish this work. The authors wish also to express their indebtedness to Drs. J. M. Parker and I. G. Walker, Defence Research Medical Laboratories, Toronto, for carrying out the citric acid assays and some of the toxicity determinations; to Dr. M. K. McPhail, Suffield Experimental Station, Ralston, Alberta, for the remainder of the toxicological results; to Mr. R. G. Dunlop, Defence Research Chemical Laboratories, Ottawa, for performing the autoclave fluorination of epichlorohydrin; to General Aniline and Film Corporation, 435 Hudson St.,

(40) The preparative details were kindly supplied by Dr. D. E. A. Rivett, National Chemical Research Laboratories, Pretoria, South Africa (April 29 and October 1, 1952), with whose permission they are here recorded.

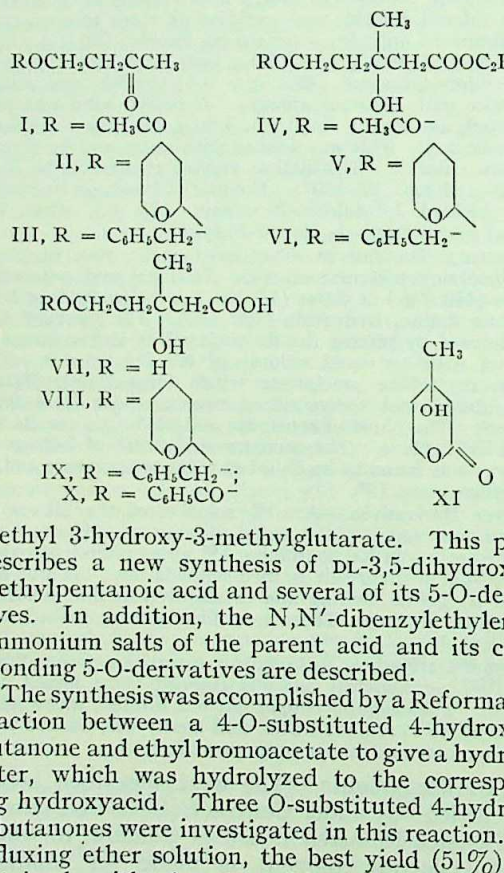
Synthesis of DL-3,5-Dihydroxy-3-methylpentanoic Acid (Mevalonic Acid)

BY CARL H. HOFFMAN, ARTHUR F. WAGNER, ANDREW N. WILSON, EDWARD WALTON, CLIFFORD H. SHUNK, DONALD E. WOLF, FREDERICK W. HOLLY AND KARL FOLKERS

RECEIVED DECEMBER 14, 1956

The racemate of a new acetate-replacing factor, DL-3,5-dihydroxy-3-methylpentanoic acid (VII), has been synthesized. The Reformatsky reaction between 4-acetoxy-2-butanone and ethyl bromoacetate gave ethyl 5-acetoxy-3-hydroxy-3-methylpentanoate (IV), which was hydrolyzed by alkali to 3,5-dihydroxy-3-methylpentanoic acid (VII).

A new acetate-replacing factor has been obtained[1] from dried distillers' solubles and has been shown[2] to be 3,5-dihydroxy-3-methylpentanoic acid (XI). The racemate was synthesized[2] from



diethyl 3-hydroxy-3-methylglutarate. This paper describes a new synthesis of DL-3,5-dihydroxy-3-methylpentanoic acid and several of its 5-O-derivatives. In addition, the N,N′-dibenzylethylenediammonium salts of the parent acid and its corresponding 5-O-derivatives are described.

The synthesis was accomplished by a Reformatsky reaction between a 4-O-substituted 4-hydroxy-2-butanone and ethyl bromoacetate to give a hydroxyester, which was hydrolyzed to the corresponding hydroxyacid. Three O-substituted 4-hydroxy-2-butanones were investigated in this reaction. In refluxing ether solution, the best yield (51%) was obtained with 4-acetoxy-2-butanone (I). With the acetal, 4-(2-tetrahydropyranyloxy)-2-butanone (II), the yields were about 20%, while with the ether, 4-benzyloxy-2-butanone (III), the yields were even lower. When the condensation was carried out in refluxing benzene, the yields of hydroxyester were extremely low with both the 4-acetoxy derivative I and the 4-(2-tetrahydropyranyloxy) derivative II.

The hydroxyesters (IV, V, VI) were hydrolyzed with alkali to the corresponding free acids (VII, VIII, IX), which were isolated as oils and purified by conversion to N,N′-dibenzylethylenediammonium salts. Ethyl 5-acetoxy-3-hydroxy-3-methylpentanoate (IV) was hydrolyzed to the corresponding dihydroxyacid VII, which was isolated as an equilibrium mixture of the hydroxyacid and its δ-lactone. The pure lactone XI was isolated from the equilibrium mixture by a short-path distillation. The distilled lactone was crystallized from acetone–ether to yield DL-β-methyl-β-hydroxy-δ-valerolactone (XI), m.p. 27–28°. The acid–lactone mixture was converted by an excess of N,N′-dibenzylethylenediamine in semi-aqueous media into N,N′-dibenzylethylenediammonium-bis-(3,5-dihydroxy-3-methylpentanoate).

Both the lactone XI and the salt of VII are fully active in the *Lactobacillus acidophilus* ATCC 4963 assay.[3]

Ethyl 3-hydroxy-3-methyl-5-(2-tetrahydropyranyloxy)-pentanoate (V) and ethyl 5-benzyloxy-3-hydroxy-3-methylpentanoate (VI) were hydrolyzed with alkali to the corresponding hydroxyacids (VIII and IX), which formed crystalline N,N′-dibenzylethylenediammonium salts. The acetal derivative, N,N′-dibenzylethylenediammonium-bis-[3-hydroxy-3-methyl-5-(2-tetrahydropyranyloxy)-pentanoate], had 65% of the calculated activity in the L-4963 assay. This derivative is the only one of this series which showed activity in the L-4963 assay. The acetal VIII was converted to the dihydroxyacid VII by acid hydrolysis.

Benzoylation of the 5-hydroxyl group in 3,5-dihydroxy-3-methylpentanoic acid was accomplished in low yield with benzoyl chloride in aqueous alkali. The product, 5-benzoyloxy-3-hydroxy-3-methylpentanoate (X), was isolated as an oil and characterized as the N,N′-dibenzylethylenediammonium salt. This derivative was inactive in the L-4963 assay; alkaline hydrolysis regenerated full activity. Using other acylating reagents, little or none of the 5-acylated products could be isolated. These results indicate that self-acylation to the

lactone was the preferred reaction under the acylating conditions.

Acknowledgment.—The authors are indebted to Mr. R. N. Boos and associates for elemental analyses and to Dr. L. D. Wright and associates for *Lactobacillus*-4963 assays.

Experimental

4-Acetoxy-2-butanone.—To a mixture of 200 ml. of acetic anhydride and one drop of concentrated sulfuric acid was added 100 g. of 4-hydroxy-2-butanone[4] during a period of one hour. The temperature of the reaction mixture was maintained at 50° by occasional cooling. The reaction mixture was fractionated under reduced pressure and the fraction boiling at 92–95° (25 mm.) was collected yielding 119 g. (80%) of 4-acetoxy-2-butanone, $n^{25}D$ 1.4148.

Anal. Calcd. for $C_6H_{10}O_3$ (130.14): C, 55.37; H, 7.75. Found: C, 55.51; H, 7.79.

4-(2-Tetrahydropyranyloxy)-2-butanone.—Equimolar quantities (0.59 mole) of 4-hydroxy-2-butanone (51.5 g.) and dihydropyran (48.7 g.) were mixed and 4 drops of concentrated hydrochloric acid was added. The mixture was cooled to keep the temperature below 45° and then was allowed to stand overnight at room temperature.

The reaction mixture was dissolved in 500 ml. of ether and the solution was washed with dilute aqueous sodium bicarbonate and then with water. The ether solution was dried over anhydrous magnesium sulfate, filtered and concentrated *in vacuo* yielding 78 g. (78%) of product, $n^{26}D$ 1.4492.

The product was distilled *in vacuo* yielding 57 g. of 4-(2-tetrahydropyranyloxy)-2-butanone, b.p. 60–63° (100 μ), $n^{26}D$ 1.4488.

Anal. Calcd. for $C_9H_{16}O_3$ (172.22): C, 62.77; H, 9.37. Found: C, 62.85; H, 8.99.

4-Benzyloxy-2-butanone.—A solution of 90 g. (0.5 mole) of 4-benzyloxy-2-butanol[5] in 200 ml. of acetic acid was cooled to 10–15°. A solution of 33.3 g. (0.33 mole) of chromium trioxide in 30 ml. of water and 180 ml. of acetic acid was added to the stirred reaction mixture over a period of 2 hours. The reaction mixture was diluted with 1 liter of water and extracted with 3 portions of chloroform. The combined chloroform extracts were washed with water, sodium bicarbonate solution and water. The residue (77 g.) obtained after removal of the chloroform was distilled at reduced pressure yielding 54 g. (60%) of 4-benzyloxy-2-butanone, b.p. 88–91° (0.5 mm.), $n^{28}D$ 1.5040.

Anal. Calcd. for $C_{11}H_{14}O_2$ (178.22): C, 74.13; H, 7.92. Found: C, 74.51; H, 8.19.

Ethyl 5-Acetoxy-3-hydroxy-3-methylpentanoate.—A mixture of 124 g. (0.96 mole) of 4-acetoxy-2-butanone and 166 g. (1.0 mole) of ethyl bromoacetate in 450 ml. of dry ether was added slowly to 120 g. (1.84 moles) of clean, dry, granular zinc. The reaction began immediately and the addition of reagents was regulated so that a gentle refluxing of ether was maintained. The time required for the addition was about 1 hour. The mixture was stirred gently and warmed an additional 2 hours.

The solution was decanted onto an excess of crushed ice, and the mixture was acidified to congo red with concentrated hydrochloric acid. The layers were separated; and the ether phase was washed with sodium bicarbonate solution, then with saturated ammonium sulfate solution, and was dried over sodium sulfate. The aqueous mother liquor and washes were combined, reacidified to congo red and were extracted twice with chloroform. The chloroform extracts were washed with sodium bicarbonate solution and were dried over sodium sulfate. The chloroform and ether extracts were combined and concentrated. The residue was fractionated under reduced pressure and the fraction boiling at 86–87° (0.2 mm.) was collected. The yield of ethyl 5-acetoxy-2-hydroxy-3-methylpentanoate was 106 g. (51%), $n^{25}D$ 1.4458; d^{25}_{25} 1.090, $M^{25}D$ 53.34 (calcd. 53.22).

Anal. Calcd. for $C_{10}H_{18}O_5$ (218.24): C, 55.03; H, 8.31; sapn. equiv., 109. Found: C, 55.32; H, 8.03; sapn. equiv., 114.

Ethyl 3-Hydroxy-3-methyl-5-(2-tetrahydropyranyloxy)-pentanoate.—An equimolar mixture (0.32 mole) of 4-(2-tetrahydropyranyloxy)-2-butanone (55 g.) and ethyl bromoacetate (54 g.) in 200 ml. of ether was added slowly to a stirred mixture of 21 g. of granular zinc in 30 ml. of anhydrous ether. The rate of addition was such that the ether refluxed gently. After all the reactants had been added the mixture was warmed for 3 hours.

The reaction mixture was poured into 200 ml. of cold 2 *N* sulfuric acid. The ether phase was separated and the aqueous phase was extracted with three 150-ml. portions of chloroform. The chloroform and the ether extracts were washed with 10% aqueous sodium bicarbonate, saturated aqueous ammonium sulfate and dried over anhydrous magnesium sulfate. The combined organic phases were concentrated *in vacuo*.

The residue (55.3 g.) was distilled *in vacuo*. After two distillations 28 g. of ethyl 3-hydroxy-3-methyl-5-(2-tetrahydropyranyloxy)-pentanoate, b.p. 96–98° (100 μ), $n^{25}D$ 1.4562; d^{25}_{25} 1.054, $M^{25}D$ 67.13 (calcd. 66.50), was obtained.

Anal. Calcd. for $C_{13}H_{24}O_5$ (260.32): C, 59.98; H, 9.29. Found: C, 59.29; H, 8.78; sapn. equiv., 255.

N,N′-Dibenzylethylenediammonium Bis-(3,5-dihydroxy-3-methylpentanoate).—Ethyl 5-acetoxy-3-hydroxy-3-methylpentanoate (47.5 g.) was dissolved in 100 ml. of ethanol and 50 ml. of water was added. The solution was warmed to *ca.* 60° and 6 *N* sodium hydroxide was added slowly to the stirred solution keeping the *p*H just at the turning point of phenolphthalein indicator. A total of two equivalents of alkali was added. The solution was cooled to room temperature and two equivalents of 6 *N* hydrochloric acid was added. The aqueous solution was concentrated *in vacuo* and the final traces of water were removed *in vacuo*. The residue was extracted with two 200-ml. portions of chloroform and the insoluble salts were removed by filtration. The combined chloroform extracts were dried over anhydrous magnesium sulfate, filtered and concentrated *in vacuo* yielding a 28.7-g. residue.

The residue was dissolved in 100 ml. of water and a solution of 26 g. of N,N′-dibenzylethylenediamine in 100 ml. of methanol was added; the solution was kept at room temperature about 18 hours. The mixture was concentrated *in vacuo* to remove most of the methanol and the aqueous solution was extracted with 50 ml. of chloroform. The aqueous phase was concentrated *in vacuo* yielding 40 g. of salt.

The salt was dissolved in 125 ml. of hot methanol and 1 liter of ether was added to the warm solution. The product crystallized yielding 22 g. (38%) of N,N′-dibenzylethylenediammonium bis-(3,5-dihydroxy-3-methylpentanoate), m.p. 124–125°.

Anal. Calcd. for $C_{28}H_{44}N_2O_8$ (536.65): C, 62.64; H, 8.26; N, 5.22. Found: C, 62.77; H, 8.24; N, 5.10.

The mother liquors and the chloroform wash of the aqueous solution were combined and concentrated *in vacuo* yielding a 32-g. residue. The residue was taken up in 100 ml. of water and a solution of 25 g. of N,N′-dibenzylethylenediamine in 100 ml. of methanol was added. After standing overnight, the reaction mixture was worked up in the manner described above yielding 9.5 g. (16%) of N,N′-dibenzylethylenediammonium-bis-(3,5-dihydroxy-3-methylpentanoate), m.p. 125–126°.

β-Hydroxy-β-methyl-δ-valerolactone.—N,N′-Dibenzylethylenediammonium-bis-(3,5-dihydroxy-3-methylpentanoate) (44.4 g., 0.08 mole), was dissolved in *ca.* 100 ml. of water and 170 ml. of 1 *N* sodium hydroxide was added. The N,N′-dibenzylethylenediamine was removed by ether extraction. The aqueous solution of sodium salt was passed through a column of Amberlite resin, IR 120 (H^+), and the eluate was lyophilized. The residue was taken up in chloroform and the solution was dried over anhydrous magnesium sulfate, filtered and concentrated *in vacuo* yielding 20.3 g. of oil.

A sample of the oil was evaporatively distilled at *ca.* 90° (0.3 mm.)[6] to yield the pure lactone, β-hydroxy-β-methyl-δ-valerolactone, $\lambda_{max}^{CHCl_3}$ 2.95 and 5.79 μ.

Anal. Calcd. for $C_6H_{10}O_3$ (130.14): C, 55.37; H, 7.75. Found: C, 55.44; H, 7.56.

A portion of the distilled lactone (0.84 g.) was dissolved in a small amount of acetone, and ether was added to the point of incipient cloudiness. When the solution was cooled in a Dry Ice–acetone-bath, the lactone crystallized. The

product was collected by filtration and washed with ether yielding 0.73 g. of β-hydroxy-β-methyl-δ-valerolactone, m.p. 26–28°. Recrystallization of the product gave material melting at 27–28°. The product is hygroscopic.

Anal. Calcd. for $C_6H_{10}O_3$ (130.14): C, 55.37; H, 7.75. Found: C, 55.94; H, 7.75; sapn. equiv., 131.

N,N′-Dibenzylethylenediammonium-bis-(3-hydroxy-3-methyl-5-(2-tetrahydropyranyloxy)-pentanoate.—Ethyl 3-hydroxy-3-methyl-5-(2-tetrahydropyranyloxy)-pentanoate (6.1 g.) was dissolved in 30 ml. of ethanol and 10 ml. of 3 *N* sodium hydroxide was added. The mixture was warmed on a steam-cone for 30 minutes.

The mixture was cooled, acidified to *p*H 4 and extracted with ether. The ether solution was washed with water, dried over anhydrous magnesium sulfate, filtered and concentrated *in vacuo* yielding 2.7 g. of oil.

The oil was dissolved in *ca.* 100 ml. of ether and 2.7 g. of N,N′-dibenzylethylenediamine in 20 ml. of ether was added. The salt precipitated and was collected by filtration yielding 3.3 g. of N,N′-dibenzylethylenediammonium-bis-(3-hydroxy-3-methyl-5-(2-tetrahydropyranyloxy)-pentanoate), m.p. 137–139°.

Anal. Calcd. for $C_{38}H_{60}N_2O_{10}$ (704.88): C, 64.74; H, 8.58; N, 3.98. Found: C, 64.69; H, 8.29; N, 4.46, 4.71.

N,N′-Dibenzylethylenediammonium-bis-(3,5-dihydroxy-3-methylpentanoate) from N,N′-Dibenzylethylenediammonium-bis-[3-hydroxy-3-methyl-5-(2-tetrahydropyranyloxy)-pentanoate].—N,N′-Dibenzylethylenediammonium-bis-[3-hydroxy-3-methyl-5-(2-tetrahydropyranyloxy)-pentanoate] (3.3 g.) was suspended in 10 ml. of water and 12 ml. of 1 *N* hydrochloric acid was added and warmed on the steam-cone for 10 minutes. The mixture was cooled and 10.8 ml. of 1 *N* sodium hydroxide was added. The mixture was filtered and the filtrate was lyophilized.

The residue was leached with 25 ml. of hot methanol. The methanol solution was cooled and diluted with ether yielding 450 mg. of N,N′-dibenzylethylenediammonium-bis-(3,5-dihydroxy-3-methylpentanoate), m.p. 122–123°. A mixture of this sample with an authentic specimen of the salt melted at 122–123°.

N,N′-Dibenzylethylenediammonium-bis-(5-benzyloxy-3-hydroxy-3-methylpentanoate).—A mixture of 40 g. (0.23 mole) of 4-benzyloxy-2-butanone and 37.5 g. (0.23 mole) of ethyl bromoacetate in 100 ml. of ether was added dropwise to 20 g. (0.32 mole) of clean, dry granular zinc. The reaction mixture was stirred at the reflux temperature for about two hours and was then added to a mixture of ice and 30 ml. of concentrated hydrochloric acid. The ether layer was separated and the aqueous phase was extracted with ether. The combined ether layers were washed with saturated sodium chloride solution, sodium bicarbonate solution and, again, with sodium chloride solution. The ether layer was concentrated yielding 40 g. of residual oil. A 30-g. portion of the product was distilled *in vacuo* to give *ca.* 15 g. of material boiling at <70° (0.4 mm.). The residue (14.7 g.) from this distillation was hydrolyzed on the steam-cone with 22 ml. of 1 *N* sodium hydroxide and 50 ml. of methanol. The solution was diluted with 50 ml. of water and concentrated at reduced pressure to a volume of *ca.* 50 ml. The solution was extracted with ether and the ether phase was discarded. The aqueous phase was acidified with concentrated hydrochloric acid and extracted with ether. The ether extract was washed with saturated sodium chloride solution, dried and concentrated, yielding 2.2 g. of 5-benzyloxy-3-hydroxy-3-methylpentanoic acid.

A 1.93-g. portion of the acid was dissolved in 5 ml. of methanol and treated with 0.97 g. of N,N′-dibenzylethylenediamine. When *ca.* 75 ml. of ether was added, 1.5 g. of the salt, m.p. 123–127°, crystallized. A 400-mg. portion of the salt was recrystallized from chloroform–ether, chloroform–petroleum ether and finally from methanol–ether yielding 200 mg. of N,N′-dibenzylethylenediammonium-bis-(5-benzyloxy-3-hydroxy-3-methylpentanoate), m.p. 131–133°.

Anal. Calcd. for $C_{42}H_{56}N_2O_8$ (716.89): C, 70.36; H, 7.87; N, 3.91. Found: C, 70.40; H, 7.60; N, 4.14.

5-Benzyloxy-3-hydroxy-3-methylpentanoic Acid.—Four hundred and eighty milligrams of N,N′-dibenzylethylenediammonium-bis-(5-benzyloxy-3-hydroxy-3-methylpentanoate) was suspended in 25 ml. of water and acidified with 2.5 *N* hydrochloric acid. The free acid was extracted into ether and then extracted into aqueous potassium bicarbonate. The bicarbonate solution was acidified and the product was extracted into ether. The ether extract was washed with water, dried and concentrated yielding 169 mg. of 5-benzyloxy-3-hydroxy-3-methylpentanoic acid, $n^{25}D$ 1.5130, neut. equiv. 243 (calcd. 238).

N,N′-Dibenzylethylenediammonium-bis-(5-benzoyloxy-3-hydroxy-3-methylpentanoate).—Ten grams of N,N′-dibenzylethylenediammonium-bis-(3,5-dihydroxy-3-methylpentanoate) was dissolved in 37 ml. of 1 *N* sodium hydroxide. The solution was extracted with ether and the ether extract was washed with 15 ml. of water. The combined aqueous phases were stirred and cooled while 6 g. of benzoyl chloride was added dropwise. Sodium hydroxide (1 *N*) was added dropwise during the addition of benzoyl chloride to keep the *p*H at *ca.* 9. After being stirred for one hour, the reaction mixture was washed with chloroform. The aqueous phase was acidified to *p*H 3 with hydrochloric acid and extracted with two 75-ml. portions of chloroform. The combined chloroform extracts were washed with water, dried over anhydrous magnesium sulfate, filtered and concentrated *in vacuo*.

The residue was leached with hot petroleum ether and then dissolved in 8 ml. of methanol. N,N′-Dibenzylethylenediamine (2.16 g.) was added, and the solution was diluted with *ca.* 80 ml. of ether. Two grams of N,N′-dibenzylethylenediammonium-bis-(5-benzoyloxy-3-hydroxy-3-methylpentanoate), m.p. 142–143°, crystallized from the solution.

Anal. Calcd. for $C_{42}H_{52}N_2O_{10}$ (744.86): C, 67.70; H, 7.04; N, 3.76. Found: C, 68.42, 68.31; H, 6.76, 6.93; N, 3.71.

Light-catalyzed Organic Reactions. VI.[1] The Isomerization of Some Dienones[2,3]

BY G. BÜCHI AND N. C. YANG

RECEIVED NOVEMBER 19, 1956

The isomerization of four dienones has been studied. β-Ionone yielded pyran X and spiroketone IX containing a cyclopropane ring. Irradiation of both pseudoionone and 6-methyl-3,5-heptadiene-2-one led to polymers. *trans–trans*-Crotonylideneacetone was converted to the $\Delta^{3,4}$-*cis* isomer. The changes observed are compared with the isomerization of tachysterol (III) and possible interpretations of the results are discussed.

The conversion of ergosterol (I) to vitamin D_2 (IV) is unquestionably one of the most fascinating photochemical reactions known. The brilliant researches of Windaus and his School have led to the isolation and structure elucidation of lumisterol

(V) and tachysterol (III), both of which are convertible to vitamin D_2 by further irradiation.[4] The isolation of an additional compound, praecalciferol,[5] present in the mixture obtained on irradiation of ergosterol, has shed some new light on the mechanism of vitamin formation. Velluz recently revealed experimental findings from which he deduced structure II for praecalciferol,[6] which would thus be the *cis* isomer of tachysterol (III). Of even greater interest is the ready conversion of praecalciferol (II) to vitamin D_2 (IV) by moderate heating in neutral solvents in the *absence* of light. The "enesyntheses" of Alder were quoted as analogies in an attempt to rationalize this remarkable change.

It thus appears that the first product formed in the photoisomerization is not V but II which in a subsequent dark reaction is converted to IV. The presence of both I and V in the mixture produced on irradiation of II points strongly to the reversibility of the initial photoreaction. The appearance also of III is easily rationalized by assuming reversible *cis* ⇄ *trans* photoisomerization of II and III, for which there is ample precedent in similar systems.

Similarities in the steric as well as electronic structures of tachysterol (III) and *trans*-β-ionone (VI) prompted us to investigate the photochemical isomerization of VI, as a potential synthetic route to γ-ionone[7] (VIII), which in turn should be convertible to a number of compounds with ambergris odor. In this paper we describe the photochemical isomerization of β-ionone and some related dienones.

A solution of β-ionone (VI) in ethanol was irradiated with a low intensity mercury arc and the products separated by fractional distillation. Besides VI (12–22%) and polymers (30–50%), two new compounds, X (22–32%) and IX (2–4%), both isomeric with the starting material were isolated. In analogy to the photoisomerization of *trans*-α-ionone to *cis*-α-ionone[8] and the isomerization of III to II, we had anticipated *cis*-β-ionone (VII) in the low boiling fraction of the reaction product. This notion however was quickly dismissed after an inspection of both the ultraviolet (λ_{max} 286 mμ, log ε 3.68) and infrared spectra (*cf.* Fig. 1) of this fraction (X). The data indicated the presence of an enol ether rather than a ketone. Verification was obtained by catalytic reduction of X to a tetrahydro compound (XI) which was identical with a sample obtained by an unambiguous route.[9] Although the facts presented above show

(4) A recent review of the subject is presented by H. H. Inhoffen and K. Brückner in L. Zechmeister, "Progress in the Chemistry of Organic Natural Products," Vol. XI, Springer, Wien, 1954.

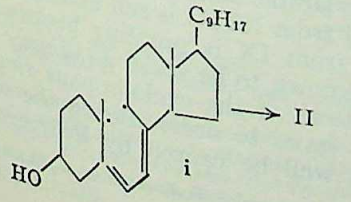
(6) L. Velluz, G. Amiard and B. Goffinet, *Bull. soc. chim.*, 1341 (1955). The stereochemical argument presented rests entirely on rather subtle differences in the ultraviolet absorption spectra of II and III. However, it seems reasonable that a transition state (approximately i) should collapse to the *cis*-(II), rather than to the *trans* isomer III.



i

(7) To our knowledge pure γ-ionone has not been described in the literature; however, a mixture of isomeric ionones containing 15% of VIII has been obtained by condensation of ii with acetone (B. Willhalm, Ph.D. thesis, ETH Zurich, 1954).

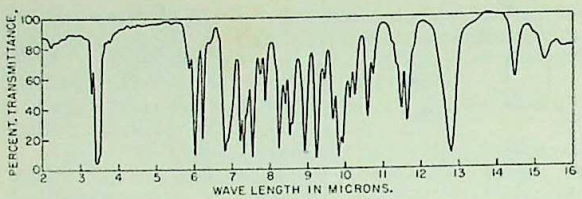

Fig. 1.

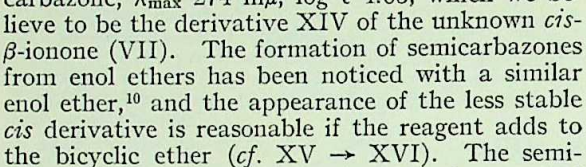
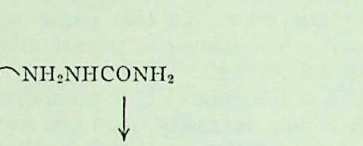
that X does not contain a carbonyl group, prolonged treatment with semicarbazide acetate in methanolic solution yielded a very unstable semicarbazone, λ_{max} 274 mμ, log ϵ 4.03, which we believe to be the derivative XIV of the unknown *cis*-β-ionone (VII). The formation of semicarbazones from enol ethers has been noticed with a similar enol ether,[10] and the appearance of the less stable *cis* derivative is reasonable if the reagent adds to the bicyclic ether (*cf.* XV → XVI). The semicarbazone of the *trans*-ketone would be the expected product of addition to the monocyclic ketone.[11]



Semicarbazone XIV was smoothly hydrolyzed by steam distillation in the presence of phthalic acid to the pyran X rather than VII. This finding suggests that the preferred elimination of semicarbazide in the intermediate XVI involves cyclization rather than direct 1,2-elimination (XVII arrows).



Isomerization of X with iodine, a reagent known to promote *cis* → *trans* isomerization in polyenes,[12] gave *trans*-β-ionone (VI) in 60% yield.

A second product formed in the photoisomerization of VI had λ_{max} 284; 214 mμ (log ϵ 2.1; 3.44). The ultraviolet absorption spectrum observed is similar to the one of 1-acetyl-2,2-dimethyl-3-(2-methyl-1-propenyl)-cyclopropane.[13] The infrared spectrum (Fig. 2) suggested the presence of CH_3CO- and $CH_2{=}C(R)_2$, and a positive iodoform test as well as the formation of formaldehyde on ozonization of IX confirmed this postulate. Ionene (XIII) was formed readily upon acid-catalyzed isomeriza-

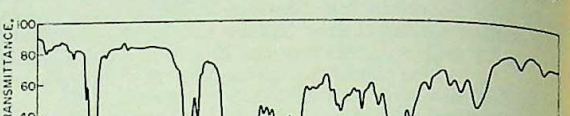


Fig. 2.

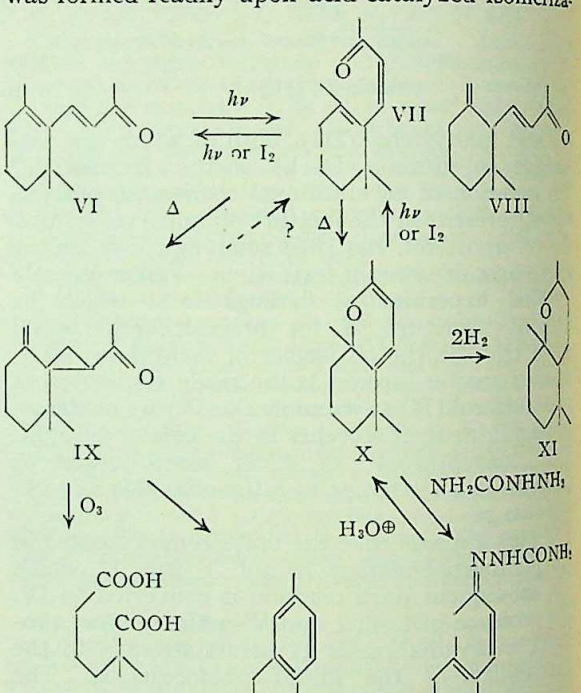

tion of IX, and this finding is interpretable with structures IX and XVIII, both of which contain the unchanged carbon skeleton of VI.

Some insight into the distribution of the functional groups in IX was gained through ozonization experiments which gave formaldehyde (12%) and 2,2-dimethyladipic acid (XII) (40%). The formation of XII from XVIII is self explanatory, but its formation from IX is puzzling because cyclopropanes are known to be stable to ozone. However, the breakdown of the cyclopropane ring does not necessarily have to occur during the ozonization and might well be caused by hydrogen peroxide

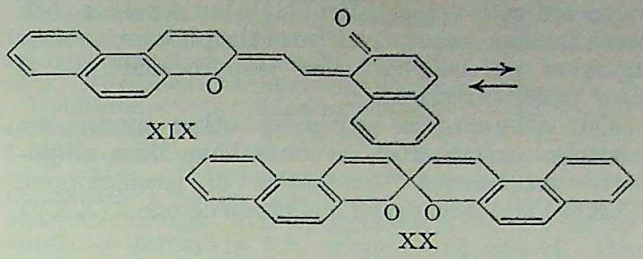
which was used to complete this oxidation.[14] Titration of IX with perbenzoic acid established the presence of only one double bond, and the photoisomer should therefore contain two carbocyclic rings. In sharp contrast to this result catalytic reduction of IX was only complete after the uptake of three moles of hydrogen. The alcohol thus formed was reoxidized with chromium trioxide and the ketone characterized by its semicarbazone. The derivative could not be obtained pure, but no melting point depression was observed on admixture of *cis*-tetrahydroionone semicarbazone.

We were thus forced to assume that our photoisomer contains either (a) two olefinic bonds, one of which is not oxidizable by perbenzoic acid, or (b) a vinylcyclopropane system reducible to the tetrahydro stage. Structure XVIII was excluded through consideration of the following facts: (i) basic conditions sufficiently drastic to cause isomerization of α- to β-ionone[15] did not bring about isomerization of the ketone to VI, and (ii) the ultraviolet absorption observed is scarcely attributable to the conjugated diene chromophore of XVIII because the less highly substituted 1,2-dimethylenecyclohexane has λ_{max} 220 mμ.[16] We therefore favor formula IX with which all of the described facts including the reduction[17] can be rationalized satisfactorily.

Discussion of Results

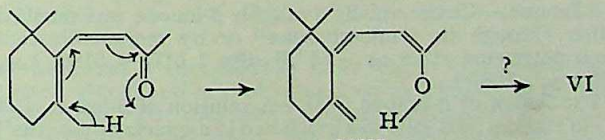
The first step in the conversion of β-ionone (VI) to IX and X is undoubtedly the reversible photoisomerization to *cis*-β-ionone (VII), a reaction for which analogies have been quoted already. We assume that the two products actually isolated are derived from the highly reactive *cis*-ketone VII by two distinct dark reactions (a) and (b). Thus (a), whenever the six atoms present in the chromophore of VII have approached planarity, cyclization can occur to give the bicyclic pyran X. As in the reversible dienone $\rightleftarrows$ pyran interconversion observed with thermochromic spiropyrans (*e.g.*, XIX $\rightleftarrows$ XX),[18] the equilibrium, at room temperature, is very much on the side of the pyran X. This seems reasonable if one compares the resonance energies of the planar pyran X with that of the *cis*-dienone VII which, in the ground state at least, is forced into a non-planar conformation by steric interference of methyl groups.



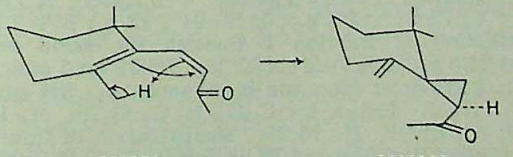
Conversely, irradiation of X in alcoholic solution produces a mixture of VI, IX and X. A considerable amount of energy (ultraviolet light) is required to convert the pyran X back to the *cis*-ketone VII from which VI is formed by photoisomerization and IX probably by a dark reaction (see below). We have no direct evidence that the *cis*-ketone VII → pyran X conversion is indeed a thermal rather than a photochemical reaction, but since the appearance of our preliminary note,[3] Schinz[11] has reported the formation of pyrans by catalytic reduction of two acetylenic ketones in the absence of light. These findings thus support our postulate.

The formation of the *cis*-ketone VII from X is therefore analogous to the photosynthesis of praecalciferol (II) from ergosterol (I); the reverse reaction (X from VII), however, seems to occur very much more readily than the formation of ergosterol (I) and lumisterol (V) from praecalciferol (II).

The question (b) whether the *cis*-ketone VII undergoes an "enesynthesis" analogous to the praecalciferol (II) → vitamin D (IV) change cannot be answered because the product (XXI) from such a reaction might well convert to β-ionone (VI) rather than γ-ionone (VIII).



The unstable *cis*-ketone VII apparently can stabilize itself by another route (b) which results in the formation of the spiroketone IX.



The atomic model of the *cis*-ketone XXII shows that in the least strained conformation in which the side chain is approximately perpendicular to the plane of the cyclohexene ring, a methyl hydrogen is close in space to the first carbon atom of the side chain, and it is conceivable that bond formation between these atoms could occur (XXII arrows). Such a concerted reaction would lead to a definite configuration of IX shown in XXIII. The ready formation of ionene (XIII) (see above) is well in accord with this formulation because only in this diastereomer (XXIII) are the carbonyl carbon

(14) The oxidation of sabinene (vi) with hydrogen peroxide in acetic acid has been investigated by G. G. Henderson and A. Robertson [*J. Chem. Soc.*, 1849 (1923); *ibid.*, 2761 (1926)], who have found that two isomeric compounds $C_{10}H_{18}O_3$ were formed. The absence of a cyclopropane ring in the products seems certain, but structure vii advanced by the authors is by no means established.

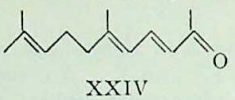
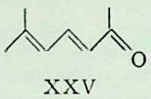
and the terminal methylene group in close spatial proximity. An analogous reaction has not been observed with praecalciferol (II), but whether such a mechanism is operative also in the photoisomerizations of pyrocalciferol and isopyrocalciferol[19] is now under investigation.

Our attempts to synthesize other pyrans by photoisomerization of dienones have been singularly unsuccessful. Irradiation of pseudoionone (XXIV) and 6-methyl-3,5-heptadiene-one-2 (XXV)



XXIV



XXV

has led to polymeric materials rather than the desired pyrans. We have been unable to determine whether the polymers have originated from the pyrans or the ketones. Photoisomerization of *trans–trans*-crotonylideneacetone (XXVI), λ_{max} 272 mμ, log ϵ 4.30, on the other hand has led to a new stereoisomer (XXVII), λ_{max} 279 mμ, log ϵ 3.99. We prefer the Δ-*cis*-5,6 structure for this isomer because (a) the ultraviolet absorption at longer wave lengths indicates that the newly introduced *cis* double bond is at the end of the chromophore[12] and (b) the $\Delta^{3,4}$-*cis* isomer would be expected to isomerize to the pyran.[11] The aliphatic nature of XXVII was established by hydrogenation to the known 2-heptanone.

Acknowledgment.—The authors wish to acknowledge generous financial assistance from Eli Lilly and Co.

Experimental[20]

β-Ionone.—Commercially available β-ionone was purified either through its semicarbazone[21] or by recrystallization from petroleum ether at −75°,[22] $n^{25}D$ 1.5178–1.5180, λ_{max} 296 mμ, ϵ 10800.

Irradiation of β-Ionone (VI).—A solution of β-ionone (24 g.) in ethanol (600 ml.) was irradiated in a quartz apparatus[23] for 48 hr. at 35–40°. The ethanol was then removed by evaporation under reduced pressure and the residue distilled through a Hickman flask (b.p. 35–60° at 0.05 mm.). The distillates from 5 irradiations (81 g.) were combined and fractionated through a 40-inch spinning band column at 1 mm.: fraction 1, 68–72°, 31.5 g., $n^{25}D$ 1.4980; 2, 71–75°, 2.4 g.; 3, 75–85°, 4.8 g.; 4, 85–94°, 18 g., $n^{25}D$ 1.5060. Redistillation of fraction 1 through the same column yielded 24.5 g. (30% yield) of X, b.p. 70–71° at 1 mm., $n^{25}D$ 1.4992; ultraviolet spectrum in ethanol, λ_{max} 286 mμ, log ϵ 3.86. *Anal.* Calcd. for $C_{13}H_{20}O$: C, 81.20; H, 10.48. Found: C, 81.01; H, 10.25. Redistillation of fraction 3 (17.3 g. combined from six 72-hr. irradiations) through a 1-ft. spinning-band column gave 8.4 g. of IX, b.p. 81–82° at 1 mm., $n^{25}D$ 1.4860, λ_{max} 284 mμ, log ϵ 2.10; 214 mμ, log ϵ 3.44. *Anal.* Calcd. for $C_{13}H_{20}O$: C, 81.20; H, 10.48. Found: C, 81.06; H, 10.51.

The ketone IX was further characterized by a semicarbazone, m.p. 170–171°, recrystallized from ethanol. *Anal.* Calcd. for $C_{14}H_{23}ON_3$: C, 67.43; H, 9.30; N, 16.85. Found: C, 67.29; H, 9.23; N, 16.75.

Treatment with phenylsemicarbazide in methanol gave a derivative, m.p. 144–145°, recrystallized from ethanol. *Anal.* Calcd. for $C_{20}H_{27}ON_3$: C, 73.81; H, 8.36; N, 12.91. Found: C, 73.62; H, 8.52; N, 13.23.

Irradiation of X.—A solution of X (22 g.) in ethanol (650 ml.) was irradiated for 48 hr. at 35° and the organic material isolated as described above. The products (14 g.) were separated by fractionation through a 1-ft. spinning-band column at 1 mm.: fraction 1, b.p. 69–73°, 4.6 g.; 2, 73–75°, 1.2 g.; 3, 75–85°, 3.5 g.; 4, 85–92°, 4.4 g., $n^{25}D$ 1.5108. Fraction 1 was identified as unchanged X by its characteristic infrared spectrum. A semicarbazone prepared from 3 was identical with the corresponding derivative of the bicyclic ketone IX. Fraction 4 consisted mainly of β-ionone (VI) as indicated by its infrared spectrum and the formation of β-ionone semicarbazone, m.p. 147–148°.

Isomerization of X.—To a mixture of X (2 g.) in 40 ml. of benzene was added iodine (100 mg.) and the resulting solution kept at room temperature for 2 hr. After washing with aqueous sodium thiosulfate and evaporation of the solvent, an oil remained which was distilled, b.p. 63–66° (0.02 mm.), 1.2 g., $n^{25}D$ 1.5134, and identified as β-ionone by its infrared spectrum as well as by semicarbazone comparison.

Hydrogenation of X to XI.—A solution of X (1.92 g.) in glacial acetic acid (5 ml.) was stirred with Adams platinum catalyst (0.4 g.) under hydrogen at room temperature. The uptake of hydrogen ceased after 1.96 mole had been absorbed. After removal of the catalyst by filtration, the filtrate was diluted with water (40 ml.) and the product isolated by extraction with petroleum ether. The dried solution was passed over 50 g. of neutral alumina. Removal of the solvent from the eluate yielded a product which after distillation had b.p. 45–48° (0.05 mm.), 1.56 g., $n^{25}D$ 1.4714. *Anal.* Calcd. for $C_{13}H_{24}O$: C, 79.53; H, 12.32. Found: C, 79.82; H, 12.06. The infrared spectrum of the product was indistinguishable from the spectrum of authentic epoxy-3,2[3]-tetrahydroionane (XI).

***cis*-β-Ionone Semicarbazone (XIV).**—The pyran X (4.0 g.) was allowed to react with excess semicarbazide–acetate in methanol solution in the absence of oxygen and sunlight. A crystalline precipitate formed slowly and was collected on a filter after 24 hr. After two rapid recrystallizations from aqueous methanol, the compound had m.p. 184–185° (vacuum capillary); λ_{max} 274 mμ, log ϵ 4.03. *Anal.* Calcd. for $C_{14}H_{23}ON_3$: C, 67.43; H, 9.30. Found: C, 67.38; H, 9.28. The infrared spectrum showed that a true semicarbazone was present (5.9, 6.25 μ).

Hydrolysis of *cis*-β-Ionone Semicarbazone (XIV).—The derivative (3.6 g.) was mixed with phthalic anhydride (3.6 g.) by grinding in a mortar and hydrolyzed by steam distillation. The organic material was extracted into petroleum ether and washed successively with aqueous sodium bicarbonate and water, concentrated to a liquid which on distillation gave the pyran X (0.7 g.), identified by b.p., $n^{25}D$ and infrared spectrum.

Air Oxidation of X.—On prolonged standing in the presence of air, X is converted to a crystalline colorless material which after recrystallization from benzene–petroleum ether had m.p. 130° dec. *Anal.* Calcd. for $C_{13}H_{22}O_3$: C, 69.00; H, 9.80. Found: C, 68.96, 69.01, 69.34; H, 9.46, 9.63, 9.55. No absorption in the ultraviolet region of the spectrum; principal infrared bands in KBr: 2.88, 3.05, 3.45, 7.20, 7.35, 8.2, 9.08, 9.25, 9.45, 9.64, 10.05, 10.55 and 11.65 μ.

Acid Isomerization of IX to XIII.—A solution of IX (240 mg.) in aqueous methanol (80%) containing sulfuric acid (400 mg.) was allowed to reflux for 90 min. The mixture was then poured into water (10 ml.) and extracted with ethyl ether. After washing, drying and evaporation, an oil was isolated which was purified successively by chromatography over alumina and vacuum distillation, b.p. 48–50° (0.05 mm.), $n^{25}D$ 1.5205 (*Anal.* Calcd. for $C_{13}H_{18}$: C, 89.59; H, 10.41. Found: C, 89.85; H, 10.10) and shown to be identical by b.p., $n^{25}D$ and infrared spectrum with ionene (XIII).

Oxidation of IX with Perbenzoic Acid.—The bicyclic ketone IX (0.256 g.) was added to a solution of perbenzoic

(19) K. Dimroth, *Chem. Ber.*, **70**, 1631 (1937).

(20) Melting points and boiling points are uncorrected. Analyses by Mmes. N. Alvord and G. Kula and Dr. S. M. Nagy, M.I.T. Microanalytical Department. The infrared spectra were determined with a Baird double beam recording spectrophotometer. Ultraviolet spectra were measured with a Cary recording spectrophotometer.

Digitized by Arya Samaj Foundation Chennai and eGangotri

acid in chloroform (5 ml., 1.17 *N*) and the mixture allowed to stand at 0–5°. Aliquot parts were removed for titration after 6, 8 and 24 hr. The following consumption of perbenzoic acid was observed: 1.02, 1.03 and 1.02 moles.

Hydrogenation of IX.—One gram of IX was hydrogenated in glacial acetic acid (5 ml.) over Adams platinum catalyst (from 0.5 g. of PtO_2) at atmospheric pressure. Hydrogen (368 ml., 3.0 mole equiv.) was absorbed within 12 hr. In two additional reductions, carried out under identical conditions, 2.86 and 2.95 moles of hydrogen was absorbed. Reoxidation of the secondary alcohol(s) thus formed with chromium trioxide in acetic acid solution gave a ketone which was characterized by its semicarbazone, m.p. 173–174°. Repeated recrystallization did not raise the melting point. No depression was observed on admixture of pure *cis*-tetrahydroionone semicarbazone, m.p. 179–180°.

Oxidation of IX with Ozone.—A large excess of ozone (2% in oxygen) was passed through a solution of IX (1 g.) in carbon tetrachloride at 0–5°. The escaping gases were passed through an absorption tube containing water (10 ml.) and after completion of the oxidation, dimedone (1.6 g.) in ethanol (20 ml.) was added to this water. The precipitate which had formed was filtered and on recrystallization yielded the dimedone derivative of formaldehyde, 180 mg., 12%, m.p. 188–190°. The actual reaction mixture was concentrated under reduced pressure and the remaining oil warmed to 85° for 4 hr. after a solution of aqueous hydrogen peroxide (10%) had been added. Aqueous sodium hydroxide was added and the small amount of neutral material extracted with ether. The water layer was then acidified with concd. hydrochloric acid and extracted exhaustively with ether. Purification of the residue obtained after evaporation of the solvent was achieved by chromatography on silica gel (Davison mesh size 28–200, 30 g.). A mixture of chloroform–ethyl acetate (7:3) was used to elute the material which was further purified by recrystallization from acetone–water. The acid (350 mg., 38% yield) had m.p. 86–87° (*Anal.* Calcd. for $C_8H_{14}O_4$: C, 55.16; H, 8.10. Found: C, 55.28; H, 8.00), and was found to be identical by mixture melting point and infrared spectrum with authentic 2,2-dimethyladipic acid (XII).

Attempted Base-catalyzed Isomerization of IX.—A solution of IX in carefully dried ethanol containing 10% sodium ethoxide was allowed to stand for 24 hr. at room temperature. No change in the ultraviolet spectrum was observed.[24]

Irradiation of Crotonylideneacetone (XXVI).—A solution of crotonylideneacetone,[25] 20 g., b.p. 77–78° (24 mm.), $n^{25}D$ 1.5200, λ_{max} 272 mμ, log ε 4.30, was irradiated in ethanol (600 ml.) for 24 hr. The solvent was removed carefully by distillation through a Fenske column and the residue fractionated in a Hickman flask. The distillate was further purified by distillation through a 1-ft. spinning-band column. The first fraction, b.p. 62–77° (24 mm.), yielded 2.3 g. of a light yellow liquid which on redistillation through a semimicro fractionating column gave 700 mg. of XXVII, b.p. 62–64° (21 mm.), $n^{25}D$ 1.5040, λ_{max} 279 mμ, log ε 3.99; principal infrared bands: 3.48, 6.0, 6.15, 12.0, 13.5 and 14.6 μ. *Anal.* Calcd. for $C_7H_{10}O$: C, 76.32; H, 9.15. Found: C, 75.78; H, 9.15. The semicarbazone, m.p. 118–140° dec., decomposed on attempted recrystallization from ethanol.

Hydrogenation of XXVII to 2-Heptanone.—A solution of XXVII (100 mg.) in absolute ethanol (5 ml.) was stirred with 2% palladium-on-calcium carbonate catalyst (100 mg.) under hydrogen at room temperature. The calculated amount of two mole equivs. of hydrogen (100%) was rapidly absorbed. After removal of the catalyst by filtration 2,4-dinitrophenylhydrazine reagent was added. The derivative (160 mg.) had m.p. 73–74° after two recrystallizations from methanol and was identical by mixture melting point determination with an authentic derivative of 2-heptanone.

(24) We would like to thank Dr. Hans Rennhard for performing this experiment.

Perfluoroalkyl-substituted Dicarboxylic Acids and Derivatives[1,2]

BY E. T. MCBEE, C. W. ROBERTS[3] AND GORDON WILSON, JR.

RECEIVED JULY 2, 1956

The condensation of ethyl malonate with $C_3F_7CH{=}CHCO_2Et$ produced a tricarboxylic ester which was hydrolyzed and decarboxylated to $C_3F_7CH(CH_2CO_2H)_2$. The corresponding ester, glycol and acid chloride were synthesized from the acid. By the same synthetic route $C_7F_{15}CH(CH_2COCl)_2$ also was prepared. The addition of hydrogen sulfide to $C_3F_7CH{=}CHCO_2Et$ produced mainly $S[CH(C_3F_7)CH_2CO_2Et]_2$ with some $C_3F_7CH(SH)CH_2CO_2Et$. The acid, glycol and acid chloride of the sulfide were prepared.

Discussion

Recent interest in elastomers which are not affected by extremes in temperature and by organic solvents has led to investigations of fluorine-containing polyesters. This paper reports several dicarboxylic acids and derivatives containing perfluoroalkyl side chains which were prepared from 3-perfluoroalkylpropenoates and which are convertible to polymers by appropriate reactions.

In earlier investigations, 3-perfluoroalkylpropenoates were prepared by reaction of a perfluoroaldehyde with ethyl bromoacetate in the presence of zinc dust followed by dehydration of the resulting β-hydroxy ester.[4] Higher and more consistent over-all yields of ethyl 4,4,5,5,6,6,6-heptafluoro-2-hexenoate and ethyl 4,4,5,5,6,6,7,7,8,8,9,9,10,10,10-pentadecafluoro-2-decenoate have now been obtained by an alternate procedure in which the perfluoroaldehyde is first condensed with malonic acid in pyridine solution to give a β-hydroxy acid. This Knoevenagel reaction is somewhat surprising since perfluoroaldehydes are readily polymerized by organic bases and, in fact, when the pyridine solution of malonic acid is added to the aldehyde, polymerization occurs rapidly with the evolution of heat. However, as the reaction mixture is heated the polymer slowly dissolves and the condensation proceeds. The stability toward dehydration of β-hydroxy-β-perfluoroalkyl esters[4] and

ketones[5] compared to the non-fluorinated analogs is well known. Thus, although the Knoevenagel reaction usually leads to α,β-unsaturated acids, with perfluoroaldehydes the isolation of the stable β-hydroxy acids is not unusual. The β-hydroxy acids were converted to the α,β-unsaturated esters by esterification followed by dehydration with phosphorus pentoxide.

Several ionic additions to 3-perfluoroalkylpropenoates have been reported[6,7] and in all cases the products were those expected by analogy with similar reactions of non-fluorinated compounds. In the present study, the Michael condensation of ethyl 4,4,5,5,6,6,6-heptafluoro-2-hexenoate with diethyl malonate gave diethyl 2-carbethoxy-3-perfluoropropylpentanedioate. This tricarboxylic ester was hydrolyzed and decarboxylated to 3-perfluoropropylpentanedioic acid. The reaction of phosphorus pentachloride with the acid produced the acid chloride. When the acid was treated with thionyl chloride, however, 3-perfluoropropylpentanedioic anhydride resulted. This is not unusual since 3-phenylpentanedioic anhydride is formed from the corresponding acid by the action of not only thionyl chloride but also phosphorus chlorides.[8] Reduction of the acid, or esterification and then reduction, gave the glycol, 3-perfluoropropyl-1,5-pentanediol. When the glycol was heated with a trace of mineral acid, dehydration occurred and 3-perfluoropropyltetrahydropyran resulted.

3-Perfluoroheptylpentanedioyl chloride was prepared by the same synthetic route. In this case, the tricarboxylic ester resulting from the Michael condensation was not isolated in a pure state but was hydrolyzed and decarboxylated directly to 3-perfluoroheptylpentanedioic acid.

The 3-perfluoroalkyl acids, esters and glycols do not undergo degradation in the presence of acids or bases. Furthermore, they are stable at temperatures as high as 200°. The anhydride and acid chlorides are rapidly hydrolyzed on exposure to moist air. The physical properties are those expected by comparison with the non-fluorinated analogs.[9]

The incorporation of sulfur into the central chain of monomers which contain perfluoroalkyl groups also has been accomplished. Addition of hydrogen sulfide to ethyl 3-perfluoroalkylpropenoates was performed by the method of Barkenbus and coworkers.[10] In the presence of BTA hydroxide[11] and piperidine, ethyl 4,4,5,5,6,6,6-heptafluoro-2-hexenoate and hydrogen sulfide gave primarily diethyl 3,5-bis-(perfluoropropyl)-4-thiaheptanedioate. A by-product of the reaction was ethyl 3-mercapto-4,4,5,5,6,6,6-heptafluorohexanoate. In a similar manner, diethyl 3,5-bis-(perfluoromethyl)-4-thiaheptanedioate was prepared. Acidic hydrolysis of the former ester gave two forms of the dicarboxylic acid. Since there are two identical asymmetric centers, one form is presumed to be the *meso*-acid and the other a racemic modification. 3,5-Bis-(perfluoropropyl)-4-thiaheptanedioyl chloride was prepared from the acid by reaction with thionyl chloride. Reduction of the bis-(perfluoropropyl)-thiaheptanedioate with lithium aluminum hydride gave the glycol, 3,5-bis-(perfluoropropyl)-4-thia-1,7-heptanediol.

Although the sulfide esters are prepared in the presence of a strong base, they are not stable to aqueous base. Even in 5% aqueous sodium hydroxide at room temperature, they decompose to dark red tars in a matter of a few minutes. Traces of impurities appear to cause disproportionation during fractionation but once pure the esters and acid chloride appear to be stable at distillation temperatures. Several attempts at mild oxidation of diethyl 3,5-bis-(perfluoropropyl)-4-thiaheptanedioate were made. In all cases there was apparent cleavage of a carbon–sulfur bond and oxidation to an extremely hygroscopic solid, probably the sulfonic acid.

Experimental[12]

3-Hydroxy-3-perfluoroalkylpropanoic Acids.—A cold solution of 193 g. (1.85 moles) of malonic acid in 1 l. of pyridine was added to 341 g. (1.72 moles) of perfluorobutanal[13] in 400 ml. of dry toluene. The resulting slush of polymerized aldehyde was heated slowly to boiling and refluxed until the evolution of carbon dioxide ceased. The cooled reaction mixture was poured over 4 kg. of ice and 500 ml. of concentrated sulfuric acid. The product was taken up in ether, dried and the ether removed by distillation. Recrystallization of the residue from benzene gave 389 g. (88%) of 3-hydroxy-4,4,5,5,6,6,6-heptafluorohexanoic acid, m.p. 78–80°.[4]

By the same procedure, 159 g. (0.40 mole) of perfluorooctanal[13] and 41.6 g. (0.40 mole) of malonic acid gave 128 g. (68%) of 3-hydroxy-4,4,5,5,6,6,7,7,8,8,9,9,10,10,10-pentadecafluorodecanoic acid, m.p. 123–123.5°.

Anal. Calcd. for $C_{10}H_5F_{15}O_3$: C, 26.21; H, 1.10. Found: C, 25.92; H, 1.13.

Ethyl 3-Hydroxy-3-perfluoroalkylpropanoates.—3-Hydroxy-4,4,5,5,6,6,6-heptafluorohexanoic acid (550 g., 2.13 moles) was dissolved in a large excess (2278 g., 49.1 moles) of absolute ethanol, and hydrogen chloride was bubbled through the solution until 22 g. (0.6 mole) had been absorbed. After standing at room temperature for a day, the solution was refluxed 4 hr. and then distilled. The yield of ethyl 3-hydroxy-4,4,5,5,6,6,6-heptafluorohexanoate was 518 g. (85%), b.p. 92–93° (15 mm.), n^{20}D 1.3538.[4]

In a similar manner, 90 g. (0.196 mole) of 3-hydroxy-4,4,5,5,6,6,7,7,8,8,9,9,10,10,10-pentadecafluorodecanoic acid, 619 g. (13.4 moles) of absolute ethanol and 8 g. (0.22 mole) of hydrogen chloride gave 95.3 g. (86%) of ethyl 3-hydroxy-4,4,5,5,6,6,7,7,8,8,9,9,10,10,10-pentadecafluorodecanoate, b.p. 97° (1.9 mm.), n^{20}D 1.3429.[14]

Ethyl 3-Perfluoroalkylpropenoates.—The dehydration of ethyl 3-hydroxy-3-perfluoroalkylpropanoates with phosphorus pentoxide was conducted by the previously reported method.[4] From 572 g. (2.0 moles) of ethyl 3-hydroxy-4,4,5,5,6,6,6-heptafluorohexanoate there was obtained 451 g. (84%) of the corresponding α,β-unsaturated ester, b.p. 140–141°, n^{20}D 1.3444.[4]

Seventy-five grams (0.155 mole) of the 3-hydroxypentadecafluorodecanoate gave 48 g. (66%) of ethyl 4,4,5,5,6,6,7,7,8,8,9,9,10,10,10-pentadecafluoro-2-decenoate, b.p. 101° (18 mm.), n^{28}D 1.3340.

Anal. Calcd. for $C_{12}H_7F_{15}O_2$: C, 30.78; H, 1.51. Found: C, 30.59; H, 1.57.

Diethyl 2-Carbethoxy-3-perfluoropropylpentanedioate.—Diethyl malonate (23.0 g., 0.144 mole) and 26.8 g. (0.10 mole) of ethyl 4,4,5,5,6,6,6-heptafluoro-2-hexenoate were added to a cold solution of 2.5 g. (0.109 g. atom) of sodium in 100 ml. of absolute ethanol. After 1 hr. at room temperature the mixture was heated under reflux for 1.5 hr., poured into water and made acidic with hydrochloric acid. The product was taken up in ether, dried and distilled to give 38.5 g. (90%) of the triester, b.p. 104° (0.7 mm.), $n^{20}D$ 1.3900, d^{20}_4 1.306.

Anal. Calcd. for $C_{15}H_{19}F_7O_2$: C, 42.06; H, 4.47. Found: C, 41.83; H, 4.61.

3-Perfluoropropylpentanedioic Acid.—A mixture of 133 g. (0.264 mole) of diethyl 2-carbethoxy-3-perfluoropropylpentanedioate and 200 ml. of dilute (1:1) hydrochloric acid was stirred and heated until no further evolution of carbon dioxide could be observed. The water and hydrochloric acid were removed by distillation under reduced pressure and the white solid residue was recrystallized from water to yield 77.2 g. (98%) of product, m.p. 121–122.5°.

Anal. Calcd. for $C_8H_7F_7O_4$: C, 32.00; H, 2.78; F, 44.33. Found: C, 32.02; H, 2.43; F, 43.57.

3-Perfluoroheptylpentanedioic Acid.—Ethyl 4,4,5,5,6,6,7,7,8,8,9,9,10,10,10-pentadecafluoro-2-decenoate was treated with ethyl malonate in the same manner as the ethyl heptafluorohexenoate. The resulting triester was not isolated in pure form but was immediately hydrolyzed and decarboxylated with hydrochloric acid. Since the crude 3-perfluoroheptylpentanedioic acid formed a gel with water, it was recrystallized from toluene. From 90.4 g. (0.20 mole) of pentadecafluorodecenoate there was obtained 53 g. (53%) of 3-perfluoroheptylpentanedioic acid, m.p. 125–126°.

Anal. Calcd. for $C_{12}H_7F_{15}O_4$: C, 28.81; H, 1.41. Found: C, 28.54; H, 1.35.

3-Perfluoropropylpentanedioic Anhydride.—A mixture of 6.0 g. (0.02 mole) of perfluoropropylpentanedioic acid and 9.5 g. (0.071 mole) of thionyl chloride was refluxed for 4 hr. The excess thionyl chloride was removed by distillation under reduced pressure and the residual oil was distilled *in vacuo* to yield 4.9 g. (86%) of the anhydride, b.p. 93–94° (0.2 mm.), m.p. 48.5–49.5°.

Anal. Calcd. for $C_8H_5F_7O_3$: C, 34.04; H, 1.78. Found: C, 34.15; H, 2.00.

3-Perfluoroalkylpentanedioyl Chlorides.—Phosphorus pentachloride (41.6 g., 0.20 mole) was added to 30.0 g. (0.10 mole) of 3-perfluoropropylpentanedioic acid, and the mixture refluxed for 1 hr. The phosphorus oxychloride was removed by distillation at atmospheric pressure and the residue distilled at reduced pressure to yield 29.6 g. (88%) of 3-perfluoropropylpentanedioyl chloride, b.p. 65° (1.6 mm.), $n^{20}D$ 1.3926.

Anal. Calcd. for $C_8H_5F_7Cl_2O_2$: C, 28.48; H, 1.48; Cl, 21.07. Found: C, 28.36; H, 1.69; Cl, 21.45.

In a similar experiment, 25 g. (0.05 mole) of 3-perfluoroheptylpentanedioic acid gave 19.6 g. (73%) of 3-perfluoroheptylpentanedioyl chloride, b.p. 88° (0.7 mm.), $n^{20}D$ 1.3699.

Anal. Calcd. for $C_{12}H_5F_{15}Cl_2O_2$: C, 26.81; H, 0.93; Cl, 13.20. Found: C, 26.57; H, 1.10; Cl, 13.44.

Diethyl 3-Perfluoropropylpentanedioate.—3-Perfluoropropylpentanedioic acid was esterified by dissolving 23 g. (0.07 mole) of the acid and 5.0 g. of hydrogen chloride in 450 ml. of absolute ethanol, allowing the solution to sit 12 hr. and finally refluxing for 1 hr. before removing the excess alcohol. Distillation of the residue gave 22.8 g. (92%) of the ester, b.p. 79–80° (1.5 mm.), $n^{20}D$ 1.3738, $d^{21.5}_4$ 1.320.

Anal. Calcd. for $C_{12}H_{15}F_7O_4$: C, 40.45; H, 4.21. Found: C, 40.41; H, 4.23.

3-Perfluoropropyl-1,5-pentanediol.—To a suspension of 25.0 g. (0.66 mole) of lithium aluminum hydride in 1 lb. of anhydrous ether was added a solution of 60.0 g. (0.20 mole) of 3-perfluoropropylpentanedioic acid in 1 lb. of anhydrous ether. After refluxing for 3 hr., 100 ml. of 95% ethanol was added dropwise, and the partially hydrolyzed mixture was diluted with 500 g. of ice and 45 ml. of concentrated sulfuric acid. The product was taken up in ether, washed with sodium bicarbonate solution and dried. Distillation gave 33.5 g. (62%) of colorless, viscous product, b.p. 82° (0.1 mm.), $n^{20}D$ 1.3752.

Anal. Calcd. for $C_8H_{11}F_7O_2$: C, 35.29; H, 4.07. Found: C, 35.43; H, 4.30.

3-Perfluoropropyltetrahydropyran.—The same reduction procedure as given for the preparation of 3-perfluoropropyl-1,5-pentanediol was used with the exception that the ether extracts of the reaction mixture were not washed with base. After removal of the ether, the residue was refluxed 12 hr. before being distilled. From 35.6 g. (0.10 mole) of diethyl 3-perfluoropropylpentanedioate and 4.56 g. (0.12 mole) of lithium aluminum hydride there resulted 20.4 g. (84%) of 3-perfluoropropyltetrahydropyran, b.p. 114–115°, $n^{20}D$ 1.3527, $d^{20}D$ 1.410.

Anal. Calcd. for $C_8H_9F_7O$: C, 37.78; H, 3.53. Found: C, 37.54; H, 3.84.

Diethyl 3,5-Bis-(perfluoroalkyl)-4-thiaheptanedionates.—The addition of hydrogen sulfide to α,β-unsaturated esters was conducted by the procedure of Barkenbus, Midkiff and Newman.[10] From 43.0 g. (0.256 mole) of ethyl 4,4,4-trifluorobutenoate[4] there was obtained 27 g. (57%) of diethyl 3,5-bis-(perfluoromethyl)-4-thiaheptanedioate, b.p. 114–115° (*ca.* 3 mm.), $n^{20}D$ 1.3737.

Anal. Calcd. for $C_{12}H_{16}F_6O_4S$: C, 38.92; H, 4.32. Found: C, 38.90; H, 4.31.

Ethyl 4,4,5,5,6,6,6-heptafluoro-2-hexenoate (142 g., 0.53 mole) afforded 112 g. (74%) of diethyl 3,5-bis-(perfluoropropyl)-4-thiaheptanedioate, b.p. 100–102° (0.6 mm.), $n^{20}D$ 1.3763, d^{20}_4 1.475.

Anal. Calcd. for $C_{16}H_{16}F_{14}O_4S$: C, 33.68; H, 2.81; F, 46.66; S, 5.62. Found: C, 33.40; H, 2.85; F, 46.31; S, 5.23.

Ethyl 3-Mercapto-4,4,5,5,6,6,6-heptafluorohexanoate.—In the above preparation, a forerun of 9.0 g. (5.5%) of ethyl 3-mercapto-4,4,5,5,6,6,6-heptafluorohexanoate was obtained, b.p. 35–36° (0.6 mm.), $n^{20}D$ 1.3774.

Anal. Calcd. for $C_8H_9F_7O_2S$: C, 31.82; H, 3.00. Found: C, 32.09; H, 2.96.

3,5-Bis-(perfluoropropyl)-4-thiaheptanedioic Acid.—A solution of 42.8 g. (0.075 mole) of diethyl 3,5-bis-(perfluoropropyl)-4-thiaheptanedioate in 150 ml. of concentrated sulfuric acid was warmed on a steam-bath for 45 min. and poured over 600 g. of ice. The product was taken up in ether, dried over Drierite and the ether removed by evaporation on a steam-bath. The residue was recrystallized from toluene to yield 30.0 g. (78%) of fairly pure acid. The most insoluble form melts at 156–157° while the other form melts over the range 108–16° even after repeated recrystallizations.

Anal. Calcd. for $C_{12}H_8F_{14}O_4S$: C, 28.02; H, 1.56. Found: C, 27.68; H, 1.85.

3,5-Bis-(perfluoropropyl)-4-thiaheptanedioyl Chloride.—3,5-Bis-(perfluoropropyl)-4-thiaheptanedioic acid (51.4 g., 0.10 mole) and an excess (100 g., 0.84 mole) of thionyl chloride were refluxed for 1.5 hr. The excess thionyl chloride was removed by distillation at 100 mm. and the residue rectified to give 46.6 g. (85%) of the acid chloride, b.p. 86–88° (0.7 to 0.8 mm.), $n^{20}D$ 1.3892.

Anal. Calcd. for $C_{12}H_6F_{14}Cl_2O_2S$: C, 26.15; H, 1.09; Cl, 12.88. Found: C, 26.12; H, 1.33; Cl, 12.59.

3,5-Bis-(perfluoropropyl)-4-thia-1,7-heptanediol.—By the same procedure given for the reduction of 3-perfluoropropylpentanedioic acid, 114 g. (0.2 mole) of diethyl 3,5-bis-(perfluoropropyl)-4-thiaheptanedioate was reduced with 10 g. (0.26 mole) of lithium aluminum hydride to give 83.7 g. (86%) of the diol, b.p. 109° (0.2 mm.), m.p. 47°, $n^{19.5}D$ 1.3800 (supercooled).

Anal. Calcd. for $C_{12}H_{12}F_{14}O_2S$: C, 29.65; H, 2.27; F, 54.73. Found: C, 29.68; H, 2.42; F, 54.82.

The Addition of Trichlorosilane and Methyldichlorosilane to Tetrachloroethylene

BY E. T. McBEE, C. W. ROBERTS[1] AND G. W. R. PUERCKHAUER[2]

RECEIVED SEPTEMBER 13, 1956

Trichlorosilane and methyldichlorosilane were added to tetrachloroethylene to yield tetrachloroethyltrichlorosilane and trichlorovinyltrichlorosilane. Trichlorovinyltrichlorosilane and trichlorovinyltrimethylsilane undergo addition reactions with trichlorosilane, methyldichlorosilane, chlorine and *p*-toluenethiol. Pentachloroethyltrichlorosilane with ethylmagnesium bromide gave trichlorovinyltriethylsilane.

Discussion

Addition of trichlorosilane to trichloroethylene and the dichloroethylenes to yield olefinic products has been described by Wagner[3] and Agre.[4a–c] While this work was in progress, a patent[5] was issued which describes the addition of chlorosilanes to tetrachloroethylene to produce unsaturated silanes containing the trichlorovinyl group.

This paper reports a study of the addition of trichlorosilane and methyldichlorosilane to tetrachloroethylene and an investigation of the chemical properties of the addition products. High temperatures (600°) at atmospheric pressure, a free radical initiator (*t*-butyl peroxide) at moderate temperatures (125–140°), and ultraviolet irradiation were studied as conditions for the addition. High temperatures gave only trichlorovinyltrichlorosilane (Table I) in agreement with the work of earlier investigators,[3–5] while *t*-butyl peroxide at lower temperatures gave some 1,1,2,2-tetrachloroethyltrichlorosilane. *t*-Butyl peroxide, the best of the catalysts tried (it is a liquid that is miscible with the reactants and generates free radicals at a measurable rate at moderately high temperatures (125°)[6]), gave only low conversions (Table I). Methyldichlorosilane with *t*-butyl peroxide gave the unsaturated addition compound, trichlorovinylmethyldichlorosilane, and a double addition product, 1,2-bis-(methyldichlorosilyl)-1,2-dichloroethene.

Trichlorovinyltrichlorosilane and Grignard reagents gave the corresponding trialkyltrichlorovinylsilane, with no β-elimination involving the chlorine atoms being observed; this is in accordance with the findings of Agre.[4a,7] Addition of chlorine to trichlorovinyltrichlorosilane gave pentachloroethyltrichlorosilane; this compound on treatment with ethylmagnesium bromide lost chlorine to give trichlorovinyltriethylsilane.

Trichlorosilane added in better conversions to trichlorovinyltrichlorosilane (20.9%) and trichlorovinyltrimethylsilane (44.2%) than to tetrachloroethylene (12.6%). This was expected because of the electron-releasing effect of the silicon atom and the resulting easier attack by the silyl radical.[8] The isolated products were again olefins, except in one case where a small amount of 1,2-bis-(trichlorosilyl)-1,1,2-trichloroethane was isolated.

TABLE I

t-Butyl peroxide, nickel autoclave, 120–145° (D)	11.5	2.4	18.8

[a] No saturated addition product could be isolated in pure state, but the double addition product, 1,2-bis-(methyldichlorosilyl)-1,2-dichloroethene, was isolated.

Chlorovinylsilanes are known to be readily attacked by alkali to cleave the carbon–silicon bond,[3] and this was found to be true for the trichlorovinyl compounds. Trichlorovinyltrichlorosilane gave trichloroethylene and some dichloroacetylene with strong aqueous potassium hydroxide. Trichlorovinyltrimethylsilane was more stable toward alkali but was also cleaved after several hours at reflux. 1,2-Bis-(trichlorosilyl)-1,2-dichloroethene was readily attacked and gave a violent explosion, probably caused by chloroacetylene. No dichloroethylene was obtained from this reaction.

Trichlorovinyltrimethylsilane was treated with *p*-toluenethiol and sodium ethoxide in ethanol to prepare the same product obtained from *p*-toluenethiol and trichloroethylene. In view of the structure of the addition compound obtained from trichloroethylene and sodium ethoxide,[10] the product is thought to be *p*-tolylmercapto-1,2-dichloroethene.[11]

During chlorination of trichlorovinyltrimethylsilane most of the methyl hydrogens were sub-

stituted before addition to the double bond occurred. Two products, $CCl_3CCl_2Si(CCl_3)_3$ (I) and $CCl_3CCl_2Si(CCl_3)_2CHCl_2$ (II), were obtained. Compound II was distinguished from the isomeric compounds, $C_2HCl_4Si(CCl_3)_3$ (III), which could arise by addition of hydrogen chloride, formed during the reaction to the trichlorovinyl group, by treatment with alkali. If structure II were correct, tetrachloroethylene would be obtained by this cleavage, whereas structure III would give trichloroethylene or dichloroacetylene. Tetrachloroethylene was isolated confirming structure II.

Experimental

Materials.—Tetrachloroethylene (a gift from E. I. du Pont de Nemours and Co.) was dried over phosphorus pentoxide and rectified. Trichlorosilane and methyldichlorosilane (Pure Grade unless otherwise indicated) were obtained from Anderson Laboratories and used without further purification.

Addition of Trichlorosilane to Tetrachloroethylene. Hot Tube (Method A).—A mixture of 950 g. (5.72 moles) of tetrachloroethylene and 1163 g. (8.6 moles) of technical trichlorosilane was dropped into a Vycor tube of 20 mm. i.d., loosely packed with Raschig rings and heated over a 20-cm. zone in a tube furnace. The temperature, maintained at 570–595°, was measured by a thermocouple inserted between the Vycor tube and heating element. A steady stream of purified nitrogen (Fieser train) was passed through the apparatus during the experiment (presence of oxygen caused explosions). The exit gases were liquefied in an air-cooled and a Dry Ice trap connected in series. The trap contents gave on distillation: unreacted starting materials (91.5 g., 0.68 mole of trichlorosilane and 642 g., 3.9 moles of tetrachloroethylene); 898 g. of by-product silicon tetrachloride and chlorinated disilanes, b.p. 47–111°; 94.5 g. of a carbon-containing by-product, b.p. 170–173°; a forerun; and 139.3 g. (9.2% based on starting olefin) of trichlorovinyltrichlorosilane, b.p. 193° (748 mm.) (reported[5] b.p. 93° (30 mm.)). A silane to olefin ratio of 2:1 gave an improved conversion (*ca.* 14% at 600°).

Below 385° conversion of trichlorosilane to tetrachlorosilane occurred without the formation of trichlorovinyltrichlorosilane and extensive decomposition took place above 670°.

Ultraviolet Initiation (Method B).—A dry 300-ml. quartz flask, connected through a condenser and a Dry Ice trap to a 20-cm. mercury seal,[12] was filled with 83 g. (0.5 mole) of tetrachloroethylene and 203 g. (1.5 moles) of trichlorosilane, swept with nitrogen, and exposed for 90 hr. to the irradiation from a mercury vapor lamp. The flask contents turned red-brown during this period. Trichlorosilane (168 g., 1.2 moles) and tetrachloroethylene (73 g., 0.44 mole) and a small intermediate cut consisting of silicon tetrachloride were obtained by distillation. The residue was rectified to give 9.4 g. (7.1%) of trichlorovinyltrichlorosilane, b.p. 66.5–69.5° (6.5 mm.), and 1.6 g. (1.1%) of 1,1,2,2-tetrachloroethyltrichlorosilane, b.p. 97–98° (2.5 mm.).

Table II

Absorption Bands of Unsaturated Silanes between 6 and 7 μ

Compound	Absorption between 6 and 7 μ[a,b]
Trichlorovinyltrichlorosilane	6.52(s)
Trichlorovinyltrimethylsilane	6.49(s)

1,2-Bis-(trichlorosilyl)-1,2-dichloroethene	6.12(w), 6.72–6.75(s)
1,2-Bis-(methyldichlorosilyl)-1,2-dichloroethene	6.20(vw), 6.64(s)

[a] A Perkin–Elmer no. 21 double beam infrared spectrometer was used. [b] s = strong, m = medium strong, w = weak, vw = very weak.

(12) E. W. Pietrusza, L. H. Sommer and F. C. Whitmore, This Journal, 70, 484 (1948).

t-Butyl Peroxide Initiated (Method C).—Tetrachloroethylene (44 g., 0.27 mole), *t*-butyl peroxide (3.2 g., 0.022 mole) and trichlorosilane (108 g., 0.8 mole) were distributed in equal proportions over 4 Carius tubes, which were sealed under an atmosphere of purified nitrogen (Fieser train) and heated for 60 hr. at 125–130° in a furnace. The contents of the tubes were combined and 92 g. (0.68 mole) of trichlorosilane and 36 g. (0.22 mole) of tetrachloroethylene recovered. The residue was rectified to give 8.9 g. (12.6%) of trichlorovinyltrichlorosilane, b.p. 74° (10 mm.), and 3.8 g. (4.7%) of 1,1,2,2-tetrachloroethyltrichlorosilane, b.p. 97.5–99° (3 mm.).

Method D.—The preceding experiment was repeated in a glass-lined, nickel-clad autoclave. The same proportions of reactants at 125–140° for 60 hr. gave 11.5% of trichlorovinyltrichlorosilane and 2.4% of 1,1,2,2-tetrachloroethyltrichlorosilane.

Trichlorosilane was added to trichlorovinyltrichlorosilane and trichlorovinyltrimethylsilane, methyldichlorosilane to tetrachloroethylene and trichlorovinyltrimethylsilane using method C. Method D gave better results than method C in the addition of methyldichlorosilane to tetrachloroethylene (see Table I).

1,2-Bis-(trichlorosilyl)-1,2-dichloroethane with Alkali.—A concentrated solution of potassium hydroxide (130 g. in 250 ml. of water) was placed in a 500-ml., three-necked flask, and to it was added 28 g. (0.07 mole) of 1,2-bis-(trichlorosilyl)-1,2-dichloroethene. The flask was connected through an ice-cooled trap to the atmosphere. The initially formed white precipitate dissolved on warming. Cooling the flask brought about a violent explosion in the trap and the connecting line. This explosion could have been caused by chloroacetylene formed in this reaction.

Trichlorovinyltrichlorosilane with Alkali.—To a concentrated solution of potassium hydroxide (90 g. in 200 ml. of water) in a 300-ml., three-necked flask was added 22 g. (0.083 mole) of trichlorovinyltrichlorosilane. A white precipitate formed which dissolved on heating and a small layer formed on the bottom of the flask. Several small explosions took place in the flask. After cooling, the small organic layer was separated, dried over Drierite and distilled to give 4 g. (36.7%) of trichloroethylene, b.p. 86.5–86.7° (747 mm.), $n^{20}D$ 1.4773–1.4775. Huntress lists[13] b.p. 86–88°, $n^{20}D$ 1.4775–1.47782.

Trichlorovinyltrimethoxysilane.—From 31.2 g. (0.12 mole) of trichlorovinyltrichlorosilane and a mixture of 13.6 g. (0.43 mole) of methanol and 28.8 g. (0.36 mole) of pyridine there was obtained, using the previously described procedure,[14] 20.5 g. (68%) of trichlorovinyltrimethoxysilane, b.p. 94.5–95° (12 mm.), $n^{20}D$ 1.4646, d^{20}_4 1.345.

This compound did not hydrolyze appreciably with water or dilute acid but was attacked by alkali.

Anal. Calcd. for $C_5H_9Cl_3O_3Si$: C, 23.86; H, 3.58; Cl, 42.34; M_R, 51.24. Found: C, 24.12; H, 3.86; Cl, 42.08; M_R, 51.65.

Grignard Reactions: Preparation of Alkyl Derivatives.—From 14.4 g. (0.054 mole) of trichlorovinyltrichlorosilane and 5.29 g. (0.22 g. atom) of magnesium turnings in 150 ml. of anhydrous ether and 30.9 g. (0.22 mole) of methyl iodide in 50 ml. of anhydrous ether there was obtained[14] 9.3 g. (84.5%) of trichlorovinyltrimethylsilane, b.p. 82° (31 mm.), $n^{20}D$ 1.4890, d^{20}_4 1.189.

Anal. Calcd. for $C_5H_9Cl_3Si$: C, 29.48; H, 4.42; Cl, 52.32; M_R, 48.96. Found: C, 29.51; H, 4.50; Cl, 52.46; M_R, 49.94.

Trichlorovinyltrimethylsilane was prepared in a similar way from trichlorovinyltrimethoxysilane and from trichlorovinylmethyldichlorosilane in 60.6 and 50.9% yields, respectively.

Trichlorovinyltriethylsilane, b.p. 113° (11 mm., $n^{20}D$ 1.4986, d^{20}_4 1.141, was obtained from trichlorovinyltrichlorosilane in 73.7% yield using the same procedure[14] with 7 moles of ethylmagnesium bromide used per mole of silane to make certain any reduction of the β-chlorine substituent would be evidenced; no reduction was observed.

Anal. Calcd. for $C_8H_{15}Cl_3Si$: C, 39.12; H, 6.11; Cl, 43.38; M_R, 62.85. Found: C, 39.30; H, 6.36; Cl, 43.74; M_R, 63.13.

[a] All boiling points are corrected. [b] This compound was isolated from accumulated distillation residues of the addition of methyldichlorosilane to tetrachloroethylene. [c] All analyses by Dr. Yeh, Purdue University.

Attempted Preparation of 1,2-Bis-(trimethylsilyl)-1,2-dichloroethene.—From 31 g. (0.096 mole) of 1,2-bis-(methyldichlorosilyl)-1,2-dichloroethene in 50 ml. of anhydrous ether and 14 g. (0.58 g. atom) of magnesium turnings in 500 ml. of anhydrous ether and 81.8 g. (0.58 mole) of methyl iodide in 100 ml. of anhydrous ether, no isolable pure product was obtained. An attempt to prepare this compound from 1-(trichlorosilyl)-2-(trimethylsilyl)-1,2-dichloroethene using the same technique also gave no isolable product.

Pentachloroethyltrichlorosilane.—A Carius tube was charged with 9.3 g. (0.13 mole) of dry chlorine and 24 g. (0.09 mole) of trichlorovinyltrichlorosilane and irradiated with light from an AH-1 bulb (Gartner Scientific Co.) for 3 days. After removal of the excess chlorine under reduced pressure, the white solid residue was distilled to give 28.6 g. (94.1%) of pentachloroethyltrichlorosilane, b.p. 98.7° (6 mm.).

Anal. Calcd. for C_2Cl_8Si: C, 7.14; Cl, 84.52. Found: C, 6.98; Cl, 84.32.

Trichlorovinyltriethylsilane from Pentachloroethyltrichlorosilane.—A solution of 28.4 g. (0.085 mole) of pentachloroethyltrichlorosilane in 50 ml. of anhydrous ether was added dropwise at 0° to a solution prepared from 18.5 g. (0.76 g.-atom) of magnesium turnings in 500 ml. of anhydrous ether and 82.9 g. (0.76 mole) of ethyl bromide in 100 ml. of anhydrous ether. The resulting mixture was stirred for 4 hr. at room temperature, 9 hr. at reflux temperature, the ether distilled and the residue heated on a steam-bath for 5 hr. After the ether was returned to the flask, the mixture was decomposed with ice and dilute hydrochloric acid, the aqueous layer extracted with ether and the combined ether layers dried over Drierite. Rectification gave 13.2 g. (63.6%) of trichlorovinyltriethylsilane, b.p. 87.3–88° (3 mm.), $n^{20}D$ 1.4986, d^{20}_4 1.140.

The infrared spectrum of this compound was identical with that of the trichlorovinyltriethylsilane prepared from trichlorovinyltrichlorosilane.

Chlorination of Trichlorovinyltrimethylsilane.—A Carius tube was charged with 5.8 g. (0.08 mole) of chlorine and 2 g. (0.01 mole) of trichlorovinyltrimethylsilane and irradiated for 4 days with light from an AH-1 bulb. From the opened tube there was isolated 4.5 g. of a white solid, m.p. 132–139.5°; this was recrystallized several times from petroleum ether to give the product, m.p. 134.2–135.1°.

Anal. Calcd. for $C_5Cl_{14}Si$: C, 10.26; Cl, 84.94. Found: C, 10.40; Cl, 84.99.

In a subsequent experiment, 4.06 g. (0.02 mole) of trichlorovinyltrimethylsilane and 21 g. (0.3 mole) of chlorine irradiated for 9 days with light from an AH-1 bulb gave 11.7 g. of a white solid, m.p. 130–132°, after one recrystallization from petroleum ether (b.p. 35–37°). On repeated recrystallization from petroleum ether (b.p. 65–67°), the solid had a m.p. 128.3–128.6°. A mixed melting point with the compound obtained in the preceding experiment gave m.p. 129–131.8°.

Anal. Calcd. for $C_5HCl_{14}Si$: C, 10.91; H, 0.18; Cl, 83.82. Found: C, 10.84; H, 0.25; Cl, 83.90, 84.10.

This compound (5.7 g.) was refluxed with a 40% aqueous potassium hydroxide solution. The mixture was steam distilled and the aqueous layer extracted with ether. After drying and removal of the solvent, 0.7 g. of tetrachloroethylene,[13] b.p. 119–120.8°, $n^{20}D$ 1.5064, was obtained.

Attempts to introduce only one chlorine atom into one of the methyl groups of trichlorovinyltrimethylsilane by the above technique and the use of an excess of the silane were unsuccessful, leading to polychlorinated or unreacted materials.

Trichlorovinyltrimethylsilane and *p*-Toluenethiol.—In a 300-ml., three-necked flask (stirrer, addition funnel, Friedrich condenser protected with a calcium chloride tube) was placed 75 ml. of absolute ethanol and 2.53 g. (0.11 mole) of sodium. To this solution was added 12.4 g. (0.1 mole) of *p*-toluenethiol in 60 ml. of absolute ethanol followed by 20.3 g. (0.1 mole) of trichlorovinyltrimethylsilane. The mixture was refluxed for 46 hr. The resulting solid (5 g.) was filtered and proved to be sodium chloride. The filtrate was evaporated to give a yellow liquid, which was separated into two fractions by simple distillation: b.p. 114–127° (3 mm.), 15.2 g., and b.p. 165–270° (3 mm.), 2.7 g.

Part of the lower boiling fraction was rectified to give *p*-tolylmercaptodichloroethene, b.p. 127–127.5° (3 mm.), $n^{25}D$ 1.5966–1.5970, d^{20}_4 1.270.

Anal. Calcd. for $C_9H_8Cl_2S$: C, 49.32; H, 3.66; Cl, 32.42; S, 14.61; M_R, 58.72. Found: C, 49.62; H, 3.65; Cl, 32.15; S, 14.86; M_R, 58.86.

Another part of the lower boiling fraction was oxidized to the sulfone: 2.8 g. (0.013 mole) of *p*-tolylmercaptodichloroethene was refluxed for 2.5 hr. with 95 ml. of glacial acetic acid and 10 ml. of 30% hydrogen peroxide and then allowed to stand overnight. The solution was evaporated and a dark gray mass was left, which gave after recrystallization from ethanol 1.2 g. of a brown solid. Several recrystallizations from ethanol gave a white crystalline product, m.p. 76–77°; reported[15] for the oxidized addition product of *p*-toluenethiol to trichloroethylene, m.p. 74–77°. A mixed melting point of our compound with the one prepared by McManimie gave no depression.

Trichlorovinyltrimethylsilane and Sodium Ethoxide.—Absolute ethanol (400 ml.) and 7.59 g. (0.33 g.-atom) of sodium was placed into a 1000-ml., three-necked flask (stirrer, Friedrich condenser, addition funnel through which dry nitrogen was admitted). To this solution was added 61 g. (0.3 mole) of trichlorovinyltrimethylsilane. The resulting mixture was refluxed for 46 hr. A white precipitate was formed during this period. The solution was filtered and 19 g. (0.32 mole) of sodium chloride remained. The filtrate was rectified to give 37.4 g. of trimethylethoxysilane–ethanol azeotrope, b.p. 66° (744 mm.), $n^{20}D$ 1.3729; an ethanol fraction, b.p. 77.5–78° (744 mm.); and 11.1 g. (30.5%) of ethyl chloroacetate,[13] b.p. 63° (34 mm.), 141.7° (747 mm.), $n^{20}D$ 1.4217, d^{20}_4 1.150.

The trimethylethoxysilane–ethanol azeotrope was poured into water and the silane layer washed with water, dried over Drierite and rectified to give 15.5 g. (43.7%) of trimethylethoxysilane,[16] b.p. 75° (742 mm.), $n^{20}D$ 1.3747, d^{20}_4 0.762.

The first third of the ethanol fraction yielded on dilution with water a heavy layer, which was washed with water, dried over Drierite and rectified to give 10 g. (23.6%) of 1,2-dichlorovinyl ethyl ether,[13] b.p. 42.2° (31 mm.), 126–127.6° (746 mm.), $n^{21}D$ 1.4519, d^{20}_4 1.197.

The infrared spectra of the compounds obtained in this

experiment were identical with the spectra obtained from authentic compounds.

Attempted Addition of Carbon Tetrachloride to Trichlorovinyltrimethylsilane.—Trichlorovinyltrimethylsilane (23.3 g., 0.12 mole) and carbon tetrachloride (70.5 g., 0.46 mole) were placed into a quartz flask and irradiated with light from a mercury vapor lamp for 2 weeks. An atmosphere of purified nitrogen was maintained throughout the experiment. Practically all the starting materials were recovered from the greenish reaction mixture.

The Addition of Trichlorosilane and Methyldichlorosilane to Fluorine- and Chlorine-containing Olefins

BY E. T. MCBEE, C. W. ROBERTS[1] AND G. W. R. PUERCKHAUER[2]

RECEIVED SEPTEMBER 13, 1956

Trichlorosilane and methyldichlorosilane were added using ultraviolet irradiation and peroxides to 1,1,2-trichloro-3,3,3-trifluoropropene to give trifluorodichloropropenyltrichlorosilane and trifluorodichloropropenylmethyldichlorosilane, respectively. Trichlorosilane and methyldichlorosilane were added to 3,3,3-trifluoropropene and to 2,3,3,4,4,4-hexafluorobutene, and trichlorosilane was added to chlorotrifluoroethylene to give chlorotrifluoroethyltrichlorosilane. The products were converted to their trimethyl and triethyl derivatives. Trifluorotetrachloropropyltrichlorosilane gave trifluorodichloropropenyltriethylsilane with ethylmagnesium bromide.

Discussion

Trichlorosilane has been added with[3a-e] or without[3f,g] catalysts to olefins. Since this work was initiated, two reports have appeared on the addition of trichlorosilane to fluorine-containing olefins[4,5]; these involve the addition of trichlorosilane to 1,1-difluoroethylene with a platinum-on-charcoal catalyst and to tetrafluoroethylene photochemically.

The addition of methyldichlorosilane to olefins has been less extensively investigated.[3c-f,6a-c] Additions of trichlorosilane and methyldichlorosilane to olefins containing chlorine atoms at the carbon atoms forming the double bond have been shown to form olefinic products[7a-f] by subsequent dehydrohalogenation of the original saturated adduct.

This paper reports the addition of trichlorosilane and methyldichlorosilane to the fluorine-containing olefins, perfluoropropene, 2,3,3,4,4,4-hexafluorobutene and 3,3,3-trifluoropropene, and to the olefins containing both fluorine and chlorine, namely, 1,1,2-trichloro-3,3,3-trifluoropropene and chlorotrifluoroethylene. Ultraviolet irradiation and *t*-butyl peroxide were both used as initiators and the latter proved to be more dependable because it is a liquid miscible with the reactants and generates free radicals at a measurable rate at elevated (125°) temperatures.[8]

The reactivity of the olefins studied increased as the influence of fluorine on the character of the double bond decreased. Thus, 3,3,3-trifluoropropene gave better conversions than 2,3,3,4,4,4-hexafluorobutene, while perfluoropropene gave only traces of an addition compound (Table I). The inertness of perfluoropropene in these reactions was somewhat surprising since it has been reported to add trifluoromethyl iodide[9] and since it adds bromine under the influence of ultraviolet irradiation to give an 83% yield of 1,2-dibromo-1,1,2,-3,3,3-hexafluoropropane.

The proposed mechanism for the addition reaction[10] postulates the formation of a silyl free radical, the addition of this free radical to the olefin, and the removal of a hydrogen from the silane by the resulting radical to generate another silyl radical. This mechanism explains the lesser reactivity of methyldichlorosilane because the silyl free radical may be considered as electrophilic, and if the methyldichlorosilyl radical obtained from methyldichlorosilane is the reactive species in the addition of methyldichlorosilane to olefins, it should be less electrophilic than the trichlorosilyl radical due to the electron-supplying influence of the methyl group.

Although the addition of trichlorosilane and methyldichlorosilane to 1-olefins has been shown to yield the 1-isomer exclusively,[10] the addition compound of trichlorosilane to 3,3,3-trifluoropropene could be either $CF_3CH_2CH_2SiCl_3$ (I) or CF_3-

$CH(CH_3)SiCl_3$ (II). In order to distinguish between structures I and II, the product was converted to the trimethoxy derivative; this was found to be identical with 3,3,3-trifluoropropyltrimethoxysilane prepared by a different procedure.[11] By analogy, the addition compound of trichlorosilane to 2,3,3,4,4,4-hexafluorobutene is presumed to be $CF_3CF_2CHFCH_2SiCl_3$ (III).

In comparison to the addition of trichlorosilane to tetrachloroethylene, one would expect the silane to add to 1,1,2-trichloro-3,3,3-trifluoropropene to give an olefinic product[7c]; experimental evidence supported this, and trifluorodichloropropenyltrichlorosilane was isolated. Methyldichlorosilane added less readily and gave also an olefinic product, trifluorodichloropropenylmethyldichlorosilane. The addition product could be either $CF_3CCl{=}CClSiCl_3$ (IV) or $CF_3C(SiCl_3){=}CCl_2$ (V). These compounds were distinguished by alkaline cleavage.[12] Although the physical constants of the resulting olefins are relatively close,[13] the melting point of the olefin obtained by alkaline cleavage of the addition product to 1,1,2-trichloro-3,3,3-trifluoropropene agreed with that for 1,1-dichloro-3,3,3-trifluoropropene and the addition compound is therefore compound V.

The literature and the evidence presented indicate that chlorosilanes will add to chlorinated olefins to give chiefly an unsaturated addition product which arises by the elimination of the elements of hydrogen chloride, while fluorinated olefins such as 2,3,3,4,4,4-hexafluorobutene or 1,1-difluoroethylene gave saturated addition products. It seemed, therefore, of interest to investigate the addition of trichlorosilane to an olefin that contained both fluorine and chlorine at the double bond. Chlorotrifluoroethylene was used and gave a saturated addition product that was somewhat unstable at its boiling point but could be prepared in analytical purity by relatively rapid rectification of a previously distilled sample.

According to the observations made by Sommer and co-workers[14] on the behavior of β-chloroalkylsilanes, 2,3,3,4,4,4-hexafluorobutyltrichlorosilane might be expected to undergo elimination reactions involving the β-fluorine atom with Grignard reagents and bases. However, this β-fluorine is more stable than β-chlorine since even excess of ethylmagnesium bromide with I or III gave the triethyl derivatives with no observed loss of fluorine. Moreover, the products were stable to base under such vigorous conditions as prolonged refluxing with 40% potassium hydroxide. Agre[3] and McBee, *et al.*,[7c] observed that β-chlorovinylsilanes will not undergo reduction or β-elimination with Grignard reagents. Trifluorodichloropropenyltrichlorosilane behaved similarly and the trimethyl and triethyl compounds were prepared by a known procedure[15] with methylmagnesium iodide and ethylmagnesium bromide, respectively.

Chlorine was added in good yields to trifluorodichloropropenyltrichlorosilane to give trifluorotetrachloropropyltrichlorosilane which underwent reduction with ethylmagnesium bromide to give back trifluorodichloropropenyltriethylsilane. This reduction seems to be a general reaction for silanes of this structure as pentachloroethyltrichlorosilane underwent a similar reaction.[7c]

The results of the addition reactions are summarized in Table I and the new compounds in Tables II and III.

Table I

Silane Addition Products

	Addition, % Trichlorosilane		Methyldichlorosilane	
	Ultraviolet	(*t*-BuO)$_2$	Ultraviolet	(*t*-BuO)$_2$
Perfluoropropene	1	1	..	..
2,3,3,4,4,4-Hexafluorobutene	29.3	52.1	8.6[b]	45.8
3,3,3-Trifluoropropene	72	75.3	3.6[c]	69.5
1,1,2-Trichloro-3,3,3-trifluoropropene[a]	9.3	33.5	..	21.2
Chlorotrifluoroethylene	19.1	37.7	..	..

[a] This addition was also brought about by passing a mixture of 1,1,2-trichloro-3,3,3-trifluoropropene (1 mole) and trichlorosilane (1.2 mole) through a horizontal tube (20 mm. interior diameter) that was heated over a 20-cm. zone to 580–620°. Although extensive carbonization took place, 3.9% of trifluorodichloropropenyltrichlorosilane could be obtained; this reaction did not take place below 510°. [b] 8.5 days irradiation. [c] 90 hr. irradiation, impure product.

Experimental

Materials.—3,3,3-Trifluoropropene[16] and 2,3,3,4,4,4-hexafluorobutene[17] were prepared by published methods. Trichlorosilane and methyldichlorosilane (pure grade) were purchased from Anderson Laboratories and used without further purification. 1,1,2-Trichloro-3,3,3-trifluoropropene was obtained from Columbia Organic Chemicals Co., Inc., and chlorotrifluoroethylene from General Chemicals Division, Allied Chemical and Dye Corp.

Addition of Trichlorosilane and Methyldichlorosilane to Olefins.—The following experiments exemplify the different methods used to add trichlorosilane and methyldichlorosilane to 3,3,3-trifluoropropene, 2,3,3,4,4,4-hexafluorobutene, 1,1,2-trichloro-3,3,3-trifluoropropene and chlorotrifluoroethylene.

Ultraviolet Initiation.—A Carius tube was charged with 9.2 g. (0.096 mole) of 3,3,3-trifluoropropene and 39 g. (0.29 mole) of trichlorosilane and exposed to irradiation from an AH-1 bulb (Gartner Scientific Co.) for 90 hr. Olefin (0.9 g.) and trichlorosilane (21.3 g.) were recovered from the tube and 16 g. (72% based on olefin) of 3,3,3-trifluoropropyltrichlorosilane, b.p. 112.9–114.8°, was obtained by rectification.

***t*-Butyl Peroxide Initiation.**—3,3,3-Trifluoropropene (12.8 g., 0.13 mole), *t*-butyl peroxide (1.5 g., 0.01 mole) and trichlorosilane (52.1 g., 0.39 mole) were distributed over three Carius tubes that were sealed under a purified nitrogen atmosphere (Fieser train) and heated in a tube furnace for 60 hr. at 125–130°. The reaction mixture gave 30.3 g. (0.22 mole) of trichlorosilane and 22.3 g. (75.3%) of 3,3,3-trifluoropropyltrichlorosilane, b.p. 112.8–113.7°.

Although attempts to run these reactions in a stainless steel autoclave gave poor conversions, a nickel-clad autoclave was a satisfactory reaction vessel. A glass liner, filled with 219.6 g. (1.1 moles) of 1,1,2-trichloro-3,3,3-trifluoropropene, 12.83 g. (0.088 mole) of *t*-butyl peroxide and 448 g. (3.3 moles) of trichlorosilane was placed in a nickel-clad autoclave

[e] Bond refractions calculated by K. G. Denbigh, *Trans. Faraday Soc.*, 36, 936 (1940), and E. L. Warrick, THIS JOURNAL, 68, 2435 (1946), were used. [f] Calcd.: Cl, 29.96. Found: Cl, 30.01. [g] Calcd.: Cl, 25.48. Found: Cl, 25.24. [h] Distilled with decomposition at 117–120° (743 mm.). Calcd.: Cl, 18.63. Found: Cl, 18.20. [i] At 22°.

(750-ml. capacity) and heated at 140–155° (external temperature) for 46 hr. The reaction mixture gave, on rectification, 244.3 g. of chlorosilanes, b.p. 30–80°, 69.4 g. (0.35 mole) of unreacted 1,1,2-trichloro-3,3,3-trifluoropropene and 110 g. (33.5%) of trifluorodichloropropenyltrichlorosilane, b.p. 77.5–78.5° (35 mm.). The residue from this distillation was combined with the residues from other runs and rectified to give the saturated addition product, trifluorotrichloropropyltrichlorosilane.

Structure Proof of Trifluorodichloropropenyltrichlorosilane.—Trifluorodichloropropenyltrichlorosilane (101.6 g., 0.34 mole) was added dropwise to a warm solution of 250 g. of potassium hydroxide in 550 ml. of water. The solution was stirred under a nitrogen atmosphere and the exit gases led into a series of ice and Dry Ice traps. After all of the silane had been added, the reaction mixture was heated and refluxed for 45 min. There was no organic layer in the flask after cooling.

The organic layers from the traps were separated, combined, dried over Drierite and rectified to give 5 g. of 1,1-dichloro-3,3,3-trifluoropropene, b.p. 54.3–55° (uncor.), b.p. 53.5–54.2° (cor.), $n^{21}D$ 1.3682, m.p. −88° to −83° (uncor.); reported[13]: for 1,1-dichloro-3,3,3-trifluoropropene, b.p. 55.1°, 54.5°, $n^{20}D$ 1.3688–1.3690, m.p. −87.2°; for 1,2-dichloro-3,3,3-trifluoropropene, b.p. 53.7°, $n^{20}D$ 1.3670, m.p. −109.2°.

Part of the olefinic product was treated with bromine in carbon tetrachloride to give the dibromide, b.p. 71° (23–24 mm.), $n^{20}D$ 1.4788–1.4791.

Anal. Calcd. for $C_3HBr_2Cl_2F_3$: C, 11.08; H, 0.38; Br, 49.23; Cl, 21.84; F, 17.54. Found: C, 11.36; H, 0.46; Br, 50.81; Cl, 20.07; F, 19.00.

Addition of Trichlorosilane to Perfluoropropene.—Perfluoropropene[18] (48.6 g., 0.32 mole), *t*-butyl peroxide (3.8 g., 0.026 mole) and trichlorosilane (131.7 g., 0.97 mole) were distributed over 4 Carius tubes, which were sealed under an atmosphere of purified nitrogen (Fieser train) and heated in a furnace for 60 hr. at 125–132°. Most of the starting materials were recovered and the residue distilled to give 5.7 g. of fluorine-containing materials, b.p. 95–104°, from which 0.8 g. of a liquid, b.p. 99–99.2°, was isolated. This product contained fluorine and hydrolyzable chlorine atoms and is believed to be the desired addition compound 1,1,-2,3,3,3-hexafluoropropyltrichlorosilane.

(18) L. H. Hals, T. S. Reid and G. H. Smith, THIS JOURNAL, 73, 4054 (1951).

Similar results were obtained, the conversion being always below 1%, with ultraviolet irradiation on 10 weeks exposure, with benzoyl peroxide at various temperatures up to 190°, by passing over silica gel at 250–500°, or without catalyst in an autoclave at 250°. No reaction except some halogen interchange took place with aluminum chloride.

Perfluoroisobutylene did not yield any isolable products when treated with trichlorosilane and *t*-butyl peroxide at 125–130°.

3,3,3-Trifluoropropyltrimethoxysilane.—3,3,3-Trifluoropropyltrichlorosilane (42 g., 0.18 mole) in 160 ml. of dry petroleum ether (b.p. 60–70°) was placed into a 500-ml., three-necked flask (stirrer, Friedrich condenser, addition funnel), and methanol (19.9 g., 0.62 mole) and pyridine (42.9 g., 0.54 mole) were added dropwise at 0°. After standing overnight the pyridine hydrochloride was removed by filtration and the filtrate rectified to give 24.9 g. (63%) of 3,3,3-trifluoropropyltrimethoxysilane, b.p. 141–142° (740 mm.), $n^{21}D$ 1.3546, $d^{20}D$ 1.137.[11]

Attempted conversion of this compound to 3,3,3-trifluoropropyltriethylsilane with ethylmagnesium bromide gave only impure material, the infrared spectrum of which indicated silicon–oxygen bonds.

Alkyl Derivatives.—The following experiment exemplifies the preparation of the alkyl derivatives: a Grignard solution was prepared in a 500-ml. three-necked flask from 9.06 g. (0.37 g.-atom) of magnesium turnings in 250 ml. of anhydrous ether and 40.7 g. (0.37 mole) of ethyl bromide in 50 ml. of anhydrous ether, After this solution was stirred for 2 hr., 27.9 g. (0.093 mole) of 2,3,3,4,4,4-hexafluorobutyltrichlorosilane in 25 ml. of anhydrous ether was added dropwise at 0°. The mixture was stirred for 4 hr. at room temperature and for 12 hr. at reflux temperature. The ether was distilled and the residue heated on a steam-bath for 4 hr. The distilled ether was returned to the flask and the solids broken up and suspended by stirring. The mixture was decomposed with ice and dilute hydrochloric acid. The separated water layer was extracted with ether and the combined ether layers were dried over Drierite. Rectifi-

cation gave 17.3 g. (66.3%) of 2,3,3,4,4,4-hexafluorobutyltriethylsilane, b.p. 173.1°.

The methyl Grignard reactions were run with a 33% excess of Grignard reagent over the theoretically required amount, while a larger excess was used in ethyl Grignard reactions in order to ensure finding any reaction of the β-halogen substituent.

All the tetraalkyl compounds derived from trifluoropropyltrichlorosilane and hexafluorobutyltrichlorosilane were found to be stable toward concentrated hydrochloric acid and 40% aqueous potassium hydroxide at reflux for 14 hr.

Trifluorotetrachloropropyltrichlorosilane.—A Carius tube was charged with 12.1 g. (0.17 mole) of dry chlorine and 27.8 g. (0.093 mole) of trifluorodichloropropenyltrichlorosilane, sealed under a purified nitrogen atmosphere, and irradiated with light from an AH-1 bulb (Gartner Scientific Co.) for 3 days. After removal of the excess chlorine *in vacuo* the white solid residue was distilled to give 31.7 g. (94.9%) of trifluorotetrachloropropyltrichlorosilane, b.p. 118–120° (8.5 mm.). This compound hydrolyzed only slowly in dilute acid.

Anal. Calcd. for $C_3Cl_7F_3Si$: C, 9.74; Cl, 67.28; F, 15.42. Found: C, 10.02; Cl, 67.01; F, 14.79.

Trifluorodichloropropenyltriethylsilane from Trifluorotetrachloropropyltrichlorosilane.—A solution of 30.5 g. (0.075 mole) of trifluorotetrachloropropyltrichlorosilane in 50 ml. of anhydrous ether was added at 0° to a Grignard solution prepared from 12.81 g. (0.54 g.-atom) of magnesium turnings in 300 ml. of anhydrous ether and 57.7 g. (0.54 mole) of ethyl bromide in 100 ml. of anhydrous ether. The resulting suspension was stirred at reflux temperature for 12 hr., the ether distilled, the residue heated on a steam-bath for 5 hr., the ether added again, the mixture decomposed with ice and hydrochloric acid, the aqueous layer extracted with ether and the combined ether layers dried over Drierite. Rectification gave 11.8 g. (56.2%) of trifluorodichloropropenyltriethylsilane, b.p. 112.5–113.5° (23 mm.), $n^{20}D$ 1.4534–1.4535, d^{20}_4 1.189.

The infrared spectrum of this compound was identical with the one of trifluorodichloropropenyltriethylsilane prepared from trifluorodichloropropenyltrichlorosilane.

The Cleavage of Ethers by Hydrogen Bromide

BY ROBERT L. BURWELL, JR., AND MILTON E. FULLER

RECEIVED OCTOBER 29, 1956

The relative reactivities of several alkyl groups have been determined in the internal competitive reaction RR′O + HBr = (RBr, R′Br) + (R′OH + ROH). With initial mole fraction hydrogen bromide of about 0.65, relative reactivities at 26° are: methyl 11.1, ethyl 1.00, propyl 1.00, butyl 0.93, *i*-butyl 0.053, *i*-propyl 0.87, 3-pentyl 4.2 and cyclopentyl 3.8. The first five groups are cleaved apparently by an SN2 reaction, the last three by a reaction to which there is considerable SN1 contribution. The relative reactivities of secondary alkyl groups in ethers decrease with decreasing mole fraction of hydrogen bromide. In the competitive reaction of butyl ether and propyl alcohol with hydrogen bromide, the ether reacts about 7.5 times faster at an initial mole fraction of hydrogen bromide of 0.63; about 1.4 times faster at an initial mole fraction of 0.32. At the higher initial mole fraction, butyl ether reacts about 12 times faster than isopropyl alcohol.

Despite the importance of the alkyl–oxygen bond in organic chemistry, relatively little mechanistic attention has been given to its cleavage in simple ethers and alcohols. Although both ethers and alcohols involve similar factors, the investigation of ethers offers advantages which will appear in the discussion.

The alkyl–oxygen bond cannot be cleaved by displacement reactions in alkyl ethers and alcohols as such but only in complexes in which considerable positive charge is transferred to the oxygen atom, *e.g.*, in such species as R_2OH^+ and $R_2O{:}BCl_3$.[1] In the present work, hydrogen bromide is employed as the cleaving agent. Cleavage by hydrogen bromide of primary alkyl–oxygen and of tertiary alkyl–oxygen bonds seems to occur by typical SN2 and SN1 reactions, respectively.[1] The nature of the cleavage of secondary alkyl–oxygen bonds is in doubt.

The stoichiometry of the reaction is

$$R'RO + HBr = (R'Br, RBr) + (ROH, R'OH) \quad (1)$$

Determination of the ratio R′Br/RBr in the product gives the relative rates of cleavage of the two alkyl–oxygen bonds in the unsymmetrical ether, R′RO. The relative rates of displacement of two groups attached to the same center is an unusually favorable case of competitive reactions.[2] The present paper reports the results of the cleavage of a number of unsymmetric ethers and of the relative rates of cleavage of butyl ether *vs.* propyl and isopropyl alcohols in conventional competitive reactions.

Experimental Procedure

Materials.—The following ethers were prepared by the Williamson synthesis: methyl butyl, b.p. 69.2°; ethyl butyl, 91.9°; propyl butyl, 116.2°; isobutyl butyl, 138.8°; cyclopentyl butyl, 168°; isopropyl propyl, 80°; isobutyl propyl, 107°; 1-ethylpropyl propyl, 128.5°; and diisobutyl, 120–121°. Since unreacted alcohol usually would form an azeotrope with the ether, gross quantities of alcohol were removed by formation of borate esters[3] followed by distillation. Certain ethers were next chromatographed on silica gel with elution by methanol. The ethers were then fractionated from sodium in a 50-plate Stedman column. Butyl ether (Eastman Kodak Co., White Label) was given the last treatment. The infrared absorption spectra of these and the other compounds employed in this research are presented in the doctoral thesis of Milton E. Fuller, Northwestern University, 1956.

The following alkyl halides were either commercial materials subjected to purification or compounds prepared from the corresponding alcohols by standard methods: butyl bromide and isobutyl bromide, Eastman Kodak Co., White

Label; cyclopentyl bromide, Arapahoe Chemicals, Inc.; ethyl bromide, Fisher Scientific Co., certified reagent; methyl bromide, Matheson; propyl bromide and isopropyl bromide. 2-Pentanol was prepared from acetaldehyde and propylmagnesium bromide, 3-pentanol by the hydrogenation of ethyl ketone on nickel–kieselguhr (Harshaw) at 110°, 100 atm. Both pentanols were converted to the corresponding bromides *via* treatment of the tosylates with sodium bromide.[4] Infrared spectra demonstrated the absence of each bromide in the other.

Ether Cleavage.—About 5 cc. of ether was placed in a tube in the form of the Ostwald–Sprengel pycnometer. Anhydrous hydrogen bromide was passed into the tube leading to the bottom of the bulb while the tube was cooled in ice. At the desired weight increase, the inlet and outlet tubes were sealed off. Saturation of an ether gives a mole fraction of hydrogen bromide close to $^2/_3$.

Analytical Procedures.—The reaction mixture contained unreacted ether and hydrogen bromide, both alcohols and both bromides. The analytical scheme involved the removal of everything except the bromides and then analysis of the bromide mixture for the ratio of the two bromides. The reaction tube was opened and its contents blown into a scrubbing tube containing 85% phosphoric acid. Continued passage of dry air carried the bromides and some of the hydrogen bromide and ether forward. The hydrogen bromide was removed by a tube containing sodium hydroxide. The vapor stream then passed through two scrubbing units containing 96% sulfuric acid to remove ether and any residual alcohols. The sulfuric acid traps were kept at 0° to minimize conjunct polymerization. Bromides were then condensed from the vapor stream in a Dry Ice trap. When methyl and ethyl bromides were present, liquid nitrogen was used as the condensing agent and the sweep gas was purified nitrogen. The procedure was carefully checked with known mixtures. Bromide recoveries of over 90% were obtained. Since there were transfer losses in introducing these mixtures into the purification line and in removing the bromides from the trap, recovery in the purification system was substantially quantitative. We estimate that preferential volatilization leads to changes in the bromide composition of less than 0.5 percentage unit.

Samples of liquid bromide mixtures were analyzed by infrared spectroscopy with the Baird double beam instrument.[5] For example, for cleavage of propyl butyl ether, mixtures containing 48.8, 58.5 and 64.6 mole % propyl bromide and the rest butyl bromide were prepared. With the 58.5 mole % sample in cell A, runs were made in succession with each of the three synthetic samples and the product of an actual ether cleavage in cell B. Plots of the logarithm of the % transmission of the synthetic samples against mole % propyl bromide were prepared for a number of wave lengths. The mole % propyl bromide was then determined at the four most favorable wave lengths and averaged. A number of "known" unknowns of isopropyl and propyl bromides and of butyl and propyl bromides were analyzed by this method. The average deviation of the average from the known value was 0.3 percentage unit. The average maximum deviation of the results at any one wave length from the average of all wave lengths was 1.1 percentage units. We estimate that the reported percentage compositions may involve errors amounting over-all to about 1 percentage unit.

The accuracy of these analyses was checked a number of times by preparing a mixture whose composition was that of the analysis of a reaction product. The infrared spectra of the experimental and synthetic samples were compared by the techniques described above. Agreement was satisfactory.

The infrared technique could not be used with the volatile methyl and ethyl bromides. In these cases analysis was by density determination. A series of about five capillary tubes suspended vertically from a larger tube was provided. The volumes of the bulbs were chosen so that in at least one case the sample of mixed bromides would fill the bulb and part of the capillary. The purified sample of bromides was then totally transferred into the appropriate bulb by vacuum distillation, sealed off and the level of the mixture in the capillary at 0° determined. The density was determined by calibration with butyl bromide. The over-all possible errors are about the same as in the infrared method.

At the very end of this research, vapor phase chromatography became available to us. Results of the density analysis of ethyl butyl ether were checked on the Podbielniak Chromacon using tricresyl phosphate on Celite as the stationary phase and hydrogen as the sweep. Actually, all of our reaction products probably could have been analyzed by this means and without the necessity of isolating the bromide mixture. In the one case which we report, the bromide mixture was isolated before analysis.

Experimental Results

Alcohol–Ether Mixtures.—If the analytical determinations just described are to represent relative rates of cleavage of alkyl–oxygen bonds in ethers, reaction 1 must not be subject to interference with the possible subsequent reaction

$$ROH + HBr = RBr + H_2O \qquad (2)$$

To check this, the bromide ratio in the product of reaction of a mixture of symmetrical ether and alcohol was determined and, in most detail, with butyl ether and propyl alcohol. If the reactions of both species with hydrogen bromide have the same kinetics and if both rates are first order in alcohol or ether, the ratio of the rate constants of the two reactions are

$$k_{ether}/k_{alc} = \log(X^0_{ether}/X_{ether})/\log(X^0_{alc}/X_{alc}) \qquad (3)$$

The assumptions cannot be exactly valid and the reaction also suffers interference from reaction 2. However, equation 3 becomes increasingly valid as total conversions decrease. Results of a series of runs are given in Table I. Times of reaction

TABLE I

RELATIVE RATES OF REACTION OF BUTYL ETHER AND PROPYL ALCOHOL

Mole fraction Ether	Mole fraction Alc.	HBr	Reacted, % Ether	Reacted, % Alc.	$\frac{\log(X^0_{ether}/X_{ether})}{\log(X^0_{alc}/X_{alc})}$
0.56	0.12	0.32	11.4	8.0	1.5
.55	.12	.33	15.3	11.4	1.4
.50	.11	.39	26.0	19.2	1.4

.29	.07	.64	48.5	7.6	8.3

varied from 2 to 26 hr. at ambient temperatures. At $X^0_{HBr} = {}^1/_3$, the ether reacts about 1.4 times as fast as the alcohol. This value increases to 7.5 as X^0_{HBr} increases to $^2/_3$. Higher conversions at low values of X^0_{HBr} result in heterogeneous mixtures. Such runs were discarded since the hydrogen bromide rich layer may preferentially extract alcohol from the other phase. Because of the low concentration of propyl bromide in the product in the last 5 runs of Table I, about 4%, the relative reactivity is subject to an error of about ±1. The probable error for the first 5 runs (about 14% propyl bromide) is ±0.2.

At $X^0_{HBr} = 0.62$, the ratio of the rates of reaction of butyl ether and isopropyl alcohol is about 12.

The relative rate of reaction of alcohols is substantial but, since in cleavage of unsymmetric ethers the ether starts at a finite mole fraction and the alcohol at zero, the effect of reaction 2 can be made negligible by confining the cleavage reaction to low conversions. The data in the next section appear free of interference from reaction 2 to within the estimated experimental error.

Ether Cleavage by Hydrogen Bromide.—The results of ether cleavages are shown in Tables II–V. Reaction temperatures were the ambient, about 26°.

Isomerization During Cleavage.—As shown in Table V, substantial amounts of 2-pentyl bromide appeared in the cleavage of propyl 3-pentyl ether. However, much or all of this isomerization could have occurred during isolation of the bromides. Reaction of hydrogen bromide with a mixture of propyl ether and 3-pentyl bromide yielded a bromide fraction in which about 8% isomerization of the 3-pentyl to 2-pentyl bromide had occurred. Also, on merely carrying a sample of 3-pentyl bromide through the isolation apparatus, 10.7% isomerization occurred.[6] Vapor phase chromatography of the total reaction mixture might yield analyses devoid of accompanying isomerization.

Isobutyl bromide passed through the isolation apparatus without detectable change. No detectable content of *t*-butyl bromide appeared in the products of cleavage of propyl isobutyl and butyl isobutyl ethers (Tables III and IV); however, with the low concentration of isobutyl bromide, this test of isomerization was not sensitive. Accordingly, isobutyl ether was cleaved with hydrogen bromide. About 0.4% *t*-butyl bromide was found in the product.

Discussion

The reaction mixtures of most of our experiments (initial mole fraction of hydrogen bromide about $^2/_3$, of ether about $^1/_3$) are undoubtedly rather complicated mixtures of various species. The relatively high electrical conductivity[7] and the Raman spectra[8] of ether–hydrogen chloride solutions indicate the presence of dialkylhydronium ions, $RR'HO^+$.

The saturation ratio of about two moles of hydrogen bromide to one of ether suggests that the negative ion $BrHBr^-$ is important.[9] Most of the

ionized species must be involved in ion pairs or in higher aggregates.

Presumably, there will also be substantial concentrations of hydrogen bonded species, RR'O·HBr, particularly at lower concentrations of hydrogen bromide. In any case, the drastically reduced partial pressure of hydrogen bromide from ether solutions (the vapor pressure of pure hydrogen bromide is 12.3 atm. at 0°) indicates strong interaction between ether and hydrogen bromide.

The reactive form of the ether must be the dialkylhydronium ion[1] and the displacing species is presumably an anion such as Br^- or $BrHBr^-$, although, particularly at lower concentrations of hydrogen bromide, RR'O·HBr may be involved.

Bennett and Reynolds[10] investigated the cleavage of the R–O bond by measurement of the rate of reaction between alcohols and hydrogen bromide in aqueous phenol. Variation in basicities of the alcohols must have influenced rates. Such an effect may be small, but it represents an uncontrolled variable. The problem of relative basicities does not enter into an analysis based on equation 1. However, a new uncertainty does; each reaction occurs in a slightly different medium because of the change of ether. In addition, the possibility of steric hindrance of one alkyl group by the other must be considered, but models indicate that such effect is negligible in the ethers under consideration.

Table VI

Relative Rates of Reaction

Methyl	Ethyl	Propyl	Butyl	*i*-Butyl	*i*-Propyl	*s*-Butyl	3-Pentyl	Cyclopentyl
ROR' + HBr at 26°, X^0_{HBr} *Ca.* 0.65								
11.1	1.00	1.00	0.93	0.053	0.87		4.2	3.8
ROH + HBr in aqueous phenol, 83° (ref. 10)								
5.6	1.00	0.87	0.90	0.11	2.30	5.5		
$ROSO_3^-$ + H_2O, first order, 138° (ref. 14)								
1.79	1.00	0.65		0.15	16	19.5		
Br^- + RBr in acetone, 25° (ref. 13)								
76		1.00	0.65		0.033	0.011		

The first line of Table VI presents the relative rate of cleavage compared with ethyl for various alkyl groups at a mole fraction of hydrogen bromide of about 0.65. These are derived from the data on competitive cleavage of unsymmetrical ethers presented in Tables II–V. We did not plan to obtain absolute kinetics, but the data of these tables indicate that the time in minutes required for 20% cleavage of the various ethers at $X_{HBr} = 0.65$ was: ethyl butyl, propyl butyl and isopropyl propyl, 55; methyl butyl, 5 to 6; isobutyl propyl, 90; isobutyl butyl, 110; cyclopentyl butyl and 3-pentyl propyl, 30. These times are in good agreement with the relative rate data of Table VI. The agreement suggests that the change in medium consequent to the change in ether for each competitive cleavage is not too serious, although the variation in medium remains, to some extent, as an uncontrolled variable.

There is some disagreement in the older literature as to the products of the cleavage of propyl isopropyl ether.[1] With the mole fraction of hydrogen bromide about 0.65, both bromides are formed with propyl bromide in slightly the greater quantity. On the basis of Ingold's kinetic criterion[11] then, the isopropyl group is cleaved by a mechanism differing from that of the propyl group. The secondary alkyl groups apparently are cleaved by a reaction to which the form R^+ OHR makes considerable contribution. Similar considerations apply to the reaction between alcohols and hydrogen bromide in aqueous phenol[10] (Table VI, second series).

Relative rates of cleavage of propyl–oxygen *vs.* isopropyl–oxygen bonds are influenced by the initial mole fraction of hydrogen bromide. As shown in Table IV, the reactivity of isopropyl *vs.* propyl decreases from 0.8 at $X^0_{HBr} = 0.66$ to 0.52 at $X^0_{HBr} = 0.35$. A similar effect is observed in the cleavage of butyl cyclopentyl ether (Table III). The decreasing relative rate of cleavage of the *sec*-alkyl–oxygen bond presumably results from the declining polarity of the medium.

To the extent that the three ethers with secondary alkyl groups are cleaved by the same mechanism, the relative figures for the three groups represent relative rate constants. However, in view of the probable change of mechanism, the relative reactivities are not ratios of rate constants in comparisons between primary and secondary groups.

The relative rates in the primary ether sequence, particularly the large value of methyl and the low value of isobutyl, are typical of S$_N$2 reactions[12] such as the exchange reaction between bromide ion and alkyl bromides[13] (Table VI, fourth series). One would not expect the relative reactivities of the primary groups to change substantially with the mole fraction of hydrogen bromide. As shown in Table III, we could detect no difference in the bromide ratio in the cleavage of propyl butyl ether in varying the mole fraction from 0.27 to 0.67. Unlike such reactions as the first-order solvolysis of the alkyl sulfate ion,[14] there is probably no large amount of S$_N$1 character in the sequence of primary alkyl ether cleavages. The near absence of isomerization of isobutyl to *t*-butyl during cleavage of isobutyl ether is consistent with this.

Our data do not establish the exact nature of the cleavage of *sec*-alkyl–oxygen bonds. We attempted to determine the degree of isomerization consequent to the cleavage of the 3-pentyl group but were prevented by the isomerization which accompanied the isolation process. Isomerization during cleavage, if any, stops well short of equilibrium so that the reaction does not involve an extreme form of carbonium ion reaction, but this would hardly be expected. Successful determination of the degree of isomerization of the 3-pentyl group and of the exact stereochemistry in cleavage of the optically active *sec*-butyl group would be of value.

Olefin formation probably does not accompany the cleavage of primary groups since, if it had, the olefin would have reacted with hydrogen bromide

to form secondary alkyl halides. In particular, none was detected in cleavage of propyl butyl ether carried to extensive conversions.

The reactivity in ether cleavage of propyl relative to ethyl, 1.00 (Table VI), is large. The value 0.65 (Table VI) is about the average for a group of halide exchange reactions.[13] In general, the value for propyl is distinctly less than 1.0.[12] Our value depends primarily upon the cleavage of ethyl butyl ether, the analyses for which were performed both by density and by vapor phase chromatography (Table II). The reactivity of propyl in a reaction which also involves a positively charged species, that of alcohols with hydrogen bromide in aqueous phenol,[9] is also large, 0.87. In fact, and not surprisingly, this reaction parallels the ether cleavage rather closely. It has been proposed that the relative reactivity of propyl in general should be about $^2/_3$ on the basis that rotation about the central carbon–carbon bond in propyl compounds would lead the terminal methyl group to obstruct the entering groups in $^1/_3$ of the possible configurations.[15] The effect would appear in the pre-exponential frequency factor.[15,16]

Relative Rates of Reaction of Ethers and Alcohols with Hydrogen Bromide.—Table I presents the first direct data on the relative rates of cleavage of the alkyl–oxygen bond in ethers and in alcohols. Ethers appear to be less basic than alcohols.[17] At concentrations of hydrogen bromide high enough to protonate both ether and alcohol completely, the relative reactivity would be that of the hydronium ions. With decreasing acidity, the ratios of hydronium ions would involve the relative basicities, and the alcohol would become relatively more reactive. The observed data fit this scheme. At a total mole fraction of hydrogen bromide of 0.63, butyl ether reacts 7.5 times as fast as propyl alcohol; at a mole fraction of 0.33, 1.4 times faster. At the higher mole fraction, butyl ether reacts about 12 times faster than isopropyl alcohol. To within the rather low precision of the data, the computed relative reactivities of propyl and isopropyl alcohols are the same as those of propyl and isopropyl groups in propyl isopropyl ether, 0.8 (Table VI). The ether–HBr medium is somewhat more favorable to nucleophilic displacement than hydrogen bromide in aqueous phenol in which isopropyl alcohol reacts 2.6 times faster than propyl alcohol (second series in Table VI).

EVANSTON, ILLINOIS

COMMUNICATIONS TO THE EDITOR

THE POLYMERIZATION OF α-BENZYL-L-GLUTAMATE N-CARBOXY ANHYDRIDE

Sir:

In a recent communication[1] Doty and Lundberg have claimed that during the primary-amine-initiated polymerization of γ-benzyl-L-glutamate N-carboxy anhydride in dioxane solution at 25° two successive stages may be recognized. Using *n*-hexylamine as initiator these authors concluded that the initial part of the polymerization (up to a degree of polymerization of approximately 8) is comparatively slow, with a rate constant of $5–7 \times 10^{-3}$ mole^{-1} l. sec.$^{-1}$. Following this stage in the growth of the polymer an acceleration was reported, the final rate constant being approximately 3×10^{-2} mole^{-1} l. sec.$^{-1}$. The acceleration was correlated with the adoption by the growing polymer chain of an α-helical configuration at a degree of polymerization of about 8. A similar effect, rather smaller in magnitude, was obtained with the DL-anhydride.

We have previously reported[2] that under certain conditions the polymerization of DL-leucine and DL-phenylalanine N-carboxy anhydrides show auto-acceleration. This is in no way connected with the size of the growing polymer, but results from the presence of impurities in the anhydrides. It can be eliminated in these cases by the use of dry-box techniques and purification of the anhydrides by sublimation. In view of these results it appeared desirable to repeat the experiments of Doty and Lundberg, particularly since γ-benzyl-L-glutamate N-carboxy anhydride cannot be purified by sublimation.

We have studied chloride and acid-free samples of the anhydride prepared by phosgenation of the amino acid (the technique apparently used[3] for the anhydrides of Doty and Lundberg) and also from the carbobenzoxy derivative of the amino acid by treatment with phosphorus pentachloride.[4] The materials were crystallized from chloroform in both cases and stored *in vacuo* until required. Dry-box techniques were used throughout, and the rates of reaction were measured in constant-volume and

(5) L. F. Fieser, "Experiments in Organic Chemistry," 2nd Ed., D. C. Heath and Co., Boston, 1941, p. 369.

When several recrystallizations were required to obtain chloride-free anhydride it was always found that the polymerization was auto-catalytic. However, the rate constant never increased to more than twice its initial value, and generally the change was much less than this. We have never observed the much larger increases noted by Doty and Lundberg. Our results are in fact those which would be anticipated for an unsublimed anhydride on the basis of our previous work.[2] Moreover, the acceleration was independent of the nature of the initiator, and similar results were obtained by initiation with *n*-hexylamine, and preformed polymers up to a degree of polymerization of 15. The observations are summarized in Table I.

Clearly polymeric initiators both larger and smaller than 8-mers give approximately the same rate constants. It should be noted that anhydrides which have been stored for several days in vacuum desiccators give appreciably higher rates than those in the table.

Recently, by modifying the conditions of preparation using the phosgene technique, we have been able to make an anhydride which required for its purification from chloride and acid only one rapid crystallization. The polymerization of this material showed no acceleration whatever. Figure 1

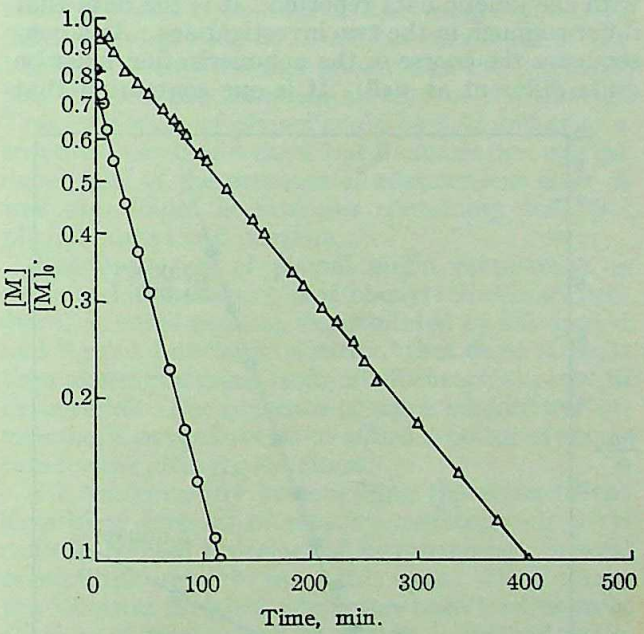

Fig. 1.—The polymerization of γ-benzyl-L-glutamate N-carbonic anhydride initiated by *n*-hexylamine, in dioxane at 25°. Initial anhydride concentration $[M]_0 = 0.151$ mole l.$^{-1}$. *n*-Hexylamine concentrations: ○, 3×10^{-2} mole l.$^{-1}$; △, 1×10^{-2} mole l.$^{-1}$.

indicates the course of the reaction for initiation by *n*-hexylamine, using anhydride to initiator ratios of 5 and 15. In both cases, after the initial rapid reaction of the *n*-hexylamine (this kind of effect has been discussed elsewhere[2]), the reaction was first order over its whole course, with a velocity constant close to 9.5×10^{-3} mole^{-1} l. sec.$^{-1}$. We consider this represents the most reliable value so far obtained for the normal propagation coefficient for this anhydride. These results show definitely that this coefficient does not depend on the length of the

growing chain (after the first one or two units have been added to the initiator if the latter is not a preformed polymer) and suggest that the propagation reaction is essentially similar to that established for the polymerization of DL-phenylalanine and DL-leucine N-carboxy anhydrides. Similar observations have been made in nitrobenzene and N,N-dimethylformamide solutions.

POLYPEPTIDES. Xa. ADDITIONAL COMMENTS OF THE AMINE-INITIATED POLYMERIZATION

Sir:

The foregoing communication by Ballard and Bamford[1] disputes our finding of two successive propagation constants in the polymerization of γ-benzyl-L-glutamate N-carboxy-anhydride and thereby casts doubt on the identification we had made of the first, relatively slow propagation with the randomly coiled configuration and the second, faster propagation with the α-helical configuration which is attained by each growing chain when it passes a critical chain length.[2]

In each case the interpretations are consistent with the kinetic data reported: it is the data that differ so much in the two investigations. As a consequence the course of the polymerization must be quite different as well. It is our contention that our N-carboxy anhydride was in such a state of purity that the polymerization consists simply of a rapid initiation followed by chain growth characterized by two successive propagation constants, the second taking over from the first when the chain reaches a length of about eight.

Since there is no indication that Ballard and Bamford[1] have followed precisely the procedure of anhydride preparation and purification[3] we employed, their failure to reproduce our results is not surprising inasmuch as the kinetic effect we have isolated is easily suppressed. On the other hand, we have observed the behavior they report with relatively unpurified anhydride. Since upon sufficient recrystallization the behavior we have reported was always found we have naturally concentrated our attention on what appeared to be the purer and more reproducible anhydride. Although this work is reported in detail in forthcoming papers,[4,5] two particularly relevant points deserve mention here.

(1) If the N-carboxy anhydride is used after its first crystallization a linear first-order behavior similar to that of Ballard and Bamford[1] is observed throughout the polymerization (A in Fig. 1). However, after one recrystallization from methylene dichloride the two successive propagations are clearly evident (B in Fig. 1). Since the HCl content of the unrecrystallized anhydride was 1.0 mole % and since this could react with the initiator, *n*-hexylamine, to produce a possibly "active" impurity, we

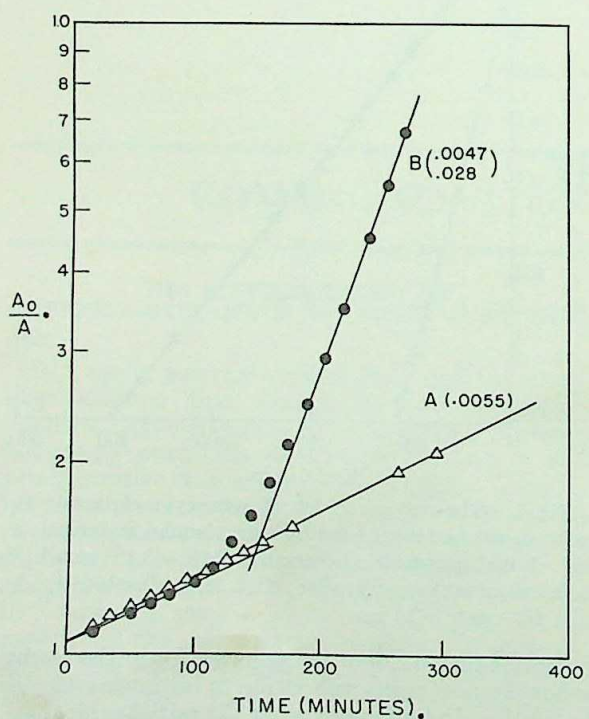

Fig. 1.—Polymerization of γ-benzyl-L-glutamate N-carboxy anhydride initiated with *n*-hexylamine ([A]/[I] = 20) in dioxane solution at concentration of 4 g./100 cc. at 25.0°. Case A corresponds to impure anhydride and case B to the same anhydride after one recrystallization.

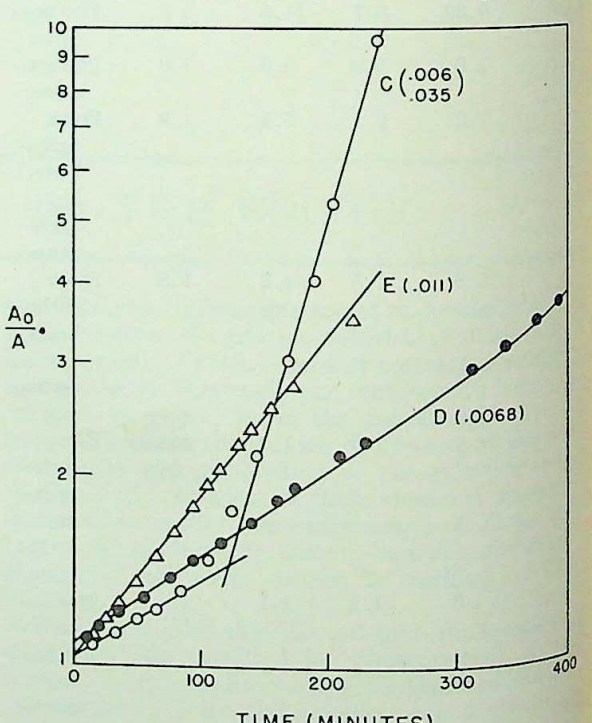

Fig. 2.—Polymerization under same conditions as Fig. 1. Case C is a highly purified anhydride (HCl < 0.1 mole %). Cases D and E correspond to the addition of *n*-hexylamine hydrochloride to the extent of 0.67 and 5.0 mole %, respectively.

carried out polymerizations with a highly purified anhydride[5] (C in Fig. 2) to which 0.67 and 5.0 mole % of *n*-hexylamine hydrochloride had been added (D and E in Fig. 2). The results show that this adduct eliminates the second propagation step and produces pseudo first-order reactions which bracket the one reported by Ballard and Bamford[1] as "the most reliable thus far obtained." It is evident, therefore, that the results of Ballard and Bamford can be reproduced by impure anhydride or by the addition to highly purified anhydride of one of the impurities removed during its purification. Thus, the sensitivity of this effect to contamination of the anhydride suggests that the presence of *some* impurity is the most likely explanation of their results. Space prevents taking up other possibilities that could arise from not carrying out the purification of the anhydride at −30° as described.[5] Moreover, the premise of Ballard and Bamford concerning the uniqueness of the sublimation in anhydride purification appears invalid inasmuch as we have observed the two successive propagation steps to be even more dramatically exhibited in L-leucine N-carboxy anhydride, both before and after sublimation of the product purified as described.[5] Consequently, we cannot concede that Ballard and Bamford's failure to observe the reported kinetic effect is evidence against its existence.

(2) The kinetic effect we have reported must, of course, be reflected in the molecular weight distribution of the product. In this case, the distribution must be exceedingly broad as we have reported.[2] In case C, for example, the number average DP is 20 and the weight average DP is 170.[6] If, on the other hand, the second propagation step is suppressed as in Case D, the distribution should narrow. This is indeed observed: for case D, $DP_w = 46$, $DP_N = 17.5$. The analysis of the products, therefore, is seen to support the original contention that two successive rate constants are observed under the conditions reported.

We wish to thank Dr. E. R. Blout for his very helpful collaboration in this work.

AN ALLEGED FREE RADICAL REACTION IN WHICH BENZENE UNDERGOES ATTACK MORE READILY THAN NITROBENZENE

Sir:

Wieland and Meyer[1] reported that the reaction of triphenylmethyl radical with aromatic substrates, in the presence of benzoyl peroxide, afforded *para*-substituted tetraphenylmethanes. The discovery[2] that these substances were, in reality, *meta* isomers, prompted us to reinvestigate the reaction.

Although nitrobenzene as a substrate was not studied in the original Wieland[1] work, it seemed of special interest to us because of its propensity to participate in free radical reactions with greater ease than benzene itself ($C_6H_5NO_2/C_6H_6)K = 4$).[3]

We found that when triphenylmethyl radicals (in the presence of benzoyl peroxide) were permitted to compete for benzene and nitrobenzene (equimolar mixture) the only products that could be detected were tetraphenylmethane (10%) and *p*-bis-triphenylmethylbenzene, m.p. 330° (9%). (The latter was identical in m.p. and infrared spectrum with material prepared by an independent synthesis.) Both infrared analysis of the crude reaction product and C^{14}-tracer experiments confirmed that nitrotetraphenylmethanes were formed only in trace amounts, if indeed at all.

In conjunction with this work, it was also found that triphenylmethyl radical is not consumed to any appreciable extent by reaction with the nitro function of nitrobenzene in the *absence* of benzoyl peroxide. This is in contradiction to the report by Hammond and Ravve[4] that a quantitative reaction occurs, to afford triphenylcarbinol, azobenzene and phenol among other products.

After a benzene solution of triphenylmethyl (prepared in benzene from triphenylmethyl chloride and mercury) and nitrobenzene had been exposed to diffuse daylight for 24 hours, practically all of the triphenylmethyl was still present and infrared analysis showed the complete absence of azobenzene. Trace amounts of phenol could be detected after a reaction period of 4 days, but its formation was independent of the presence of nitrobenzene since it was also found in mixtures containing only triphenylmethyl and benzene.

The formation of phenol might reasonably be explained by assuming that phenyl radicals are produced in some manner, as postulated by Hammond and Ravve, but the implication[4] that these radicals then abstract oxygen from nitrobenzene appears to be invalid. The presence of trace amounts of atmospheric oxygen seems to afford a better explanation for the phenol production.

We are currently investigating the cause of the surprising reversal of relative reactivity of trityl radicals toward benzene and nitrobenzene. Several possibilities occur to us at this time. (1) Perhaps the Wieland reaction, which has been traditionally considered free radical in nature is instead ionic. (2) The trityl radical may have some carbonium ion character due to the I effects of the three phenyl groups.[5] (3) An ion-pair type complex might form rapidly and reversibly between the easily oxidized trityl radical and nitrobenzene, thus vitiating normal trityl radical attack on that nucleus.

While the first of these explanations cannot be dismissed at this time, it does not seem like an attractive possibility. The Baeyer–Villiger reaction,[6] which almost certainly proceeds *via* a tritylcarbonium ion, occurs only with activated nuclei. Even toluene does not react in a four day period.[2] The

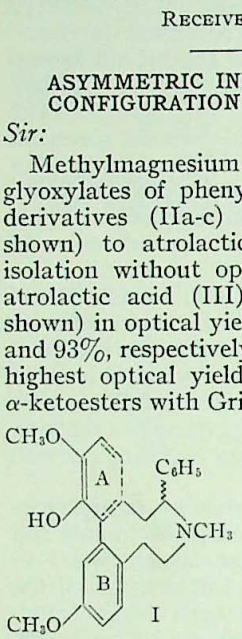
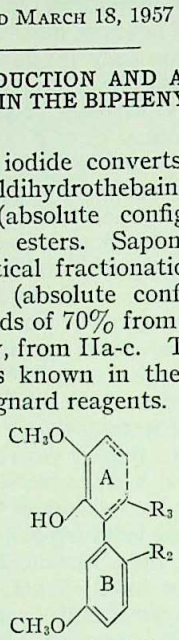
ASYMMETRIC INDUCTION AND ABSOLUTE CONFIGURATION IN THE BIPHENYL SERIES

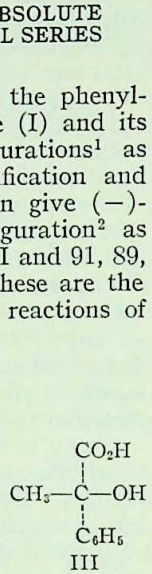
Sir:

Methylmagnesium iodide converts the phenylglyoxylates of phenyldihydrothebaine (I) and its derivatives (IIa-c) (absolute configurations[1] as shown) to atrolactic esters. Saponification and isolation without optical fractionation give (−)-atrolactic acid (III) (absolute configuration[2] as shown) in optical yields of 70% from I and 91, 89, and 93%, respectively, from IIa-c. These are the highest optical yields known in the reactions of α-ketoesters with Grignard reagents.



I

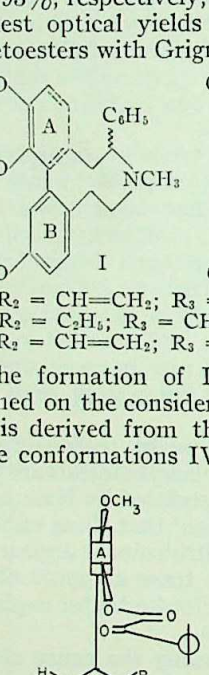




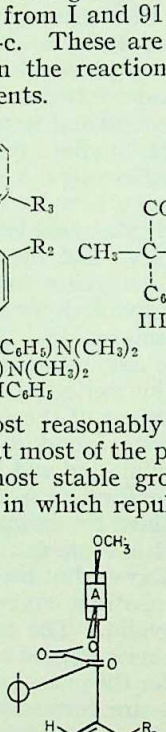
III

IIa, R_2 = CH=CH$_2$; R_3 = $CH_2CH(C_6H_5)N(CH_3)_2$
b, R_2 = C_2H_5; R_3 = $CH_2CH(C_6H_5)N(CH_3)_2$
c, R_2 = CH=CH$_2$; R_3 = CH=CHC_6H_5

The formation of III is most reasonably explained on the consideration that most of the product is derived from the two most stable ground state conformations IV and V, in which repulsive



IV



V

interactions are minimized by disposition of the two keto groups coplanar-transoid and the plane of the phenylglyoxylate chain as far away as possible from the ring A methoxyl and ring B, *i.e.*, perpendicular to ring A and at a dihedral angle of 60° with respect to ring B. Approach to the keto carbonyl group in IV and V by the attacking methyl must occur from the direction of ring A, since the underside of the keto group is shielded by ring B. If the rotational barrier between IV and V is high, the major proportion of the product is derived from V, which is more stable than IV because the phenylglyoxylate chain interferes with H instead of R. If the rotational barrier is low compared to the energy of activation for chemical reaction, the product proportions are controlled by the difference in free energy between the transition states derived from IV and V.[3] That from V is the more stable, since in it, the compression of the groups attached to the keto carbonyl as the latter begins to become tetrahedral is against H, whereas in that from IV, this compression is against the large group R. When the effective bulk of R increases (I → II), the stereoselectivity increases. A number of alternative interpretations ascribing special stability to other conformations because of chelate complexing, appear less probable. In particular, the conformation in which each carbonyl group is complexed with a ring methoxyl, and the plane of the phenylglyoxylate residue is perpendicular to ring A and parallel to ring B, would also lead to III. However, in order to explain on this basis the fact that the stereoselectivities with the phenylglyoxylates of IIa-c are 3.5 to 5.8 times greater than with that of I it is necessary to assume that the degree of complexing is less in the latter case. There is no obvious reason why this should be so and, at present, this alternative, while not rigorously excluded, appears unlikely.

In elegant studies, McKenzie, Prelog, Turner and their respective co-workers have examined a large number of reactions of the general type $R_1COCO_2R_a + R_2MgX \rightarrow \rightarrow R_1R_2C(OH)CO_2H$. In eighteen such cases, complete resolution data are available on the product hydroxyacid and, using these, we have now calculated optical yields.[4] For a fixed asymmetric group (R_a), the optical yield is quite insensitive to the size of the incoming group (R_2), but becomes larger as the size of the group (R_1) *already attached* to the keto group increases. This phenomenon requires modification of the previously proposed[5] shielding effect theory of asymmetric induction in α-ketoesters. It is most readily encompassed by the hypothesis that the relative contribution to the total product made by conformation VI diminishes with increasing size of R_1 because of compression effects of the type discussed above.

CYANOCARBON CHEMISTRY—SYNTHESIS AND CHEMISTRY OF TETRACYANOETHYLENE

Sir:

Investigation of cyanocarbons, compounds containing only —C≡N groups attached to carbon,

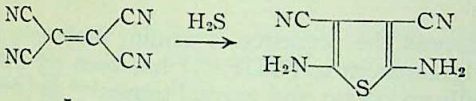
CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

and their derivatives has led to the preparation of tetracyanoethylene (I), the first example of a percyanoölefin. This compound has been shown to be exceptionally reactive and readily undergoes a series of addition and substitution reactions.

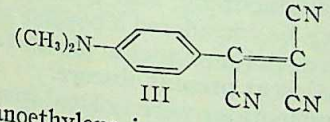
Treatment of dibromomalononitrile–potassium bromide complex[1] with copper powder in benzene under reflux yielded tetracyanoethylene in 65% yield. The product is a white crystalline solid melting at 198–200° in a sealed tube and subliming readily at temperatures above about 120°. (*Anal.* Calcd. for C_6N_4: C, 56.26; N, 43.74; mol. wt., 128. Found: C, 56.42, 56.39; N, 43.23, 43.50; mol. wt., 132.) Tetracyanoethylene is very stable thermally, being unchanged by brief treatment at 600°, and it is resistant to the action of oxygen at moderate temperatures, although it will burn in air.

Tetracyanoethylene is a mild oxidizing agent and converts mercaptans to disulfides, being itself reduced to tetracyanoethane in the process. By treatment with hydrogen sulfide in the presence of pyridine, tetracyanoethylene is converted readily to 2,5-diamino-3,4-dicyanothiophene (II) (92% yield). (*Anal.* Calcd. for $C_6H_4N_4S$: N, 34.13; S, 19.53. Found: N, 34.06, 34.22; S, 19.37.)



I II

It also reacts with alcohols to give 2,2-dicyanoketene acetals and with N,N-dialkylanilines to give *p*-tricyanovinylaryl amines, a new class of dyes of high tinctorial strength. For example, *p*-tricyanovinyl-N,N-dimethylaniline (III), m.p. 173–175°, has λ_{max} 514 mμ and ϵ_{max} 41,500. (*Anal.* Calcd. for $C_{13}H_{10}N_4$: C, 70.25; H, 4.54; N, 25.21. Found: C, 70.31; H, 4.51; N, 25.11.)



III

Tetracyanoethylene is a very active dienophile, condensing quantitatively with butadiene at 0° to give 4,4,5,5-tetracyanocyclohexene (IV), m.p. 201–202°. (*Anal.* Calcd. for $C_{10}H_6N_4$: C, 65.92; H, 3.32; N, 30.76. Found: C, 65.84, 65.67; H, 3.44, 3.42; N, 30.59, 30.65.)[2] Monoalkylation of ketones having hydrogen alpha to a carbonyl group occurs in the presence of acid catalysts to give α-tetracyanoethyl ketones.[3] For example with acetone in the presence of boron trifluoride at room temperature, 4,4,5,5-tetracyano-2-pentanone (V) is formed in 90% yield; m.p. 118–120° dec. (*Anal.* Calcd. for $C_9H_6N_4O$: C, 58.06; H, 3.25; N, 30.10. Found: C, 58.26, 58.47; H, 3.21, 3.22; N, 30.04, 30.10.)

EFFECTS OF RING SIZE ON THE REACTIONS OF CYCLIC OLEFINS: HALOHYDRINS FROM METHYLENECYCLOALKANES[1]

Sir:

As part of a study of the effects of ring size on the orientations of addition reactions with cyclic olefins, we have included additions of hypohalous acids to a series of methylenecycloalkanes (ring sizes C_4 through C_7). Although we observed no orientation effects when hydrogen bromide was the addend,[2] significant differences were obtained with hypohalous acids. Additions of hypohalous acids to acyclic 1-alkenes always occur predominantly or exclusively with "normal" orientation (primary halogen).[3] We have found however that addition of HOCl to methylenecycloalkanes gives mixtures of chlorohydrins, with "abnormal" orientation predominating with the 4- and 6-membered ring compounds,[4] and that addition of HOBr to these olefins gives only "abnormally" oriented bromohydrins.

Freshly distilled aqueous HOCl or HOBr solution[5] was added in portions to a stirred aqueous suspension of an equivalent amount of methylenecycloalkane at 15°. The mixture was stirred for an hour longer and the layers were separated. The infrared spectrum of the dried organic layer was recorded before distillation. The fractions obtained on distillation were identified by comparison with authentic samples previously synthesized. Both the spectrum taken before distillation and the proportions of distillate in the fractions were used in estimating product distributions. These data are summarized in Table I. From isobutylene and HOBr we obtained a 77% yield of addition product which was about 97% 1-bromo-2-methyl-2-propanol.

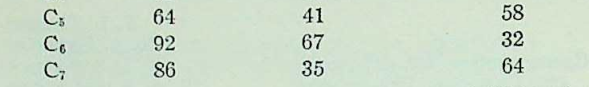
TABLE I

PRODUCT DISTRIBUTIONS IN HYPOHALOUS ACID ADDITIONS TO METHYLENECYCLOALKANES

Ring size	Hypochlorous acid: Total yield, %	Proportion of total, %			Hypobromous acid: Total yield, %	Proportion of total, %	
		>C(Cl)CH₂OH	>C(OH)CH₂OH	Other product		>C(Br)CH₂OH	Other products
C_4	72	60	40	none[a]	78	99	1[b]
C_5	64	41	58	1[b]	67	91	9[c]
C_6	92	67	32	1[b]	89	98	2[d]
C_7	86	35	64	1[b]	87	87	13[d]

[a] No rearrangement products were found. [b] Slight absorption attributable to a carbonyl group (probably in cycloalkanecarboxaldehyde) appeared in the infrared spectrum of the product. [c] Methylenecyclopentane oxide. [d] Cycloalkanecarboxaldehyde.

The preponderance of "abnormally" oriented products from the 4- and 6-membered rings is consistent with the view that trigonal carbons in those rings are unfavored.[6] The initially formed pi-complex (I) may rearrange (as usual) to the conventional carbonium ion (II),[3,7] or it may suffer direct attack by water to give III. Rearrangement of I to II is the less favored path for 4- and 6-membered rings, but is satisfactory for 5- and 7-membered



I II III

rings.[8] The formation of large amounts of III even from 5- and 7-membered rings, when acyclic olefins give corresponding products only in very small amounts, indicates that this explanation is incomplete and suggests an importance of the ring structure itself in directing orientation. That suggestion is further supported by the complete contrast between HOBr additions to methylenecycloalkanes and to isobutylene.

Since "abnormal" products were not obtained with HBr as addend,[2] it appears that the size of the attacking cation (or the "activity" of the attacking particle[9]) may have an important role in determining the actual orientation with these olefins. We hope that our continuing studies will reveal more explicit information about these effects.

Authentic 1-chloromethylcycloalkanols (except for 1-chloromethylcyclobutanol) were synthesized by hydrolysis of the appropriate methylenecycloalkane dichloride with an aqueous suspension of $CaCO_3$.[10] These chlorohydrins all reduced permanganate, gave precipitates with NaI in acetone and with alcoholic $AgNO_3$, produced immediate cloudiness in Lucas reagent and showed infrared absorption near 7.25 μ (tertiary alcohol). Authentic 1-halocycloalkylmethanols were synthesized by the action of hydrochloric or hydrobromic acid on the appropriate olefin oxide. These halohydrins all reduced permanganate, gave precipitates with alcoholic $AgNO_3$ but none with NaI in acetone, gave negative Lucas tests and showed no infrared absorption near 7.25 μ.

URIDINE DIPHOSPHATE N-ACETYLGLUCOSAMINE AND URIDINE DIPHOSPHATE GLUCURONIC ACID IN MUNG BEAN SEEDLINGS

Sir:

Whereas the presence of uridine diphosphate N-acetylglucosamine (UDPaG) has been reported in penicillium, yeast and animal tissues[1-3] and uridine diphosphate glucuronic acid (UDPGuc) in liver tissue, these nucleotides have hitherto been unknown in higher plants.

In the present communication evidence is presented for the existence of UDPaG and UDPGuc in mung bean seedlings. Furthermore, these seedlings contain a hitherto unknown enzyme which catalyzes the reaction between UDPGuc and pyrophosphate to form uridine triphosphate (UTP) and presumably D-glucuronic acid 1-phosphate. While UDPGuc may be considered a possible precursor of the synthesis of polyuronides in plants, the function of the UDPaG is at present obscure.

The two nucleotides were isolated from 10 kg. of mung bean seedlings using methods described by Ginsburg, *et al.*[4] The nucleotide fraction eluted from the Dowex-1-Cl^- column by 0.01 *N* HCl–0.15 *N* NaCl was further purified by paper chromatography.[3] In this way 14 μmoles of a nucleotide (I) corresponding in R_f to authentic UDPaG (R_f 0.45) was separated. A second nucleotide fraction, eluted by 0.01 *N* HCl–0.06 *N* NaCl, was further purified by paper electrophoresis in formate buffer at *p*H 3.5[4,5] to yield 4 μmoles of a nucleotide (II) corresponding to UDPGuc in electrophoretic mobility.

Hydrolysis of both nucleotides with 0.1 *N* HCl at 100° for 10 minutes liberated chiefly uridine diphosphate, while hydrolysis with 1.0 *N* HCl yielded

May 5, 1957

chiefly uridine monophosphate. In both cases a sugar was also set free. The degradation products were identified by paper chromatography and electrophoresis. Hydrolysis of I with 0.05 *N* HCl for 10 minutes at 100° yielded a substance which reacted as an N-acetylhexosamine.[6] It was identified as acetylglucosamine by paper chromatography,[2,7] and by paper electrophoresis at *p*H 5.8 (ammonium acetate) and *p*H 8.6 (borate).[8] Hydrolysis of I with 2 *N* HCl for 2 hours at 100° liberated a substance giving a positive reaction for hexosamine. This was identified as glucosamine by paper chromatography,[7,8] electrophoresis,[8] and by degradation to arabinose with ninhydrin.[7]

Mild acid hydrolysis of II set free a hexuronic acid (carbazole test) which was shown to be glucuronic acid by paper chromatography[9] and by electrophoresis at *p*H 3.5.[4,5] The analyses of the two nucleotides are presented in Table I. It is thus shown that substances I and II are UDPaG and UDPGuc, respectively.

TABLE I

ANALYSES OF NUCLEOTIDES FROM MUNG BEAN SEEDLINGS

	(I) μmole/μmole uridine[a]		(II)	
	Found	Calcd. for UDPaG	Found	Calcd. for UDPGuc

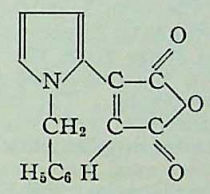
THE REACTION OF N-BENZYLPYRROLE WITH ACETYLENEDICARBOXYLIC ACID[1]

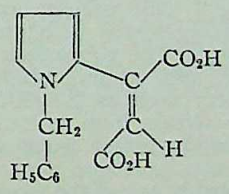
Sir:

The reaction of pyrroles with dienophiles has been shown to lead to substitution in the α-position of the pyrrole and, in some cases, to poly-substitution products such as dihydroindoles.[2] There has been no authenticated report of a pyrrole undergoing a normal Diels–Alder type of addition in the sense that, for example, furan will partake of Diels–Alder addition to dienophiles.[3]

We have found that refluxing an ether solution of N-benzylpyrrole and acetylenedicarboxylic acid for 24 hours gives rise to three products which were separated readily by taking advantage of their varying solubility properties. Two of these products, which had characteristic yellow colors, were shown to be α-substituted pyrroles on the basis of their elemental analyses, neutral equivalents, infrared spectra, common conversion by hydrolysis and hydrogenation to pyrrolidinesuccinic acid, and thus were assigned the structures I and II. This is in accord with the findings of Diels and Alder.[2]

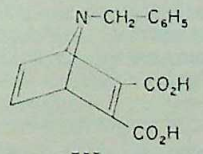


I



II

The third compound, which was colorless, was assigned structure III on the basis of the data given below.



III

The material had an elemental analysis (Calcd. for $C_{15}H_{13}O_4N$: C, 66.4; H, 4.8; N, 5.2. Found: C, 66.0; H, 4.9; N, 5.1.) and neutral equivalent (Calcd. for III: 135.5. Found: 133) which corresponded to a one-to-one adduct. The substance is amphoteric, being soluble in the cold in both dilute sodium bicarbonate and dilute hydrochloric acid, the latter indicative that the pyrrole moiety is no longer intact. On hydrogenation over 5% palladium on carbon at atmospheric pressure and room temperature, *three moles* of hydrogen were absorbed (in contrast to compounds I and II which take up *four moles* of hydrogen under these conditions) thus indicating the presence of a bicyclic skeleton. The material exhibited only end absorption in the ultraviolet (from 210 to 330 mμ) and its infrared spec-

(1) This work was supported by a Frederick Gardner Cottrell grant from Research Corporation.

trum (in KBr) indicated the presence of zwitterion formation.

In accord with this structural assignment, refluxing III for 12 hours in 10% sodium carbonate solution gave rise to N-benzylpyrrole and I.

This represents the first recorded Diels–Alder addition with a pyrrole acting as a diene. We hope to report shortly on further rearrangements of the adduct and its hydrogenation products.

BOOK REVIEWS

Organic Syntheses. Vol. 36. By N. J. LEONARD, Editor-in-Chief, John Wiley and Sons, Inc., 440 Fourth Avenue, New York 16, N. Y. 1956. vi + 120 pp. 15.5 × 23.5 cm. Price, $3.75.

"Tried and true" directions for preparing 35 organic compounds are reported in Volume 36 of "Organic Syntheses." This volume maintains the high standards of its predecessors in its editing, experimental directions and indexing. The compounds treated range from the very simple, such as propiolaldehyde, to the somewhat more complex, such as 2-hydroxycyclodecanone. The editors wisely refrain from including syntheses of very complex compounds, which would have limited applicability and interest.

Probably one of the most useful preparations will be the one for diazomethane from *p*-tolylsulfonylmethylnitrosamide. The advantage of this method is that the starting material is stable and soluble in organic solvents.

This new volume will take its place as a worthy addition to the "Organic Syntheses" series, which has for many years been one of the most valuable reference works for the organic chemist.

DEPARTMENT OF CHEMISTRY
ST. JOHN FISHER COLLEGE
ROCHESTER, NEW YORK
CARL J. CLAUS

The Chemistry of Petrochemicals. By MELVIN J. ASTLE, Professor of Chemistry, Case Institute of Technology, Cleveland, Ohio. Reinhold Publishing Corporation, 430 Park Avenue, New York 22, N. Y. 1956. v + 267 pp. 16 × 23.5 cm. Price, $6.50.

This volume is a valuable source of general information and literature references on organic chemical compounds produced from petroleum. The 14 chapters contain 255 pages of text, many equations and tables of data, and 582 literature references. However, there is no author index and the bibliographies for each chapter are not alphabetically arranged.

The discussion is reminiscent of the books of Carleton Ellis. There is much useful information presented in sufficient detail to introduce the reader to the subject. For example, alkylation is covered in 9 pages, 7 on alkylation of paraffins and 2 on alkylation of aromatics. Two and one-half pages are devoted to the theory of alkylation. This section is based almost entirely on the work of Schmerling. The bibliography omits some important papers in this field, particularly those of Dr. P. D. Bartlett and associates.

The discussion of alkylation with hydrogen fluoride starts off with the statement, "Hydrogen Fluoride is increasing in importance as an alkylation catalyst." There is no mention of the fact that HF alkylation was an important process for producing aviation alkylate during World War II, and that nearly all of these HF alkylation plants were shut down, or converted to other use, at the end of the war. In regard to the Ziegler process (p. 103) for polyolefins, it is now more or less generally known that mixed catalyses are better than aluminum alkyls alone.

There are other spots in the text which indicate a lack of familiarity with what has actually been going on in industry. For example, on page 155, a process for concentrating benzene by adsorption is described as though the plant had been built and operated. Actually this process for concentrating benzene by adsorption never got beyond the drawing board stage.

On the scientific side, there is a tendency toward rather loose statements, such as the introductory sentence of chapter 2, which reads, "Inasmuch as petroleum is made up largely of paraffin hydrocarbons, these compounds must be considered to be the ultimate starting materials for the preparation of petrochemicals." Benzene and toluene occur in natural petroleum and have been separated commercially as noted on page 153. It is quite clear that paraffins and cycloparaffins naturally occurring in petroleum are not the "ultimate" starting materials for all petrochemicals. However, it is probably true that on a tonnage basis, the chemicals produced from the paraffin and cycloparaffin constituents of petroleum will probably be more important than those produced from the naturally occurring aromatics in petroleum.

The title of this book illustrates the fact that the word "petrochemical" is better adapted to economic rather than scientific discussion. On page 2 there is an estimate that there will be 35 billion pounds of "petrochemicals" produced in 1956 of which 10.5 billion pounds will be "inorganic petrochemicals." However, the book omits entirely any discussion of the chemistry of the "inorganic petrochemicals" such as ammonia and sulfur.

The word "petrochemical," as used in the petroleum industry, brings together products which are economically related, but not chemically related.

In spite of a certain degree of superficiality, which is perhaps unavoidable in a book covering so wide a range of topics, this book should prove of real value to those who need an introduction to the field of the organic chemistry of hydrocarbons, and the more simple organic compounds derivable from hydrocarbons.

RESEARCH AND DEVELOPMENT DEPT.
SUN OIL COMPANY
MARCUS HOOK, PA.
STEWART S. KURTZ, JR.

Polymer Solutions. By H. TOMPA. Academic Press, Inc., 111 Fifth Avenue, New York 3, N. Y. 1956. xiv + 325 pp. 10.0 × 16.5 cm. Price $8.50.

This is a comprehensive review of current concepts of the solution properties of high polymeric substances. The author has wisely omitted a treatment of polyelectrolytes since this is more properly in the domain of electrolyte theory. Throughout, Dr. Tompa compares theory with experimental results. The book is practically self-contained. All the basic formulas of the thermodynamics of solutions and of the statistics of coiled molecules are derived from first principles. When the author discusses

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

viscosity and light scattering, he explains the theories in physical terms but does not derive the formulas since this would require a much larger book.

The author is to be congratulated for the manner in which he has been able to distil the many complicated theories of high polymer solutions down to their essentials. His style is lucid, and his choice of subjects and the extent to which he discusses them is excellent. This book should be studied by everyone concerned with solutions of synthetic high polymers. Workers in the field are looking forward to the day when the properties of the final plastic can be explained in a thorough-going fashion as can now be done for solutions of polymers.

INSTITUTE OF POLYMER RESEARCH
POLYTECHNIC INSTITUTE OF BROOKLYN GERALD OSTER
BROOKLYN, N. Y.

Vacuum Deposition of Thin Films. By L. HOLLAND, Head of the Vacuum Coating Research Laboratory, Edwards High Vacuum Ltd. With a foreword by PROFESSOR S. TOLANSKY, F.R.S. John Wiley and Sons, Inc., 440 Fourth Avenue, New York 16, N. Y. 1956. xix + 541 pp. + 25 plates. 15 × 23 cm. Price, $10.00.

This book is long overdue. Today, vacuum coating is an important industry and no longer just a laboratory procedure, and Mr. Holland's volume will be useful to every worker in the field. It covers all phases of vacuum coating from the point of view of the technologist. This is not a theoretical treatise but a practical volume written by one with adequate theoretical background and wide experience.

The chapters each stand by themselves without any particular continuity or grouping. The first discusses general techniques and equipment used in the production of high vacuum. The many design sketches and detailed explanations will be of value to those designing their own vacuum evaporators and will increase the understanding of others who purchase commercial units. Sources and the thickness distribution of the deposited films are described in chapters 4 and 5. Distribution functions are derived mathematically and numerous graphs depict the experimental results obtained for different sources and receivers of various shapes.

Cleaning of surfaces prior to coating and the techniques for evaporating metals and alloys are discussed in chapters 3 and 6. Problems of reactions between charge and heater and selective evaporation of alloy components are detailed and tested solutions are given.

The difficulties of degassing plastic materials and coating them are treated in chapters 2 and 12. Systems for handling commercial quantities of materials are described and the vacuum properties of plastics and lacquers used for substrates are tabulated.

The properties of deposited films are discussed in detail and the influence of rate of evaporation, substrate temperature, gas pressure, angle of incidence, etc., is evaluated. This information is carried over into a chapter on the preparation of thin films for electrical purposes in the commercial production of resistors, capacitors and electrodes. Separate chapters are devoted to very detailed treatments of the preparation and properties of aluminum and oxide films.

Chapters 9 and 10 are concerned with optical coatings. Methods of preparing anti-reflection films, high reflection films and interference filters are described. Apparatus for controlling the deposition of optical films and the properties of these coatings is given in detail. In a related vein is a section on shadow-casting and surface replication as used in light and electron microscopy. The emphasis here is on the vacuum techniques and apparatus, not on the microscope applications.

The widely used and poorly understood process of cathodic sputtering is the subject of a complete chapter. The various theories are discussed and their disagreements are enumerated. Properties of films produced by sputtering are described and illustrated graphically, and apparatus for sputtering is shown.

The entire book is admirably documented and the bibliography of 557 references is invaluable. However, considering the large number of topics discussed, an expansion of the index would be very desirable. Also, this reviewer would have appreciated a more thorough discussion of the formation and properties of metallic blacks which are treated only very briefly. Of more commercial interest is the aluminizing of television kinescopes which requires specialized apparatus that might well have been described.

It is to be hoped that subsequent printings will rectify the unusual number of misprints and other minor errors which exist throughout the book, but in no way detract from its value.

RESEARCH DEPARTMENT
CENTRAL SCIENTIFIC COMPANY R. G. PICARD
CHICAGO, ILLINOIS

Advances in Carbohydrate Chemistry. Vol. 11. By MELVILLE L. WOLFROM, Editor, and R. STUART TIPSON, Associate Editor. Academic Press, Inc., Publishers, 111 Fifth Avenue, New York 3, N. Y., 1956. xviii + 465 pp. 15.5 × 23.5 cm. Price, $11.00.

Readers of the previous volumes of this series need only be told that the editors, their board of advisors and the various contributors have joined forces to turn out a work of exceptional interest. This book amply demonstrates that the research worker will find those areas of science most rewarding where different fields of specialization overlap. Enzymology, microbiology, physical chemistry and organic chemistry supply the *leitmotif*.

The chapter dealing with the biosynthesis of the monosaccharides will be read by many grateful people. Sixty five tightly written pages cover all the significant work from Adolf von Baeyer's speculations about the polymerization of formaldehyde to the complex realities of enzyme systems and photochemistry currently under investigation. L. Hough and J. K. N. Jones take leave of their readers with a challenging statement:

> "More than one hundred enzymes, and many of their coenzymes, have been recognized in animal mitochondria. Whether or not such an organization of enzymes is present in such a cell unit for performing a sequence of reactions with carbohydrates remains to be determined."

F. Shafizadeh's chapter dealing with branched-chain sugars of natural origin is an appropriate sequel. His system of naming these compounds is logical, and it could have been used advantageously in the preceding article.

J. M. Bobbitt focusses our attention on the periodate oxidation of carbohydrates, and he brings into relief the functioning of this analytically important reagent. References to other reviews dealing with periodic acid enhance the usefulness of this chapter. S. Bayne and J. A. Fewster supply a comprehensive survey of the chemistry and biochemistry of the osones, and Andrew Beélik discusses the biosynthesis, chemical synthesis and properties of kojic acid. G. R. Barker's chapter on nucleic acids supplements and brings up to date the work published by the associate editor, R. Stuart Tipson, in *Volume I* of this series. Aspects of the Physical Chemistry of Starch, and an Addendum: The Size and Shape of Some Polysaccharide Molecules, by C. T. Greenwood point up the functions of physicochemical techniques in the study of the nature of polysaccharides. The descriptive chemistry of furan, pyrrole and other heterocyclic compounds obtained from condensation reactions of monosaccharides with β-ketonic esters is presented by F. García Gonzáles. A generalized cumulative author and subject index to *Volumes 1–10* is included.

There is an obituary of the late Kurt H. Meyer by R. W. Jeanloz. The current crop of students will find much inspiration in the personal life and achievements of the departed. The diversity of his scientific interests and his warm friendliness are movingly described by his former student.

The reviewer may be considered captious in pointing out a few little motes. Why didn't someone do something about: "Observation of mixed melting points is mandatory." Or, "General consensus of opinion"? There are ambivalent feelings toward the typographical pun in a statement dealing with the use of periodic acid: "Aliquots of the reaction mixture are periodically removed." The author who suggests a system for the naming of branched-chain sugars forgets to use it in a couple of places. Some of the charts would have been easier on the eyes if larger type and more space had been used. In the anniversary year of W. H.

LOUIS SATTLER

Elementary Wave Mechanics with Applications to Quantum Chemistry. Second Edition. By W. HEITLER, Professor of Theoretical Physics in the University of Zürich. Oxford University Press, 114 Fifth Avenue, New York 11, N. Y. 1956. viii + 193 pp. 12.5 × 19 cm. Price, $2.90.

When a book that is as small as this one is deals with the entire field of "elementary quantum mechanics," and when it also considers the "applications to quantum chemistry," many important topics must unavoidably be slighted or entirely ignored. Consequently, the reader cannot expect here to find more than a general introduction to the basic concepts, and he cannot expect to be brought to the point where he is able to make original contributions to the field.

Even within these limitations, however, there is reason to question whether the author has been successful in presenting the material in such a form that it will be helpful to the "chemists and other non-mathematical readers" for whom, according to the Preface, it is designed. The earliest developments of the theory are expounded clearly and well, but almost nothing that has been added since about 1930 is discussed. Valence, for example, is treated entirely with the aid of first-order perturbation theory, and the variation principle is not mentioned at all. The states of the individual atoms in molecules are described in terms of the spectroscopic symbols that are strictly applicable only to isolated atoms. The concepts of resonance and of molecular orbitals are not explicitly mentioned, although some of the basic principles of these concepts are briefly suggested. The Preface gives the impression that the book should be intelligible to the "non-mathematical reader," but this impression is hardly borne out by the fact that a firm understanding of calculus and at least a bowing acquaintance with the theory of determinants are presupposed.

It is difficult to see for what group of readers this book would be valuable. The chemist or physicist who is already familiar with quantum mechanics might find the discussion of the historical background interesting and informative, but he would probably be disappointed by the inadequate way in which the more recent developments are treated. On the other hand, the reader who is encountering the subject for the first time might be more bewildered than instructed by the necessarily brief and sketchy way in which the complex and rather abstruse principles are presented, and he would almost certainly be left with an incorrect idea of the methods currently employed in the approaches to many important problems.

Optical and Electrical Methods of Determining Transference Numbers of Electrolytes in Dilute Solutions by the Moving Boundary Technique

BY J. W. LORIMER, J. R. GRAHAM AND A. R. GORDON

RECEIVED JANUARY 14, 1957

With a view to transference studies in non-aqueous solvents, methods of determining transference numbers at low concentrations have been investigated. The use of rectangular channels permits the identification of the boundary by the conventional optical methods at concentrations well below those permissible in the usual circular channel; there is, however evidence of boundary instability (at 25° at any rate) and with the familiar Tiselius cell, the solvent conductance is sufficiently large and erratic as to render the results at low concentrations valueless. As an alternative, boundary movement in the channel can be followed by measuring the change in resistance across the channel between microelectrodes when the leading solution is replaced between the electrodes by the indicator. A suitable circuit is described, and it is shown that boundary movement can be followed in this way with satisfactory precision. The advantages (and disadvantages) of this technique are discussed.

It has become apparent in recent years[1,2] that the quantity significant in studies of electrolytic transfer in solution is the ionic rather than the equivalent conductance. This implies, in addition to the usual conductance measurement, the determination of the transference number, and even now only a few such data for anhydrous solvents have been reported; the conventional moving boundary measurements with KCl and NaCl in methanol, carried out in this Laboratory,[3] and Smisko and Dawson's KCNS determinations in ethanol[4] suggest the difficulties which may be encountered in non-aqueous solutions. Moreover, if as is the case with many solvents, ion-pair formation occurs, the measurements should be carried to concentrations well below those hitherto used, and this in turn requires improved methods for following boundary movement. The Kohlrausch ratio technique[5] does provide an alternative as far as limiting ion conductances are concerned, but when used as an absolute method suffers under the disadvantage that the resulting limiting ionic quantities are at best no more precise percentually than is the difference in the limiting equivalent conductances of the leading and indicator salts.

This research was therefore undertaken to determine (a) whether optical methods could be employed at high dilutions, and (b) whether alternative criteria could be used to follow boundary movement. The studies of the optical methods are discussed briefly below, the bulk of the paper being concerned with a conductimetric method of following the boundary, which seems to offer distinct advantages.

Experimental

An elementary treatment of the Abegg and Gaus[6] method of observing a sharp boundary between two solutions of different refractive index (sometimes referred to as the total reflection method[7]) shows that, other things being equal, the minimum detectable refractive index difference is roughly inversely proportional to the path length through he cell. This at once suggests the use of a rectangular channel, as in the conventional Tiselius cell, particularly since this would permit, if desirable, the use of more sophisticated optical mthods. The cell chosen was a modified form of the usual 3 mm. × 25 mm. type discussed by Longsworth and MacInnes.[8] It differs in that there are three center sections (labeled II and III in their Fig. 1) the upper two being fused to the header; the third is fused to the bottom section (IV in their figure) thus leaving only one shearing surface to minimize leakage. The electrode compartments were much reduced in size, and the cell was

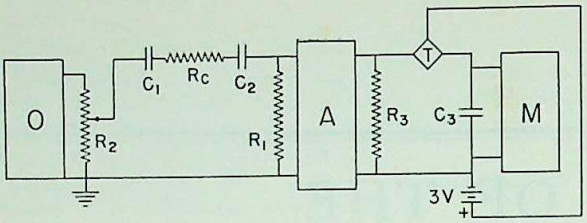

Fig. 1.—Schematic diagram of the alternating current circuit.

mounted in a Rockefeller type of frame (see Fig. 2, ref. 8); we wish to thank Dr. Longsworth for supplying us with the blue prints. The measurements were carried out in a carefully controlled air thermostat placed in a constant temperature room.

To determine the volume swept out by the boundary, two methods were employed. The boundary after passing a reference mark was displaced backward through a known volume by additions of mercury to the closed side of the cell from a calibrated pipet. Alternatively, the channel was calibrated from the known value of t_+ for 0.01 N KCl[9,10] by following boundary movement against a graticuled scale. It was found as expected that while a 0.01 N KCl/KIO_3 boundary is about the most dilute that can be observed satisfactorily in a 2.5 mm. circular channel, a 0.001 N KCl/KIO_3 boundary in the Tiselius cell could be seen with ease. Unfortunately, measurements at high dilutions proved unreliable because of large and erratic solvent conductances determined in the cell; this apparently was due, in part at least, to contamination from slight fissures where the end and side members of the channel are fused together. Moreover, in measurements at 25° in contrast to those near 4°, there was evidence of boundary instability, notably a tendency for the boundary to be arched; this may be due to the non-symmetrical temperature distribution in a channel of this shape.

As an alternative, conventional rising and falling boundary cells were constructed (types V and VIII, see Fig. 1, ref. 11) except that the channel, including that in the shearing stopcock, was of rectangular 2 mm. × 10 mm. glass tubing.[12] The cells were calibrated as to volume with 0.02 and 0.01 N KCl, using KIO_3 and LiCl as indicators for rising and falling boundaries, respectively, and as expected, visible boundaries were obtained at concentrations one quarter to one fifth those for a 2.5 mm. channel. Solvent conductances, determined in the cell, were now reproducible, but again at high dilutions there was some hint of boundary instability; even the volume calibrations showed a scatter of a part in 1500 or so, as compared with a part in 4000 at these concentrations in a 2.5 mm. circular channel. With more dilute solutions, the precision was considerably less; for example, a series of measurements with 0.0025 N KCl and potassium diiodobenzoate as indicator, gave $t_- = 0.5097 \pm 0.0005$.

The Conductimetric Method.—This procedure takes advantage of the fact that there must be a change in resistance across the channel when the leading solution is replaced by the indicator. Preliminary measurements suggested certain obvious conditions to be fulfilled if good precision were to be obtained. In the first place, the electrodes used to determine the conductivity of the solution must be as small as possible in the vertical direction to sharpen the timing of the "event" and to minimize the possibility of their acting as bipolar electrodes to the direct current. Secondly, for continuous recording, the conductance electrodes must be capacity coupled in the a.c. measuring circuit.

To construct the channel, the procedure finally adopted was to stretch a platinum ribbon, 0.07 mm. thick and 1.0 mm. wide, across the upper end of a glass tube, 2.5 mm. i.d. 0.7 mm. wall thickness. Since the ribbon was rather fragile, it was first welded to 0.5 mm. leads of platinum wire, the length of ribbon being so chosen as to leave the leads in close proximity to the glass. Another section of tubing was pressed down on the first, and the two sections were

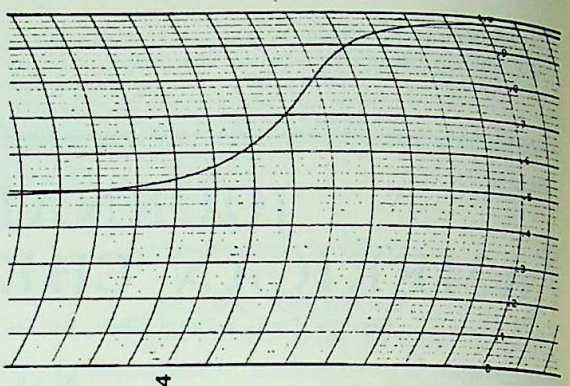

Fig. 2.—Trace on recording milammeter for passage of 0.01 N KCl/0.0069 N KIO_3 boundary; boundary velocity 0.04 mm./sec.

fused at the lowest temperature consistent with obtaining a satisfactory seal, leaving the ribbon extending from wall to wall of the tube. A thin thread of glass was next wound around the lead and fused to it and to the wall of the tube, thus protecting the ribbon from mechanical strains. A sharpened steel rod, slightly smaller than the internal diameter of the tube, was pressed down, cutting the ribbon near the walls, and any protruding platinum was removed with a stiff piano wire coated with carborundum powder and glycerol. It was found, as might be expected, that there was considerable variation in apparent resistance with different pairs of electrodes; accordingly, for reasons discussed below, a "cell factor" (using 0.01 N KCl) was determined for each pair of electrodes, and only those pairs with factors differing by not more than a few per cent. were incorporated in a channel. Each channel had as a rule five pairs of such microelectrodes spaced some 40 mm. apart. It should be noted in passing that even with an ohmic drop as high as 1 volt per mm., due to the passage of the direct current, the voltage drop across the surface of a microelectrode is only 0.07 volt.

In order to test the method in the same cell with both rising and falling boundaries, the earlier designs (after annealing) were fitted with a Type III shearing stopcock[11] at the base of the channel and a Type VIII at the top; subsequent cells, for simplicity, were designed *either* for a rising or a falling boundary. The platinum leads were soldered to stout copper wires which lead to a Lucite distributor plate at the top of the cell; the wires were enclosed in glass tubes which carried the shielding. The distributor plate carried sockets for the electrodes and an additional pair for a variable resistance which permitted the oscillator and amplifier (see below) to operate without passing alternating current through the cell.

The cell was mounted in an oil-bath, operating at 25.00 ± 0.01°, and cadmium and silver–silver chloride electrodes served as anode and cathode. The indicator concentrations were a few per cent. below the Kohlrausch values[5,11] for NaCl and LiCl, and a few per cent. above with KIO_3 and $NaIO_3$; the preparation of the salts and the solutions has been described previously.[2,10] To clean, the cell was washed with redistilled carbon tetrachloride, ethanol and water, then repeatedly with distilled and conductivity water; it was then drained and dried with a stream of dried filtered air. Periodically, before the final washing, the cell was allowed to stand filled with 20% hydrochloric acid to remove surface alkalinity. In general, the solvent conductance measured in the cell differed only negligibly from that of the stabilized conductivity water used in making up the solutions, *viz.*, $0.7–0.8 \times 10^{-6}$.

One essential precaution was the removal of any moisture from the inside of the glass tubes which enclose the copper wires leading from the distributor plate to the microelectrodes. To do this, the tubes were flushed with anhydrous ethanol and dried with dried, filtered air immediately before filling the cell. In addition, particularly in humid weather, it was found necessary to dehumidify the laboratory if leakage of the direct current through the microelectrodes to the grounded shielding on the glass tubes was to be avoided.

The a.c. circuit is indicated in Fig. 1. Here R_c is the resistance across the channel; C_1 and C_2 are 0.02 μf. condensers (rated at 10,000 working volts, leak resistance >> 50,000 megohms); O is a Hulett–Packard model AB oscillator, normally operating at 20,000 c.p.s.; R_2 is a 6000 ohm voltage divider with taps in 0.05 volt steps up to 1 volt; and R_1 is the amplifier feed resistor. A is a Williamson amplifier (maximum voltage gain 1400 at 20,000 c.p.s., internal input impedance 1.5 megohms); in general, the input, feed resistor and amplification were adjusted to give approximately full scale deflection on the recording ammeter when the leading solution was between the electrodes. R_3 is a 500 ohm load-matching resistor, T a Texas Instrument Co. Type 201 transistor, C_3 an 0.8 μf. condenser, and M an Esterline–Angus Model AW recording ammeter (1 milliamp. full scale deflection, internal resistance 1400 ohms, chart speeds 2.5 mm./sec. and 2.5 mm./minute). We wish to thank Dr. F. S. Goulding of Atomic Energy of Canada Limited, Chalk River, Ont., for suggesting the rectifier circuit to us. To correlate the time scale of the chart with the effective time for the run, a spring-returned stylus was used to record on the chart two datum points, one just before the boundary passed a given pair of electrodes, the second just after it had passed; tests showed that 30 second intervals on the chart were correct to 0.2 sec. or better.

Results

A typical trace for a 0.01 N KCl/0.0069 N KIO_3 boundary is shown in Fig. 2; the current here is 0.36 milliamp. and the actual boundary velocity slightly over 0.04 mm./sec. Zero signal is at the bottom of the chart, which is moving from left to right, the time arcs corresponding to 5 second intervals. At first glance, the duration of the event—approximately 65 seconds—is surprising, but while any calculation of the distribution of the current lines is impossible, an extremely naive estimate of the column of solution involved in the resistance measurement can be made. Since the resistance across the channel for 0.01 N KCl is approximately 12000 ohms, the factor "A/l" is 0.6 mm. If the current were confined vertically to the plane of the electrodes and horizontally to their width, the ratio of length to width would be of the order of 2.5; if this ratio were valid for the actual measurement, the corresponding "height" would be 1.5 mm., which is certainly an underestimate. Moreover, MacInnes and Longsworth's eq. 49 shows[7] that if the thickness of the boundary be taken as the distance from the plane in which the concentration of the indicator is 2% of that of the leading salt, to the plane where the concentration of the leading salt is 2% that of the indicator, the boundary thickness for the conditions obtaining here will be approximately 0.16 mm.; thus the boundary must move at least 1.66 mm. for the transition from leading to indicator solution to be complete, corresponding to an interval of 40 seconds or more—an estimate not inconsistent with the time actually observed.

In addition, if the trace be replotted on rectangular coördinate paper, and the tangent be drawn at the point of inflection, the slope of the tangent should be a measure of boundary velocity near the first moment of the boundary, and for given leading and indicator solutions and fixed a.c. circuit characteristics, the slope should be proportional to the direct current; this is in fact found to be the case.

An approximate circuit analysis shows that with the a.c. circuit components used here, the signal for fixed input voltage should be proportional to $R_1/(R_1 + R_c)$. Thus, with R_1 = 1400 ohms, as in the case in Fig. 2, the ratio of the signal when 0.01 N KCl is between the microelectrodes to that when it has been replaced by 0.0069 N KIO_3 solution,[11] should be 1.80; as is evident from the chart, the actual ratio is some 10% greater than this, and this is in general found to be the case, the observed signal ratio being greater than that computed from R_1, the cell factor and the specific conductances of the two solutions. The explanation lies in the fact, as shown by tests with known resistances in place of R_c, that the response in the circuit is not strictly linear, the recorded signal being somewhat more than proportional to $R_1/(R_1 + R_c)$. However, for given leading and indicator solutions, the observed ratio for a pair of electrodes is reproducible to 1%, is independent of the direct current passing, of the a.c. input voltage, and of the amplification, and varies only a few per cent. from one pair of electrodes to another, *i.e.*, essentially the same phenomenon is occurring at all the electrode pairs.

Since it is the time required for the boundary to move from one electrode pair to another that is the experimentally significant quantity, this suggests that any easily identified point on a trace be used to time the event and thus to compute the interval. The one we have chosen is that corresponding to the average of the signals when only leading or indicator solution is between the electrodes. In Fig. 2, this corresponds to an ordinate of 73.5 units with an uncertainty in the time of less than 0.5 second.

As an example of the results that may be obtained in this way, a volume calibration between two pairs of electrodes is summarized in Table I. With this cell, both rising and falling boundaries could be used; the values of t_+ (to which the appropriate solvent and volume corrections[7] were applied) on which the calibration is based were 0.4902 and 0.3918 for 0.01 N KCl[9,10] and 0.01 N NaCl,[9,13] respectively. It is at once evident from the table that the measured volume is independent of the leading ion, of the indicator, of the direct current employed, whether the boundary is anion or cation, and whether it is rising or falling; in other words, the volume is a function only of the cell geometry. It should be mentioned that with the later cells, designed for use with either a rising or a falling boundary, the reproducibility for a given leading solution was definitely better—a part in four thousand, which is the precision at best of transference data. We believe this was due in these cells to the elimination of the shearing stopcock from the closed side of the cell.

It is naturally pertinent to enquire as to the disadvantages and advantages of the technique as described above—particularly in comparison with optical methods of following boundary movement. Its first and most obvious disadvantage lies in the difficulties always encountered with complicated high resistance circuits—here in particular possible leakage of the direct current through the microelectrodes to ground through the shielding of the a.c. leads. A second is the fact that the recorded trace can give no information as to the actual boundary structure such as is supplied by the famil-

iar schlieren technique. On the other hand, there is much greater flexibility here in the choice of indicator ion; the ion must of course be slower than the leading ion and either lighter or heavier depending on the type of boundary, but any requirement as to its optical properties in the solvent disappears. For example, the KCl/LiCl boundary of Table I would be completely invisible under the conditions obtaining here, while the trace obtained is almost indistinguishable from that of Fig. 2. Again, with any optical procedure, there is always a minimum current below which the boundary becomes too diffuse to be observed; here this restriction disappears. It is true that halving the current, for example, and consequently the boundary velocity, roughly doubles the uncertainty in fixing the midpoint of the trace; however, the interval from one electrode pair to the next is also doubled, so that percentually the precision of the computed volume calibration or transference number is unaffected; this can be a matter of real importance where Joule heating is a serious factor. Finally, the method can be employed at concentrations well below those accessible to the optical methods and, as is shown in the accompanying paper, should be generally applicable to non-aqueous solvents.

TABLE I

The Transference Numbers of Sodium and Lithium Chlorides in Anhydrous Ethanol at 25°

BY J. R. GRAHAM AND A. R. GORDON

RECEIVED JANUARY 14, 1957

The conductimetric method of following boundary movement has been used to determine the transference numbers for NaCl and LiCl in anhydrous ethanol at concentrations from 0.001 to 0.0025 *N*. Triiodobenzoate served as a satisfactory rising anion indicator, the observed t_- satisfying the usual experimental criteria, but it was not possible to find a satisfactory cation indicator in this solvent. Moreover, even the anion boundaries showed evidence of boundary instability at 0.0005 *N*. However, the Longsworth function, computed on the basis of ionic rather than stoichiometric concentration, is linear in the ionic concentration, thus permitting an unambiguous extrapolation to infinite dilution. While the results are not as precise as those obtained with water and methanol as solvents, they nevertheless demonstrate, we believe, that reasonably reliable transference data can be obtained in many if not most anhydrous solvents.

In this paper we report the results of transference measurements, effected by the technique described in the preceding paper,[1] on sodium and lithium chlorides in anhydrous ethanol at 25°. The reasons for selecting these two salts were (a) that their ions were of the simple noble-gas type, and (b) that transference and ion conductance data were available for them in water[2] (over a range of temperatures) and in methanol.[3] While for purposes of continuity it was desirable to investigate their transport properties in another solvent in the same homologous series, the fact remains that the relatively low solubility of the salts and their low conductivity in ethanol raised special problems—in particular that of finding suitable indicator ions. The fact that it was possible to carry out these measurements at all, argues (we believe) that transference measurements are generally possible with this procedure in non-aqueous solutions subject to certain restrictions discussed below.

Experimental

The general technique already has been described.[1] In general, the amplifier feed resistance R_1 (see Fig. 1 of ref. 1) was set at about one tenth of the resistance across the channel R_c when the leading solution was between the microelectrodes and, owing to the relatively low specific conductance of the solutions, the boundary velocities were considerably lower than those employed in aqueous solutions to minimize Joule heating. The preparation and purification of solvent, salts and solutions are discussed in the accompanying paper.[4] For rising anion boundaries[5] sodium and lithium triiodobenzoate served as suitable indicators; in fact the traces recording boundary passage are almost indistinguishable from those obtained with similar boundary velocities in aqueous solution; see for example Fig. 2 of ref. 1. The 2,3,5-triiodobenzoates were prepared by the pro-

cedure described by Davies, Kay and Gordon[3a]; in the case of the lithium salt, however, the reaction between the bicarbonate and the purified acid required digestion at 60° for several hours. It should be noted that the measured transference numbers recorded in the tables are based on the time intervals between electrode pairs 1–4, 2–4, 1–5 and 2–5 to minimize the percentage error in the elapsed time; the intervals 2–3 and 3–4 were only employed to detect any significant change in boundary velocity with boundary movement. Volume corrections for the concentrations employed here are entirely negligible, and solvent corrections amount at most to a few units in the last decimal place.

While the anion transference numbers so obtained satisfied all internal criteria for a stable boundary—absence of "progression," independence of current and of initial indicator concentration over an appreciable concentration range[6]—we were unable to find suitable cation indicators. Falling 0.002 *N* NaCl/LiCl boundaries gave traces approximately ten times as long as those for the anion boundaries, and the duration of the "event" tended to increase as the boundary moved down the channel. Since the duration is primarily a function of the spread of the a.c. current lines,[1] rather than of physical boundary thickness, this raised serious doubts as to whether a boundary in the usual sense of the term existed at all, in spite of the fact that the computed t_+ was consistent within half a per cent. or so with the known value of t_-. If one assumes that cations are more highly solvated than anions, a possible explanation is that the random passage of a cation across the boundary would produce a more serious disturbance than would a similar passage of an anion across an anion boundary, particularly when, as is the case here, density stability is slight. Dodecylammonium chloride as indicator showed similar behavior, while hyamine 1622 chloride with a rising boundary showed an erratic variation of apparent transference number with boundary movement and again a steady increase in the length of the trace. Cadmium chloride as an indicator for rising cation boundaries was eliminated since it proved from rough conductance measurements to be such a weak electrolyte that it was impossible to maintain even an approximately constant direct current during a run.

It should also be noted that when rising 0.0005 *N* NaCl boundaries with triiodobenzoate as indicator were studied, while the traces were not significantly different from those obtained at higher concentrations, the apparent t_- varied erratically as the boundary moved up the channel. This was unquestionably due in part to difficulty in setting the shearing stopcock correctly, since the same behavior was noted at higher concentrations with a definitely incorrect setting; possibly a more sophisticated method of forming the junction such as that employed by Longsworth[7] might eliminate this difficulty, although the possibility of leakage with his apparatus, even with the lithium stearate lubricant[3a] used here, might be serious. A second possibility is that at high dilutions with consequently slight density stability, turbulent electroendosmotic flow may disturb the boundary, the effect being more pronounced the more dilute the solution. If this be the case, it puts a lower limit to the concentration at which moving boundary measurements are possible.

Results

As an example of the reproducibility of the measurements, the individual experimental results for 0.001 *N* NaCl are listed in Table I. Each measurement involves a solution prepared by dilution from a different stock solution[8]; the concentration of the NaCl solutions differed only negligibly from 0.001 *N* as far as variation of t_- with concentration was concerned. The first line of the table gives the initial value of the indicator concentration, the second the current in microamperes and the third the transference number corrected for solvent

(6) To take the case of 0.002 *N* NaCl as an example, the initial indicator concentration was varied from 0.0017 *N*, approximately the Kohlrausch value, to 0.002 *N* without appreciable effect on the measured t_-.

(8) In computing volume from mass concentrations, the density data of ref. 4 were employed.

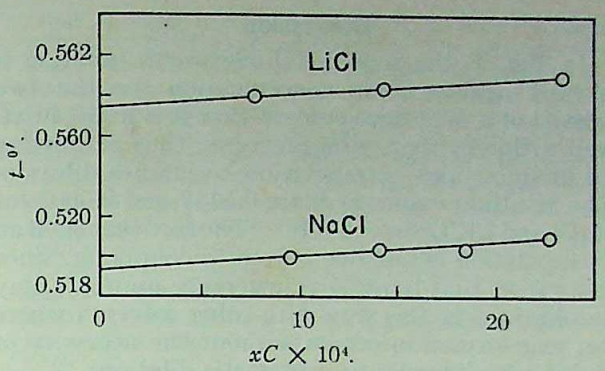

Fig. 1.—The Longsworth function plotted against ionic concentration.

conductance. It is apparent that within experimental precision t_- is independent of initial indicator concentration and of current; it is also evident (and this is generally true of the results obtained) that the reproducibility of the measurements is inferior to that obtained with water and methanol as solvents.

Discussion

In Fig. 1, the modified Longsworth function is plotted against ionic concentration for the two salts, and it is at once evident that it is linear in xC well within experimental precision, thus permitting an unambiguous extrapolation to infinite dilution. The resulting values of Λ_0 are 0.5187 and 0.5607 for NaCl and LiCl, respectively. The fact that such an extrapolation is possible here is encouraging, since it suggests that limiting transference numbers may be obtained in this way with other solvents where ion pair formation occurs without the necessity of making measurements at fantastic dilutions.

It should also be noted, in contrast to results in aqueous solution, that although the transference numbers are greater than one half, the limiting slope is approached in both cases from above. Potassium chloride in methanol showed similar behavior,[3a] and we believe that about the only generalization that can be made, based on the results in the three solvents, is that the deviation from the limiting law at finite concentrations is numerically least when the transference numbers are close to one-half.

Smisko and Dawson[10] have recently reported transference numbers for KCNS solutions in ethanol, based on measurements in an autogenic cell; a discussion of the correlation of their results with ours, and of the mutual consistency of our NaCl and LiCl data, is reserved for the accompanying paper.[4] Suffice it to say here that while the ethanol data are not of the precision obtained with water and methanol as solvents, they nevertheless fix a limiting conductance for chloride ion in ethanol which is probably reliable to a few hundredth's of a conductance unit.

In conclusion we wish to express our thanks to the National Research Council of Canada for the award to J. R. G. of two studentships.

Equivalent and Ionic Conductances for Lithium, Sodium and Potassium Chlorides in Anhydrous Ethanol at 25°

BY J. R. GRAHAM, G. S. KELL AND A. R. GORDON

RECEIVED JANUARY 14, 1957

The conductance of lithium, sodium and potassium chlorides in anhydrous ethanol has been determined for concentrations from 0.0001 to 0.0020 N. All three salts show definite ion-pair formation, the dissociation constants for the pairs (determined by the Shedlovsky procedure) being greatest as might be expected for LiCl and least for KCl. In conjunction with the transference numbers, the LiCl and NaCl results yield a limiting conductance for chloride ion of 21.85; this is probably reliable to 0.02 or 0.03 conductance units, and consequently should fix other limiting ion conductances within similar limits. The correlation of the ion conductances in ethanol with those in methanol and water is discussed.

If the transference measurements of the preceding paper[1] are to yield information as to ion conductances in ethanol solution, it is obvious that reliable equivalent conductances are necessary. Previous conductance studies of the alkali halides in ethanol have given an extraordinarily wide variation in conductance values. To take the case of Λ_0 for NaCl as an example, Goldschmidt and Dahll[2] give 46.5, Thomas and Marum[3] 43.0, and Barak and Hartley[4] 42.5. Admittedly, some of the spread is due to the methods of extrapolation employed (see below) but nonetheless such results indicate the necessity for measurements carried out under conditions much more carefully controlled than those obtaining in the earlier work. Here we report conductance data at 25° for lithium, sodium and potassium chlorides.

Experimental

The measurements were effected by the direct current method, developed in this Laboratory, employing the cells previously used with methanol[5] as solvent; their calibrations are based on the Jones and Bradshaw 25° 0.01 demal standard.[6] Bias potentials between the probe electrodes were in general no greater than in water and methanol, but great care had to be exercised, particularly in the more dilute solutions, to avoid the passage of any appreciable current through the probes as the result of significant off-balance in the initial setting of the potentiometer; if this occurred, the probes behaved erratically and had to be reanodized. It was also found impossible to determine the solvent conductance for ethanol by the direct current method; it was accordingly determined in a conventional conductance cell (cell factor 0.1005 cm.$^{-1}$) with an alternating current bridge. Work in methanol[5a] had shown that the two methods were in agreement to better than 1%.

The principal difficulty with ethanol is its preparation as a solvent with, at the same time, low water content and low specific conductance. The starting material was a Gooderham and Worts "anhydrous" alcohol, rectified by ethylene glycol distillation; it contained approximately 0.25% water, 0.01% esters and traces of aldehydes and acids, and its specific conductance was of the order 6×10^{-8} mho/cm. The procedure finally adopted was to reflux 4.5 l. of the starting material overnight under a 30-cm. Allihn condenser (condenser temperature 30°) while a slow stream of nitrogen (from which traces of oxygen, carbon dioxide and water vapor had been removed) bubbled through the charge; this removed the low-boiling impurities, which were taken off by a slight suction applied at the top of the condenser. The subsequent distillation was carried out under a slight positive pressure of the purified nitrogen, only a middle cut of 3 l. being retained. While this procedure left the water content unaltered, the specific conductance of the distillate was in general $0.5–0.8 \times 10^{-8}$ mho/cm.

To remove the water, a modification of the Lunt and Bjerrum[7] method was used. Grignard quality magnesium turnings were cleaned by refluxing with ethanol and a few iodine crystals for three hours; the liquid was then decanted and discarded, and traces of iodine were removed by repeated washings of the turnings with ethanol. This preliminary cleaning and removal of the iodine are essential, in our experience, if a final product of low specific conductance is to be obtained. The magnesium was then refluxed under purified nitrogen for 24 hours with 1.5 l. of previously dried purified alcohol to permit the magnesium ethoxide to form; the center cut from the first distillation was added, refluxed for 12 hr., and distilled under nitrogen, a center cut of 3 l. being retained. The specific conductance was unaffected by this treatment, but the water content of the distillate, determined by Karl Fischer titration,[8] was reduced in general to 0.001–0.002 weight %. Acid and ester analyses, carried out by A.O.A.C. procedures modified for trace amounts[9] and checked by tests of samples containing known amounts of ester and acid, showed that the distillate was neutral and contained less than 0.002% esters. The mercuric cyanide test of Hartley and Raikes[10] showed negligible amounts of acetone and acetaldehyde, and a spectroscopic analysis for magnesium was negative.

The density of the distillate, determined by means of a Shedlovsky and Brown[11] type pycnometer, at 25.000° was $0.78503_9 \pm 0.00001_2$ g./ml. (8 determinations). Osborne, McKelvey and Bearce[12] report 0.78505_8 for what was almost certainly a somewhat wetter alcohol, and Brunel, Crenshaw and Tobin[13] give 0.78505 for the mean of several drying procedures. If one employs Osborne, McKelvey and Bearce's data for the effect of water on density, our value for the anhydrous alcohol would be 0.78503_5. Any significant study of the effect of solution concentration on density is precluded by the narrow concentration ranges available; however density measurements show that for the concentrations of interest here the solution densities are given within two or three units in the fifth decimal place by $d = 0.78504 + AX$ where X is the salt concentration in moles/kg. solution and A is 0.04, 0.05 and 0.06 for LiCl, NaCl and KCl, respectively.

The salts were prepared as previously described,[5] except that in the final stage they were heated to temperatures slightly below the melting point instead of being fused. This was necessary owing to the extreme slowness with which they dissolved in ethanol; in general, the weighed sample of salt had to be refluxed under purified nitrogen for from 3 to 6 hours in spite of the fact that the strongest stock solutions were only 0.0025 N, well below the values quoted for saturation. The dilution technique, in particular the precautions taken against evaporation losses and contamination with air or water vapor have been previously described.[5]

There is one additional complication with this solvent in that its specific conductance, regardless of the method of storage and of the fact that its water content does not change with time, shows a steady increase (for several days at any rate) of approximately 0.6×10^{-8} mho/cm. per day. Curiously enough, aged samples of pure solvent, refluxed under the conditions obtaining when the salt was dissolved, showed a small but definite decrease in conductance and, for this reason, solvent determinations had to parallel as closely as possible the conditions obtaining in the preparation of the stock solutions and the solvent used for dilution.

Hughes and Hartley[14] report that for exceedingly small additions of water, the viscosity increases by 4% per 1% added water. A series of measurements with 0.001 N NaCl solutions showed that up to approximately 0.015% water content, the conductance decreased per % added water by the same amount, *i.e.*, decrease in conductance for this range of water content is apparently a viscosity effect, as postulated by Hughes and Hartley. The decreases were so slight—at most of the order of 0.02 conductance unit and consequently not much greater than the reproducibility of the measurements—that a detailed presentation of the results is hardly justified, but the effect is unquestionably a real one.[15] For higher water contents, there is a minimum in Λ at about 0.04 wt. %, the minimum being some 0.03 conductance units below the "anhydrous" value, with a subsequent steady increase in Λ until with 0.2% water, Λ has risen to the anhydrous value again; as Hughes and Hartley suggest, this is possibly the result of decreased ion-pair formation. Bezman and Verhoek[16] found somewhat similar behavior with addition of water to ethanolic solutions of ammonium chloride, but their minimum occurs in the neighborhood of 2% water. In any event, with the water contents normally obtaining in our solvents, the water effect on the equivalent conductance is relatively negligible, amounting at most to a few thousandth's of a conductance unit; it has nevertheless been applied where necessary in arriving at the values in the tables.

Results

Owing to the large number of individual measurements, only mean values for round concentrations are recorded. To illustrate the method used in obtaining these, the experimental data for 0.0002 N NaCl are summarized in Table I. The first line gives the concentration in equivalents/liter, each solution being prepared from a different stock solution, and the second the equivalent conductance. The third gives the value of the Shedlovsky function[17]

$$\Lambda'_0 = (\Lambda + 2\sigma C^{1/2})/(1 - \vartheta C^{1/2}) \qquad (1)$$

TABLE I

CONDUCTANCE DATA FOR 0.0002 N NaCl

10^4C	1.9965	1.9983	1.9804	2.0102	2.1404
Λ	39.710	39.719	39.749	39.694	39.613
Λ'_0	41.756	41.766	41.788	41.748	41.732
Λ'_0, 0 = 0.0002	41.756	41.766	(41.785)	41.750	71.756

where $\vartheta = 1.330$ and $\sigma = 44.66$ (see below). It must be emphasized that the Shedlovsky function as defined in eq. 1 has no theoretical significance for a solvent where ion-pair formation occurs, but it does provide a convenient method of interpolation owing to its relatively slight variation with concentration. From a large scale plot of Λ'_0 *vs.* C, $d\Lambda'_0/dC$ at 0.0002 N is -0.17×10^4 for the concentration range of the table, and the resulting values of Λ'_0 for $C = 0.0002$ are given in the last line. Thus, if the bracketed entry be ignored, Λ'_0 for 0.0002 N is 41.757 with a mean average deviation of 0.004; this corresponds to $\Lambda = 39.709$. Table I is typical of the precision and reproducibility of the results entered in Table II. Each entry in Table II is the mean of four or more independent measurements, each involving a different stock solution. The spread covering the individual results for a given concentration is of the same order as that of Table I (or less) for the more concentrated solutions and is not significantly greater for 0.0001 N.

TABLE II

EQUIVALENT CONDUCTANCE DATA IN ETHANOL AT 25°

10^4C	1	2	5	10	15	20
	LiCl, Λ_0 = 38.90, K = 0.01795					
Λ	37.360	36.695	35.300	33.780	32.650	31.770
ΛS	38.710	38.570	38.135	37.585	37.130	36.780
	NaCl, Λ_0 = 42.16, K = 0.01250					
Λ	40.450	39.710	38.095	36.300	34.970	33.910
ΛS	41.840	41.040	40.995	40.170	39.500	38.945
	KCl, Λ_0 = 45.40, K = 0.00795					
Λ	43.465	42.535	40.530	38.290	36.640	35.350
ΛS	44.890	44.500	43.455	42.135	41.090	40.260

To extrapolate the Shedlovsky procedure[18] was employed. By a short series of successive approximations

$$S = 1 + z + z^2/2 + z^3/8 \qquad (2)$$

is computed where $z = (\vartheta\Lambda_0 + 2\sigma)\ (C\Lambda)^{1/2}/\Lambda_0^{3/2}$, and $\vartheta = 8.204 \times 10^5/(DT)^{3/2}$, $\sigma = 41.21/(\eta \cdot (DT)^{1/2})$.[19] For a solvent of dielectric constant[20] 24.3 and viscosity[21] 0.01084 poise, ϑ and σ are thus 1.330 and 44.66. The degree of dissociation x is then given by

$$x = \Lambda S/\Lambda_0 \qquad (3)$$

ΛS is next plotted against $\Lambda^2S^2f^2C$, where f is the limiting law activity coefficient,[19] given by $\log f = -\alpha(xC)^{1/2}$; here $\alpha = 1.8246 \times 10^6/(DT)^{3/2} = 2.9585$. The plots should be linear, with intercept Λ_0 and a slope given by $-1/K\Lambda_0$, where K, the dissociation constant of the ion pairs is defined by

$$K = f^2x^2C/(1 - x) \qquad (4)$$

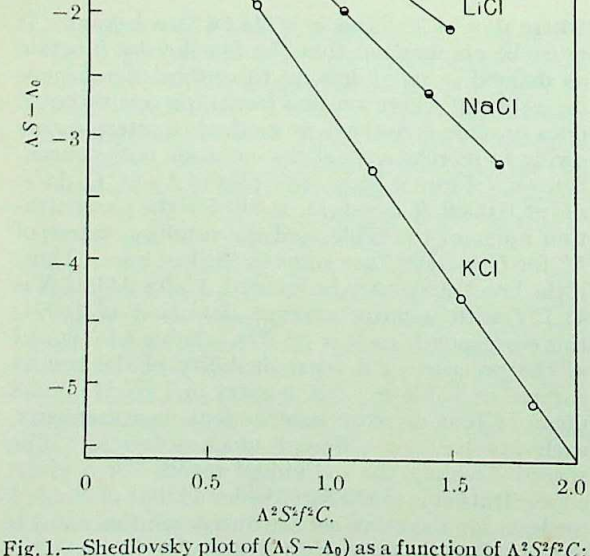

Fig. 1.—Shedlovsky plot of $(\Lambda S - \Lambda_0)$ as a function of $\Lambda^2S^2f^2C$: ○, KCl; ◒, NaCl; ●, LiCl.

Table II gives the values of Λ and of ΛS for the three salts (rounded to the nearest 0.005 conductance unit) as well as the corresponding Λ_0 and K, while Fig. 1 shows the Shedlovsky plot of the data, the ordinates for economy of space being $(\Lambda S - \Lambda_0)$. The agreement is satisfactory, the individual points lying in general within 0.02 conductance unit (or better) of the lines as drawn; the only notable exception is for the most concentrated KCl solution where the discrepancy is 0.06 unit.
